
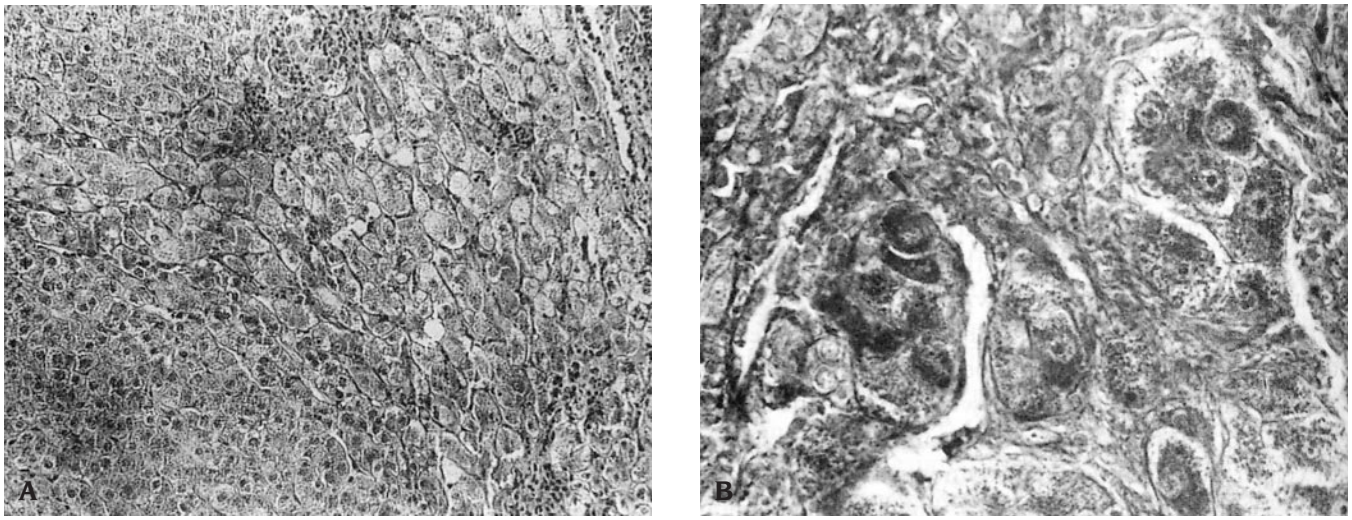

FIGURE 55.10-3 *A*, Wedge biopsy specimen from a child with Wilson disease showing a broad band of fibrous tissue at the right margin. An intense portal inflammatory response can be seen with lymphocytes spilling across the limiting plate into the lobule. Considerable hepatocellular necrosis exists with marked variations in cell size and some fat and pigment deposition. *B*, High-power view showing irregularities in cell size, hepatocellular necrosis, pigment deposition, and bile ductular proliferation. The limiting plate has been distorted, as shown by interdigitation of connective tissue and hepatocellular elements. Inflammatory cells are seen crossing the limiting plate into the lobule. Reproduced with permission from Grand RJ and Vawter GF.[122]

ease, biliary atresia, paucity of intrahepatic ducts, primary biliary cirrhosis, sclerosing or chronic cholangitis, cirrhosis, and primary hepatic tumors (Table 55.10-5). Orcein-positive granules are not seen in acute liver disease, except hepatitis B. In contrast to Wilson disease, the orcein-positive granules in other disease states are found mainly at the periphery of the liver lobules.[90] In Wilson disease, these granules are widespread in some lobules but may be completely absent in others.[90] Not all of the livers from patients with Wilson disease contain stainable copper-associated protein. In the early stages of the disease, when the liver copper concentration is highest, the copper is distributed diffusely in the cytoplasm and is absent from the lysosomes[91]; it is therefore not stainable. In the later stages of the disease, copper is redistributed to the lysosomes, and then copper may be stained by rubeanic acid and copper-associated protein by orcein.[86] However, histochemical techniques cannot confirm a diagnosis of Wilson disease, and they cannot be used to rule it out. Confirmation depends on quantitative measurement of hepatic copper content. Other disorders associated with elevated hepatic copper concentrations are listed in Table 55.10-5.

DIAGNOSIS

The diagnosis of Wilson disease may be made readily when the classic triad of hepatic disease, neurologic involvement, and KF rings is present. However, in the absence of this triad, the diagnosis begins with a high index of suspicion, especially in children. No single test can confirm the diagnosis with 100% accuracy (Table 55.10-6). Rather, the clinical and family history, physical examination, and certain key laboratory investigations collectively may establish the diagnosis. In ambiguous cases, genetic analysis may be required.

The first diagnostic test should be measurement of serum ceruloplasmin. Most children and adolescents with Wilson disease have decreased serum ceruloplasmin values, and at least 75% of those presenting with hepatic manifestations have low values.[92–94] Decreased values also may be seen in conditions associated with decreased hepatic synthetic function, such as malnutrition and severe hepatic insufficiency.[3,95] Ceruloplasmin also may be low in protein-losing enteropathy, nephrotic syndrome, and hereditary hypoceruloplasminemia.[92] Infants younger than 6 months of age normally have low serum ceruloplasmin levels.[93] Because ceruloplasmin is an acute-phase reactant, its value may be low-normal to normal in patients with Wilson disease during periods of active hepatic inflammation.[96] Its synthesis is stimulated by estrogens; hence, pregnancy (and estrogen therapy) is associated with near-normal to normal ceruloplasmin levels (Table 55.10-7).[96] Difficulty in establishing a diagnosis also occurs in 10% of heterozygotes who have low serum ceruloplasmin levels but no manifestations of Wilson disease.[96] Therefore, serum ceruloplasmin level should not be used as the sole determinant in diagnosing the disease.

Radiocopper excretion abnormal
Genetic analysis

Serum or plasma copper levels should be obtained at the time of diagnosis, although it should be noted that their concentration cannot be used as a diagnostic test for Wilson disease. In classic cases of Wilson disease, the serum or plasma copper levels are decreased, in conjunction with the low ceruloplasmin values. However, in certain stages of the disease, copper levels are elevated as a consequence of the flooding of the plasma with nonceruloplasmin-bound copper released from the liver. As will be discussed below, serum copper levels are also necessary for the assessment of the patient's adherence to therapy. Total serum copper levels are readily obtained in most laboratories.

In contrast to plasma copper determination, urinary copper excretion is a useful diagnostic test. It is normally less than 40 µg/24 h. The conventional level taken as diagnostic for Wilson disease is greater than 100 µg/24 h in symptomatic patients.[97] However, recent studies have shown that basal determination may be less than 100 µg/24 h in up to 25% of patients diagnosed with Wilson disease,[94,98,99] indicating that 24-hour urinary excretion of copper greater than 40 µg/24 h may be a better threshold for diagnosis of Wilson disease and requires further investigation. Abnormal urinary copper excretion is not specific for Wilson disease because it may be elevated in patients with primary biliary cirrhosis,[100] chronic active hepatitis,[31] fulminant hepatitis, and cholestasis (Table 55.10-8).[35] The urine collections must be obtained in copper-free containers.

The use of the penicillamine-stimulated copper excretion test remains controversial. Many studies have found no difference in penicillamine-induced copper excretion between Wilson disease and chronic hepatitis.[101] However, one study exclusively in children suggested that this test might be valuable. After collecting one 24-hour urine sample in a copper-free container, patients received 500 mg penicillamine at the start of, and 12 hours into, the second 24-hour urine collection. Urinary copper excretion was measured in both specimens. Although there was overlap between copper excretion in patients with Wilson disease and those with chronic hepatitis, a penicillamine-induced cupruresis (> 25 µmol/24 h) was shown to be valuable in the diagnosis of Wilson disease.[102] There is some question as to the capacity of such brief exposure to penicillamine to sensitize the patient and render allergic reactions later more likely. This remains to be resolved. Whether this test is useful for diagnosis, 24-hour urinary copper excretion is a good measurement to follow during treatment of patients with Wilson disease because it allows quantification of the success of chelation therapy.

The clinician should look for KF rings by using slit-lamp examination, but the rings are not pathognomonic for Wilson disease (see Table 55.10-4).[57,58] However, in Wilson disease, they are present in approximately 50% of patients with a hepatic presentation and 95% of those with neurologic or psychiatric symptoms. They may also be helpful when considering the possibility of nonadherence to treatment, as in a patient whose KF rings have faded and then returned.

A liver biopsy should be performed whenever possible because the quantification of hepatic copper concentration will, in most cases, establish the diagnosis in the absence of known obstructive liver disease. Microscopic and ultrastructural analyses are valuable, whereas copper staining is not. Measurements of quantitative hepatic copper concentrations are mandatory. Normal hepatic copper concentration is less than 50 µg/g of dry weight of liver.[103] Patients with Wilson disease generally have values greater than 250 µg/g of dry liver, and values may be greater than 1,000 µg/g of dry liver. Presymptomatic homozygous patients, especially young children, may not always have levels greater than 250 µg/g. Heterozygotes may have values up to 150 to 200 µg/g. A normal hepatic copper concentration rules out the diagnosis of Wilson disease, whereas an elevated value confirms the diagnosis in the proper clinical setting. Elevated values may be seen in

other conditions (see Table 55.10-5).[104–106] These usually can be distinguished by other techniques.

If the diagnosis is still uncertain, the rate of incorporation of radiocopper into ceruloplasmin may be determined or genetic testing obtained. The radiocopper test is performed after a fast of 8 hours; a dose of 2.0 mg of radiocopper is administered orally. The concentration of radiocopper is measured in the serum at intervals of 1, 2, 4, 24, and 48 hours later. The radiocopper rises in the 1-hour and 2-hour samples and then falls. In normal individuals, the serum concentration rises again to a higher level in the 24-hour or 48-hour sample, representing incorporation into ceruloplasmin. However, in patients with Wilson disease, even those with normal ceruloplasmin levels, the secondary rise is not achieved. One needs to be cautious in interpreting these results because considerable overlap occurs with heterozygotes, especially those with low serum ceruloplasmin concentrations.[107] If the index patient's serum ceruloplasmin is relatively high, other family members also may have near-normal values yet still have Wilson disease.

Currently, genetic analysis is mostly limited to identification of first-degree relatives of newly diagnosed patients. The pedigree analysis is performed using haplotypes based on polymorphisms surrounding the Wilson disease gene and requires the identification of a patient within the family (the proband). De novo diagnosis by molecular studies remains difficult at present owing mostly to the large numbers of disease-specific mutations of *ATP7B*; it is done only in the context of research protocols.[108]

Asymptomatic relatives, especially siblings of patients with Wilson disease, should be screened (Table 55.10-9). They should have a careful physical examination, ophthalmologic slit-lamp examination, measurement of serum ceruloplasmin and copper concentration, hepatic transaminase levels, and 24-hour urinary copper excretion. If all of these screening tests give absolutely normal results, the diagnosis is most likely excluded, although it may be prudent to repeat them at least once several months later. However, if even one test result is abnormal, a liver biopsy should be performed and samples sent for quantitative copper determination and histologic examination. In the young pediatric age group, if the 24-hour urinary copper result is normal, it should be repeated when the child is older, at which time enough copper would have accumulated to be reflected in an elevated urinary value. Subtle evidence of Wilson disease may be reflected in the presence of hemolysis, elevated reticulocyte values, depressed haptoglobin levels, and hypercalciuria. In equivocal cases, genetic analysis can be used to establish a diagnosis. In general, any liver disease in pediatric patients should be considered to be Wilson disease until proven otherwise.

NATURAL HISTORY

Deiss and others have devised a valuable staging system that explains many of the confusing findings in Wilson disease.[109] Revisions of the scheme also are available.[3] In stage I, a progressive accumulation of copper occurs in the cytosol of the hepatocytes. The process continues until all hepatic binding sites for copper are saturated. This stage is asymptomatic and usually occurs before age 5 years. In stage II, copper in the hepatocyte is redistributed from the cytosol to the lysosomes, and, at the same time, copper is released from the liver. If this release occurs gradually, the patient remains asymptomatic. If the redistribution is rapid, hepatic necrosis may occur, and the patient may become symptomatic from liver disease. In addition, rapid release of copper into the blood may result in hemolytic anemia. This stage is often accompanied by fulminant hepatic failure, leading to liver transplant. However, if patients pass through stage II without clinical illness, they remain asymptomatic. In stage III, copper continues to be stored in the lysosomes, and varying degrees of fibrosis or cirrhosis develop. In this stage, accumulation of copper also occurs in other tissues, such as brain, cornea, kidney, or skeleton. Patients may remain asymptomatic for years if the brain deposition of copper progresses slowly. Stage IV is characterized by symptomatic CNS disease. If copper accumulation occurs rapidly, then liver disease, CNS disease, or both become apparent in a short time. Stage V occurs when treatment is begun before the patient dies from hepatic failure or irreversible brain damage. In stage V, cupruresis leads to reductions in copper accumulation, repair of tissue injury, and improvement in the clinical status of the patient.[110]

Few series of patients with Wilson disease have partially characterized the long-term prognosis of patients with this disease.[111–113] These series have suggested that the long-term outcome of these patients is mainly dependent on adherence to lifelong treatment with excellent prognosis in those patients who are compliant with effective medical therapy, even if cirrhosis is present at the time of diagnosis. However, it is important to note that none of these studies have compared the long-term survival of patients with Wilson disease with that of an age- and gender-matched population. Furthermore, there is no study assessing the quality of life of patients on long-term treatment for this condition.

TREATMENT

At the time of the discovery of Wilson disease, and for many years subsequently, early diagnosis had little clinical

significance. In 1951, Denny-Brown and Porter and Cumings[115] introduced dimercaprol (BAL) as an effective treatment for Wilson disease.[114,115] However, the daily painful intramuscular injections made BAL impractical. In 1956, Walshe drastically changed the outcome of patients with Wilson disease by showing that D-penicillamine is an effective treatment.[95] Wilson disease is fatal if untreated, but successful outcome is achieved with effective pharmacologic therapy. The US Food and Drug Administration approved D-penicillamine as effective and safe for Wilson disease in 1963. In 1968, in a landmark paper, Sternlieb and Scheinberg showed its effectiveness in presymptomatic homozygous patients.[116]

Penicillamine

Penicillamine remains the chelating agent with which there has been the greatest experience. Initial therapy with trientine is emerging as an acceptable alternative. Penicillamine is a sulfur-containing amino acid that is a metabolite of penicillin; it chelates copper and then is excreted in the urine. When initiating therapy, a small dose should be used; the dose should then be gradually increased and administered orally on an empty stomach in four divided doses, 30 to 45 minutes before meals and at bedtime, or 2 or more hours after eating. In children and adolescents, the dose is 20 mg/kg of body weight; the customary adult dose is 1.0 g/d.[3] Penicillamine is better absorbed in the absence of food.[117] Patients should also receive 25 mg of pyridoxine three times a week because of the potential antipyridoxine effects of penicillamine.[118] As a consequence of treatment, urinary copper excretion may be more than 5,000 µg in a 24-hour period. However, this decreases with time; after months to years of therapy, it can be as low as 600 µg in a 24-hour period.[109] Usually, there is a dramatic improvement in symptoms within weeks of beginning therapy. If no improvement occurs, the daily dose of penicillamine may be raised to 1.5 to 2 g/d or its equivalent according to body weight, although one must consider faulty patient compliance as a possible cause of poor response. The higher dose of penicillamine is associated with an increased risk of side effects. Most patients become clinically asymptomatic, or nearly so, within months of beginning treatment, but some may not show significant functional improvement before 1 year. One concern when deciding on the correct drug for treatment is that neurologic symptoms may worsen with the initiation of penicillamine treatment. It is postulated that with treatment, large amounts of hepatic copper are mobilized and then deposited in the brain, worsening neurologic symptoms. There is also concern that treatment with penicillamine may initiate neurologic symptoms in previously asymptomatic patients with Wilson disease.[119] Such patients may not return to pretreatment baseline.[120] Trientine appears to be associated with a lower risk of this phenomenon and may be preferred as first-line therapy for neurologic Wilson disease. Perhaps gradual introduction of penicillamine prevents this occurrence. In general, neurologic manifestations improve, although dysarthria associated with mask-like facies may not disappear.[121] KF rings may disappear or fade partially. As a consequence of therapy, liver function test results improve and hepatic concentration of copper decreases.[122]

Studies have shown improvement in liver biopsy findings with decreased portal fibrosis, inflammation, and necrosis.[110,120,123] There is a report of a 10-year-old child who had advanced liver cirrhosis whose repeated liver biopsy showed practically normal results 27 months after starting penicillamine therapy. The biopsy samples were obtained by laparotomy, with multiple samples taken to decrease sampling error.[123] This report is unusual in showing virtually complete reversal of liver disease.

The patient's adherence to therapy is best assessed using sequential determinations of 24-hour urinary copper excretion. In addition, Scheinberg and Sternlieb recommend the assessment of free serum copper.[3] This is accomplished by spot determinations of total serum copper (µg/dL) and ceruloplasmin (mg/dL) concentrations. The unit designations are then ignored. A factor of 3 is multiplied by the ceruloplasmin value, and that value is subtracted from the total serum copper level. A resulting figure not greater than 20 indicates compliance.[124]

Undesirable side effects of penicillamine therapy may occur within the first 3 weeks of treatment in 20% of patients. These include fever, skin rash, lymphadenopathy, granulocytopenia, and thrombocytopenia.[125] Other reactions that may occur later include nephrotoxicity with proteinuria or even nephrotic syndrome,[126] lupus-like syndrome,[127] Goodpasture syndrome (which was fatal in three patients),[128] elastosis perforans serpiginosa,[129] and pemphigoid lesions of the mouth, vagina, and skin.[130,131] A penicillamine dermatopathy may occur in patients receiving more than 2 g of penicillamine for several months. Penicillamine interferes with crosslinking of collagen and elastin, which leads to a weakening of the subcutaneous tissue so that bleeding into the subcutaneous tissue may occur with even slight trauma.[129] If a reaction occurs, penicillamine should be stopped. The clinician may then pretreat with 20 to 30 mg of prednisone (0.5 mg/kg of body weight) daily for 2 to 3 days before reinstituting therapy. Penicillamine should be introduced in a much lower dose and gradually increased. Once penicillamine is tolerated, the prednisone may be withdrawn.[129] If the reaction was severe, the clinician may not wish to attempt this but to institute other decuprinizing agents (Table 55.10-10). The success of treatment with oral D-penicillamine may be limited by the presence of renal failure. Adding penicillamine to peritoneal dialysis solution is not beneficial.[132,133] Postdilution hemofiltration and continuous arteriovenous hemofiltration with oral penicillamine have been effective.[134] Although there are incidental reports of connective tissue defects and cleft palate in the offspring of pregnant women taking penicillamine[135,136] and other therapeutic agents available (see below), Scheinberg and Sternlieb point out that cessation of treatment is dangerous, and such complications are extremely infrequent.[3] Population-based, case-controlled studies of birth defects in the children of women taking penicillamine for Wilson disease and other disorders, compared with in the random population, are not available.

Death has occurred as early as 8 months after discontinuation of D-penicillamine in a patient who had become asymptomatic with treatment and then was noncompliant. There are several reports of death within 1 year of stopping therapy in noncompliant patients. This raises the question of the exact mechanisms of D-penicillamine action. A patient who has been decuprinized with therapy should not die after just 8 months of copper reaccumulation (because initial copper accumulation takes more than 5 years in stage I). Sternlieb and colleagues suggest that penicillamine may form a nontoxic complex with copper.[130] When penicillamine treatment is suddenly stopped, there may be a sudden dissociation of this complex, and massive amounts of copper may be released, accounting for the rapid hepatic decompensation that occurs in suddenly noncompliant patients. The first sign of relapse after stopping penicillamine is a silent rise in serum transaminase levels.[130] The rise may be low compared with the amount of ongoing hepatic injury. Bilirubin becomes elevated later, and there is a decrease in serum albumin concentration, an elevation in free serum copper levels,[3] and an elevation in 24-hour urinary excretion of copper. The urinary copper excretion may be greater than 2,000 µg in a patient who has been noncompliant and then begins taking penicillamine again before urine collection.[130] It is rarely greater than 1,000 µg per 24 hours in patients taking penicillamine regularly.

TRIENTINE

In 1969, Walshe introduced triethylene tetramine dihydrochloride (trientine) as an altemative chelating agent to penicillamine for a patient who had developed an immune complex nephritis after 6 years of penicillamine treatment.[137] Cupruresis, as great as or greater than that achieved with penicillamine, may be achieved with trientine.[138] Most patients have complete reversal of the side effects seen with penicillamine, although at least one patient with elastosis perforans serpiginosa did not improve with trientine.[139] Two other patients with penicillamine-induced lupus did not improve on discontinuation of penicillamine and introduction of trientine. Iron deficiency anemia may develop in patients treated with trientine, especially women. This resolves with daily iron supplements.[139] Trientine is safe during pregnancy.[140] Trientine is given orally in divided doses of 1 to 1.5 g daily, 1 hour before or 2 hours after meals. In children younger than 10 years of age, 0.5 g (approximately 20 mg/kg) daily is recommended.[139] Renal complications from trientine can occur.

ZINC

Zinc, a known antagonist of copper absorption, has been introduced as a possible alternative maintenance treatment for Wilson disease in patients previously successfully treated with penicillamine. In 1946, Smith and Larson reported on the antagonistic effects of zinc on copper balance in rats.[141] A decrease in liver copper content secondary to zinc supplementation in sheep was reported in 1954.[142] Patients with sickle cell anemia treated with zinc had been observed to develop copper deficiency.[143] In 1961, the role of zinc in producing negative copper balance in Wilson disease was first described.[144] Patients have subsequently demonstrated clinical improvement when treated with zinc alone.[145,146]

TABLE 55.10-10 TREATMENT OF WILSON DISEASE

Dietary restriction of copper
D-Penicillamine (with pyridoxine)

Ammonium tetrathiomolybdate
Zinc
Liver transplant

Copper is absorbed mainly in the proximal small intestine.[147] Its absorption is increased in the presence of chelating agents, a high-protein diet, anions, and L-amino acids. Fiber, bile, ascorbic acid, and zinc inhibit its absorption. Once copper crosses the intestinal brush border, it binds to metallothioneine in the cytosol of the enterocytes. Zinc, copper, cadmium, glucagon, glucocorticoids, and bacterial infections induce the synthesis of intestinal metallothioneine.[148] Metallothioneine has a higher affinity for copper than for zinc.[149] The copper that is metallothioneine bound cannot pass the serosa but is sloughed with the intestinal cells into the lumen and then excreted in the stool. Therefore, copper levels in stool are increased in patients treated with zinc.[150]

Experience is growing in the use of zinc in Wilson disease, and thus far, no treatment failures have occurred.[150,151] The adult recommended dose is 50 mg of elemental zinc taken three times a day, spacing each dose from food or liquids by at least 1 hour. Children and pregnant women should receive 25 mg per dose three times a day.[150] Treatment can be monitored by measuring 24-hour urinary copper. Because decoppering occurs in the gastrointestinal tract, urinary copper reflects body copper burden. A value greater than 125 µg per 24 hours suggests patient noncompliance. Twenty-four-hour urinary zinc levels average 3.5 mg and should be at least 2 mg when a therapeutic dose is taken.[150,152]

Because it takes 1 to 2 weeks to induce metallothioneine levels in the intestine, in addition to its slower rate of decoppering, zinc is not practical for initial treatment in symptomatic patients. As maintenance therapy, it has less toxicity than penicillamine, and there is more experience with zinc than with trientine.

Although zinc seems to be a basically safe medication, long-term effects are not known. Lymphocyte response to phytohemagglutinin, neutrophil chemotaxis, and bacterial phagocytosis were reduced in normal male subjects taking 150 mg of zinc twice a day for 6 weeks.[153] This observation has been challenged in a subsequent study because of the possibility that inducing copper deficiency in normal subjects may have been responsible for the decrease in lymphocyte function. Examining mitogenic response and levels of natural killer cell activity in patients treated with zinc for 15 years showed no evidence of decrease in lymphocyte function.[152] Zinc has been reported to reduce high-density lipoprotein cholesterol in normal male subjects.[154] Finally,

an elevation in serum amylase and lipase has been reported during zinc therapy; however, it is believed to be caused by higher levels of these proteins induced by zinc rather than by pancreatic damage.[150]

Tetrathiomolybdate

A new potential therapeutic option is ammonium tetrathiomolybdate (TM). It has two anticopper mechanisms. It complexes ingested copper, thereby preventing absorption. Second, TM forms complexes with copper and albumin in blood, making the copper unavailable for cellular uptake. Most recently, it has been found that TM has antifibrotic and anti-inflammatory effects mainly through inhibition of profibrotic and proinflammatory cytokines.[155] In a trial of 33 patients with neurologic manifestations of Wilson disease treated with TM, only 1 patient had deterioration of neurologic function, with good to excellent recovery in a 1- to 6-year follow-up period.[156] This appears to be a promising alternative to penicillamine because it is associated with a low prevalence of complications. However, this medication remains experimental in the United States and is not commercially available.

Antioxidants

Antioxidants, mainly vitamin E, may have a role as adjunctive therapy. Experimental studies have suggested that an increase in oxidative stress may play a central role in the liver injury seen in patients with Wilson disease.[157] Moreover, serum and hepatic vitamin E levels have been found to be low in patients with this condition.[158,159] Although symptomatic improvement when vitamin E was added to the treatment has been occasionally reported, further studies are still needed to better determine the possible role of this vitamin and other antioxidants in the treatment of patients with Wilson disease.

With the potential of genetic testing to establish the diagnosis of Wilson disease in presymptomatic homozygous relatives, treatment may begin at an early age. A recent retrospective review showed that 32 asymptomatic homozygous children were treated safely with penicillamine prophylaxis as early as 1.5 years of age.[125] However, the necessity for such early treatment must be balanced against the risks of increasing the total duration of exposure to penicillamine.

Liver transplant has been performed in a number of patients with Wilson disease[39] (Table 50.10-11). At least four groups of patients can be defined who should be considered for liver transplant[39]: (1) patients presenting with a clinical picture of fulminant hepatic failure, often adolescent or young patients; (2) patients with findings of severe hepatic decompensation who have not improved after several months of adequate chelation therapy; (3) patients who have been effectively treated but have developed severe progressive hepatic insufficiency acutely after stopping penicillamine; and (4) patients with progressive and/or irreversible neurologic dysfunction. Reports of Wilson disease patients surviving liver transplants have demonstrated extremely favorable outcomes, with a recent study showing a quality of life comparable to that of age- and sex-matched controls from the general population.[160] Tests of copper status, including serum ceruloplasmin, serum copper, and 24-hour urinary copper excretion, normalize within 1 to 2 months.[39,161] Several reports have shown improvement of neurologic symptoms after transplant. Polson and colleagues described two patients: one preoperatively had continued worsening of neurologic manifestations despite penicillamine treatment and the other had continued worsening of hepatic and neurologic symptoms. In both patients, recovery of neurologic function occurred but was slow.[162] The findings that clinical and laboratory abnormalities normalize after liver transplant confirm the accepted theory that the metabolic defect of Wilson disease is localized within the liver.

TABLE 55.10–11 INDICATIONS FOR ORTHOTOPIC LIVER TRANSPLANT IN WILSON DLSEASE

Fulminant hepatic failure
Cirrhosis with decompensation
Progression of hepatic dysfunction despite treatment
Exacerbation after discontinuation of therapy
Progressive and irreversible neurologic disease

Plasma exchange has been used to reduce serum copper levels and treat the hemolytic anemia associated with fulminant Wilson disease prior to liver transplant.[163] Experimental treatment for Wilson disease may involve the use of hepatocyte transplant. Using the Long-Evans cinnamon rat, hepatic disease has been prevented with infusion of normal rat hepatocytes.[164]

SUMMARY

Wilson disease should be considered in every pediatric patient with liver disease of unknown origin. Early diagnosis and institution of therapy prevent progression of disease and permit normal life expectancy. A variety of therapeutic strategies are available, but penicillamine remains the initial therapy of choice. Lifelong copper chelation or zinc therapy is mandatory.

CHAPTER 56

PARENTERAL NUTRITION–ASSOCIATED LIVER DISEASE

Julie E. Bines, MD, FRACP

Liver dysfunction is reported to occur in 7.4 to 84% of patients receiving parenteral nutrition (Table 56-1).[1–4] In most patients, this presents as a transient abnormality in serum liver enzyme levels that return to normal with cessation of parenteral nutrition. Cholestasis is the most common manifestation in infants and children, whereas steatosis is more common in adults.[3,4] The incidence of parenteral nutrition–associated liver disease (PNALD) in neonates receiving parenteral nutrition for more than 2 weeks has decreased from 31 to 25% over the past 10 to 15 years, although mortality related to PNALD has not significantly altered.[5] Children with short bowel syndrome requiring long-term parenteral nutrition are at increased risk for the development of complicated PNALD, and liver failure is reported in 3 to 19% of these patients.[6–8]

The etiology of PNALD is unknown. Initially, it was presumed that parenteral nutrition solutions contained a toxic substance or lacked an essential component required for normal hepatic function.[9,10] However, in animal studies, the administration of parenteral nutrition solutions results in hepatic injury but not liver failure.[11,12] The role of sepsis in the early development of PNALD has been the focus of a number of studies.[6,13–15] Current evidence suggests that the developing liver is particularly sensitive to injury resulting from a range of individual factors, such as infection and intestinal stasis, and that PNALD has a multifactorial etiology that reflects the underlying clinical indication for administration of parenteral nutrition (Table 56-2).[6,9,16]

TABLE 56-1 SPECTRUM OF HEPATOBILIARY DYSFUNCTION IN PATIENTS RECEIVING PARENTERAL NUTRITION

Patient-Related Factors

Birth Weight and Gestational Age. Low birth weight is a key predisposing factor for the development of PNALD.[9,17] PNALD was reported in 50% of infants with a birth weight < 1,000 g compared with 7% of infants weighing > 1,500 g at birth (Figure 56-1).[17] Gestational age has been identified as an independent factor for the development of PNALD in some but not all studies.[9,17–19] There is a direct relationship between the duration of parenteral nutrition administration and the prevalence of PNALD in premature infants.[17] Almost two-thirds of all infants weighing less than 2,000 g at birth develop cholestasis after 2 weeks of parenteral nutrition therapy.[17]

The increased incidence of PNALD observed in premature infants is thought to reflect the immaturity of hepatic function and the enterohepatic circulation of bile acids.[17,20–22] Normal enterohepatic circulation requires that bile acids are delivered to the intestinal lumen, reabsorbed, and then returned to the hepatocyte for recirculation. However, neonates have reduced hepatic uptake, bile acid synthesis, and the volume of the total bile salt pool.[20–23] Intraluminal concentration and intestinal reabsorption of bile acids are also reduced in premature infants.[24,25] Glutathione is required for normal bile secretion. Glutathione levels are depleted in weanling rats during administration of parenteral nutrition.[26]

Ninety percent of the normal bile acid pool consists of cholic acid, deoxycholic acid, and chenodeoxycholic acid.[27] Bacterial overgrowth of the small intestine induces intraluminal deconjugation of bile salts and increases production of potentially toxic bile acids such as lithocholic acid.[27,28] Patients with PNALD have increased serum and bile concentration of lithocholic acid.[29,30] Lithocholic acid impairs bile flow and, in animals, is associated with hepatic injury similar to the histologic changes observed in patients with PNALD.[30,31] Lithocholic acid is solubilized in the liver by sulfation. Infants have reduced hepatic sulfation and, as a result, may be at increased risk of hepatic injury owing to toxic bile acids.[32]

TABLE 56-2 FACTORS ASSOCIATED WITH DEVELOPMENT OF PARENTERAL NUTRITION–ASSOCIATED LIVER DISEASE

PATIENT FACTORS
Low birth weight
Prematurity
Male sex
Preexisting liver disease
DISEASE FACTORS
Gastrointestinal disease status
Primary disease etiology
Length of residual small intestine
Dysmotility in remaining segment of small intestinal
Residual intestinal disease (ie, Crohn disease)
Length of time with diverting ileostomy or colostomy
Small intestinal bacterial overgrowth
Sepsis
Type of microorganism
Source of infection
NUTRITIONAL FACTORS
Enteral nutrition
Lack of enteral feeding
Undigested nutrients and bacterial overgrowth
Substrate related
Proportion of enteral calories
Formula composition
Parenteral nutrition
Duration of parenteral nutrition administration
Overfeeding
Substrate related
Glucose excess
Specific amino acid excess/deficiency
Lipid excess
Accumulation of phytosterols
Specific micronutrient excess/deficiency

Gender. An association between male sex and the development of PNALD was recently reported.[13] The investigators postulate that a genetic and/or hormonal effect on immune function predisposes males to infection and PNALD.

Preexisting Illness. Preexisting liver disease or a parenteral nutrition–independent risk factor for liver disease is associated with an increased incidence of PNALD.[33]

DISEASE-RELATED FACTORS

Gastrointestinal Disease. Massive small bowel resection is an important risk factor for the development of PNALD in children and adults.[6,33] Parenteral nutrition–associated cholestasis is reported in 30 to 60% of children with short bowel syndrome.[7,8] Residual small intestinal length was identified as the only independent predictor of peak serum bilirubin level in infants and children with parenteral nutrition–associated cholestasis.[34] Seventy percent of infants with < 50 cm of residual small intestine and all adults with entire small intestinal resection developed parenteral nutrition–associated cholestasis.[33,35,36] Chronic cholestasis is the precursor of complicated PNALD and liver failure.[33,37,38]

A link between gastroschisis and PNALD has been reported.[6] Infants with gastroschisis frequently develop intestinal obstruction in utero, and, following surgery, there is a high rate of dilatation and dysmotility of the proximal intestine.

The approach to surgical management of short bowel syndrome in the neonatal period may influence the development of progression of PNALD. Although emphasis is placed on retaining the maximal length of intestine, there is a risk of enhancing exposure of the liver to intestinally derived endotoxin from retained ischemic bowel.[16] Absence of disease in the remaining small intestine is associated with improved survival in patients receiving home parenteral nutrition for intestinal failure.[33] The number of operations and the length of time with a diverting ileostomy or colostomy have been identified as risk factors for the development of PNALD.[34,37] Conversely, the absence of the ileocecal valve did not predispose patients to PNALD.[34]

As part of the adaptive process following resection, the residual small intestine becomes dilated and intestinal transit is slowed in an attempt to compensate for loss of bowel length. Intestinal stasis predisposes the patient to the proliferation of strict anaerobic and facultative anaerobic bacteria within the small intestine. Incomplete absorption of enteral feeds provides a rich source of nutrients for luminal bacteria. Sixty-four percent of infants receiving parenteral nutrition who have bacterial overgrowth later develop sepsis with the same microorganism (such as *Klebsiella*, *Escherichia coli*, enterococci, *Candida*).[38] Bacterial overgrowth is also associated with the deconjugation of bile acids and the production of potentially hepatotoxic bile acids.

Sepsis. Sepsis is associated with cholestasis in infants receiving parenteral nutrition and in infants who have never received parenteral nutrition.[3,14,17,37,39,40] Cholestasis occurs more commonly after gram-negative bacterial infections (in particular *E. coli*).[41] In patients with a normal gastrointestinal tract, cholestasis during an episode of sepsis is usually transient.[16] However, in patients with short bowel syndrome, sepsis has been closely linked to the development of parenteral nutrition–associated cholestasis and progressive PNALD.[6,16,33]

Lipopolysaccharide and peptidoglycan-polysaccharide endotoxins produced by gram-negative and gram-positive

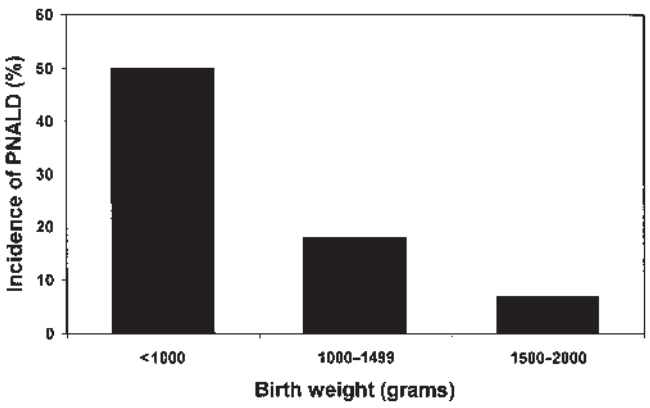

FIGURE 56-1 Relationship between the incidence of parenteral nutrition–associated liver disease (PNALD) and low birth weight. Adapted from Beale EF et al.[17]

bacteria promote the release of tumor necrosis factor (TNF)-α and interleukin-2 from Kupffer cells in rats, resulting in hepatic inflammation and fibrosis.[42] The potential role of TNF in the pathogenesis of PNALD has been a recent focus of interest.[43,44] The administration of antibodies to TNF to rats fed parenteral nutrition results in an improvement in PNALD.[44] Polymyxin B is effective against gram-negative bacteria. In rats with PNALD, polymyxin B blocked endotoxin activity and TNF production and resulted in an improvement in steatosis.[45]

Cholestasis occurred in 26% of 152 neonates who developed an infection while receiving short-term parenteral nutrition.[14] In contrast, cholestasis was not observed in any patient who did not develop an infection.[14] A close association between invasive bacterial or fungal infection and the onset of jaundice in neonates with short bowel syndrome has been observed.[6] Infection occurred before the onset of jaundice in 90% of infants and occurred earlier in cholestatic patients compared with noncholestatic patients (Figure 56-2).[6] Cholestatic patients had more episodes of infection in the first 6 months of life, although the total number of episodes was the same in both groups. Importantly, once established, cholestasis did not resolve with antibiotic therapy and continued to rise, either progressing to hepatic failure or gradually resolving.[6] These data suggest that early exposure to infection is important in the development of PNALD in infants with short bowel syndrome, in whom the liver is immature and susceptible to cholestatic injury and potentially sensitized or stressed by parenteral nutrition administration.[6]

Nutrition-Related Factors

Enteral Nutrition. ***Lack of Enteral Feeding.*** A lack of enteral feeding has been reported as an important risk factor for the development of PNALD in a number of studies.[15,37,46] Enteral feeding induces hormonal stimulation of bile flow, gallbladder emptying, and hepatobiliary development.[47,48] Serum cholecystokinin, glucagon, enteroglucagon, gastrin, motilin, gastric inhibitory polypeptide, and secretin levels differ markedly between infants who are enterally fed and parenterally fed infants.[47,48] In animals with PNALD, treatment with cholecystokinin-octapeptide resulted in decreased periportal inflammation and fibrosis but no improvement in bile flow, bile acid secretion, or hepatocellular injury.[49] Human studies suggest that cholecystokinin (or cholecystokinin-octapeptide) may improve the conjugated hyperbilirubinemia associated with PNALD provided that liver failure is not established.[50,51]

Luminal nutrients aid in the maintenance of gut mucosal barrier function. In the absence of enteral nutrition, the intestine undergoes atrophy, which may increase the risk of bacterial translocation and portal sepsis.[52] In the absence of enteral feeding, intestinal motility and the enterohepatic circulation of bile acids are decreased.[53] These factors may contribute to hepatocyte stress and injury.

Enteral Nutrition Substrates. In neonates with short bowel syndrome, there is a significant relationship between the proportion of calories received enterally at 6 and 12 weeks and subsequent weaning from parenteral nutrition therapy.[6,34] The composition of the enteral feed may also contribute to the development of PNALD. Breast milk or amino acid formulas are associated with greater success at weaning from parenteral nutrition in children with short bowel syndrome.[34,54] Formula composition or excess macronutrients may increase the risk of bacterial overgrowth. Increased bacterial overgrowth and bacterial translocation were observed in mice fed a commercial liquid enteral formula compared with control animals fed chow.[55]

Parenteral Nutrition. ***Duration of Parenteral Nutrition Administration.*** There is a direct relationship between the duration of parenteral nutrition administration and the prevalence of PNALD in premature infants.[17] In surgical neonates, the incidence of cholestasis is reported to increase from 35% after 2 weeks of parenteral nutrition therapy to 75% after 90 days and 100% after 180 days of therapy.[41] The incidence of cholestasis is higher in infants commencing parenteral nutrition at an earlier age and in infants who have had a delay in the introduction of enteral feeds.[37] Chronic cholestasis developed in 65% of adults receiving parenteral nutrition for a median of 6 months.[33] Complicated PNALD developed in 50% of adults after receiving parenteral nutrition for 6 years.[33]

Overfeeding. Total caloric and carbohydrate overfeeding is associated with metabolic changes and alteration in bile flow and liver function.[56] In normal healthy subjects and in clinically stable patients, excessive glucose intake increases insulin concentration, resulting in a decrease in ketogenesis, an increase in glucose oxidation and lipogenesis, and a decrease in fatty acid oxidation.[57] The insulin-to-glucagon ratio is increased in the portal vein. These metabolic changes have been associated with increased levels of serum hepatic enzymes and hepatic steatosis.[57] Clinically stable adult patients fed a glucose-based parenteral nutrition solution to an average of 177% of predicted energy expenditure developed fatty infiltration and intrahepatic cholestasis on liver biopsy within 5 days of commencing parenteral nutrition.[56] Abnormal serum tests of liver function were detected by 14 days in 83% of

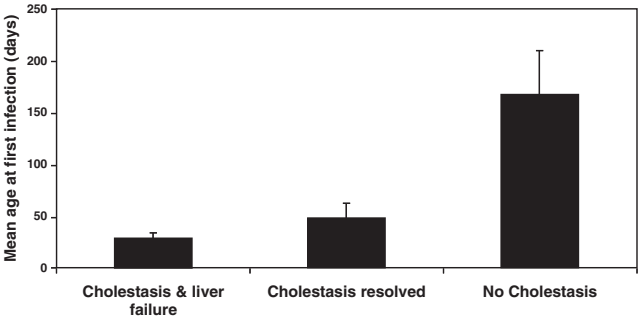

FIGURE 56-2 The effect of age at first infection on the development and severity of parenteral nutrition–associated cholestasis in neonates with intestinal resection. Adapted from Sondheimer JM, Asturias E, Cadnapaphornchai M. Infection and cholestasis in neonates with intestinal resection and long-term parenteral nutrition. J Pediatr Gastroenterol Nutr 1998;27:131–7.

patients, with abnormalities occurring in proportion to the increase in carbohydrate load.[56] Repeat liver biopsy at day 21 showed bile duct proliferation, canalicular bile plugs, centrilobular cholestasis with accumulation of bile pigment within hepatocytes, and periportal inflammation.[56] Similar abnormalities have been observed in stable infants receiving glucose-based parenteral nutrition.[58]

Acute metabolic stress may exacerbate the impact of carbohydrate overfeeding on hepatic morphology and function. With acute stress, lipolysis and fatty acid oxidation increase relative to glucose oxidation owing to the action of counterregulatory hormones, resulting in insulin resistance.[59] In the presence of excessive glucose administration, serum glucose and insulin concentrations are elevated.[59] These factors may increase the risk for hepatic injury. Pyruvate dehydrogenase is a rate-limiting step in glucose oxidation; however, during sepsis, the activity of this enzyme may be inhibited.[60] Increased glucose load during a period of inhibition of this enzyme may further add to the insult to the hepatocyte during stress.[60] Overfeeding during a stress-free period is reported to diminish the hepatic response to subsequent injury, in particular sepsis.[61] In addition, bacterial translocation from the gut is increased during periods of nonprotein overfeeding in animals.[62] Overfeeding during critical illness may further contribute to the hypermetabolic response and hepatocyte injury.

Overfeeding with lipid emulsions containing long-chain triglycerides has been associated with decreased clearance of bacteria from the reticuloendothelial cells. Although this may be clinically significant in terms of posing an increased risk of bacterial sequestration into the lung, these changes have not been associated with characteristic features of hepatocyte injury or disturbances in bile flow.[63]

Substrate-Related Mechanisms. The chemical composition of parenteral nutrition solutions has been implicated in the development of PNALD.[9,28,56] These solutions may include specific nutrient deficiency or excess/toxicity. Contaminants infused with the parenteral nutrition solution may also contribute to hepatic injury.

Glucose infusion has been associated with hepatic steatosis.[9,28] Bile flow is reduced during glucose infusion in animal studies.[64,65] Preterm infants require approximately 4 to 8 mg/kg/min of glucose to suppress hepatic glucose oxidation; however, infusions should not exceed 12.6 mg/kg/min because excess exogenous glucose that is not oxidized may be converted to glycogen or fat in the liver.[66]

Amino acid infusions have been associated with cholestatic liver disease in both human and animal studies.[19,56] A more rapid rise and higher bilirubin concentration were reported in premature infants receiving 3.6 g amino acids/kg/d compared with infants receiving 2.5 g amino acids per kilogram body weight per day.[19]

Individual amino acids have been implicated in the development of parenteral nutrition–associated cholestasis.[9,28] This may reflect immaturity of amino acid metabolism, resulting in an excess of precursor amino acids or a defect in the synthesis of amino acids or proteins. Serum methionine levels are increased in some infants receiving parenteral nutrition owing to a block in the transsulfuration pathway, remethylation of homocystine, or impaired oxidation of sulfur-containing amino acids.[67] Hepatocellular injury observed in neonatal rats receiving infusions of methionine was prevented by supplementation with arginine and glycine.[68,69] Increased cystine has been related to cholestasis and morphologic alterations, including bile duct proliferation, periportal necrosis, portal fibrosis, and inflammation of portal triads.[70] Increased homocystine causes hepatocellular injury and iron deposition in animal studies.[71] Photo-oxidation of amino acid solutions may result in production of hepatotoxic metabolites.[72] The extent of cholestasis was dependent on the dose of tryptophan and degree of light protection in newborn rats receiving an intraperitoneal amino acid solution.[72]

Owing to the immaturity of amino aid metabolic pathways, some amino acids become conditionally essential in premature infants. Evidence supporting the role of a lack of taurine in the development of PNALD remains controversial.[73] Taurine is important in the conjugation of bile acids in neonates, and a lack of taurine results in bile acids becoming predominantly glycine conjugated. These bile acids are potentially hepatotoxic in the infant.[73] The benefit of taurine-supplemented parenteral nutrition to reduce the incidence of PNALD has not been confirmed.[74,75]

Carnitine is absent from most commercially available amino acid solutions. Carnitine is synthesized from methionine and lysine; however, in infants, this conversion may be limited owing to immature metabolic pathways.[76] Carnitine is required for fatty acid oxidation in the mitochondria, and carnitine deficiency is associated with hepatic steatosis. Low serum carnitine levels have been observed in infants and adults receiving parenteral nutrition; however, intravenous carnitine supplementation has not consistently improved serum and hepatic carnitine levels or features of PNALD.[77–79]

High-dose infusion of lipid emulsion is associated with impaired bilirubin excretion in adults.[79] Early lipid emulsions containing cottonseed oil were associated with the development of cholestasis and liver damage.[80] These solutions are no longer in use. Long-chain triglyceride lipid emulsions are a rich source of linoleic acid that promote the synthesis of leukotriene B_4, a proinflammatory cytokine, and may contribute to an increased inflammatory response to cytokines.[81] Commercially available long-chain triglyceride lipid emulsions were not thought to cause PNALD if administered in doses of 1 to 2 g per kilogram body weight per day.[19,56,80] However, in a recent study in intestinal failure patients receiving home parenteral nutrition, cholestasis and complicated PNALD were associated with a dose of lipid emulsion ≥ 1 g/kg/d.[33]

Clayton and colleagues have reported that the long-term use of a long-chain triglyceride lipid emulsion (Intralipid) results in the progressive accumulation of phytosterols.[82] In some patients, plasma concentrations of phytosterols were up to 25% of total plasma sterols and were even higher than in the Intralipid preparation.[82] Phytosterols are present in small amounts as contaminants of the lipid emulsion. Because they are insufficiently metabolized by the liver, it has been suggested that phytosterols

accumulate in the macrophages of hepatic sinusoids and disrupt normal macrophage function.[83] Intravenous phytosterol infusion caused reduced bile flow but not liver injury in newborn piglets.[82]

Choline is absent from commericially available parenteral nutrition solutions, and low serum choline levels have been reported in adults on parenteral nutrition therapy.[84] Phosphatidylcholine is required for the synthesis of lipoproteins. Choline deficiency in rats is associated with hepatic steatosis; however, it is not known if this relationship also exists in man.[85]

Selenium and molybdenum deficiency has been reported in association with PNALD; however, the role they may play in the pathogenesis is uncertain.[86] Serum manganese levels are increased in 79% of long-term parenteral nutrition patients.[87] Manganese can be toxic to the brain and the liver. There is a significant correlation between serum manganese levels and asparate transaminnase levels; however, it is unclear whether this is a primary or a secondary effect owing to delayed biliary excretion.[88]

CLINICAL MANIFESTATIONS

Hepatic Steatosis

Fatty infiltration of the liver is the most common manifestation of PNALD in adults.[4] It usually occurs secondary to excessive parenteral carbohydrate intake and resolves with a reduction in parenteral carbohydrate intake. Hepatic steatosis clinically presents as hepatomegaly associated with a mild to moderate increase in serum aminotransferase levels.[4]

Cholestasis

Chronic cholestasis is the primary manifestation of PNALD in infants and children and in adults with intestinal failure.[4,6,33] Persistent elevation of serum conjugated bilirubin level is the most consistent biochemical predictive marker of progressive PNALD.[16,89] Cholestasis is usually defined as a serum conjugated bilirubin level of > 1.5 mg/dL or 40% total bilirubin concentration. In infants, serum bilirubin levels may begin to rise as early as 1 to 2 weeks after initiation of parenteral nutrition therapy. Elevation of serum bile acids, either total bile acids or specific cholic acid conjugates, including lithocholate, has been reported to detect early evidence of PNALD prior to elevation of serum conjugated bilirubin level.[90,91] Total serum bile acids and conjugated bilirubin levels correlate with histologic changes in the liver and duration of exposure to parenteral nutrition in animals receiving parenteral nutrition.[92]

Cirrhosis and Complicated PNALD

With progression of disease, the serum alkaline phosphatase gradually increases. However, this may be difficult to interpret in infants and children because the bone isoenzyme may be elevated owing to bone disease or decreased owing to zinc deficiency. γ-Glutamyl transpeptidase or 5′-nucleotidase may also be elevated but does not add significant diagnostic benefit over serum bilirubin concentration alone in infants.[16,89] Levels of serum transaminases and alkaline phosphatase did not correlate with the severity of liver histology in PNALD.[92]

Reduced serum albumin levels are associated with increased mortality owing to PNALD.[4] However, in patients with excessive protein loss or severe protein-energy malnutrition, hypoalbuminemia and hypoproteinemia may reflect nutritional deficit and not liver dysfunction. Similarly, nutritional vitamin K deficiency may also result in a prolonged prothrombin time.

Biliary Tract Abnormalities

Biliary sludge and/or cholelithiasis occur in 12 to 40% of children receiving long-term parenteral nutrition.[93,94] These may occur as a result of gallbladder hypomotility, changes in the composition of bile, or altered enterohepatic circulation of bile acids. The risk of cholelithiasis is increased in children with ileal resection, ileal disease, or hemolytic anemia or in those receiving furosemide therapy. Biliary stones usually consist of both cholesterol and pigment. Acalculous cholecystitis is associated with high morbidity and mortality.[95]

HISTOPATHOLOGY

Characteristic histologic features are observed in liver biopsies of patients receiving parenteral nutrition; however, these changes are not specific or diagnostic.[9,96,97] The histologic changes progress with duration on parenteral nutrition. The initial lesion, steatosis, may occur within the first 2 weeks of parenteral nutrition administration. The degree of steatosis correlates with the amount of energy infused.[98] Cholestasis occurs predominantly in the centrilobular region and involves hepatocytes, canaliculi, and Kupffer cells (Figure 56-3). Serum conjugated bilirubin concentration may not accurately reflect the extent of cholestasis observed on liver

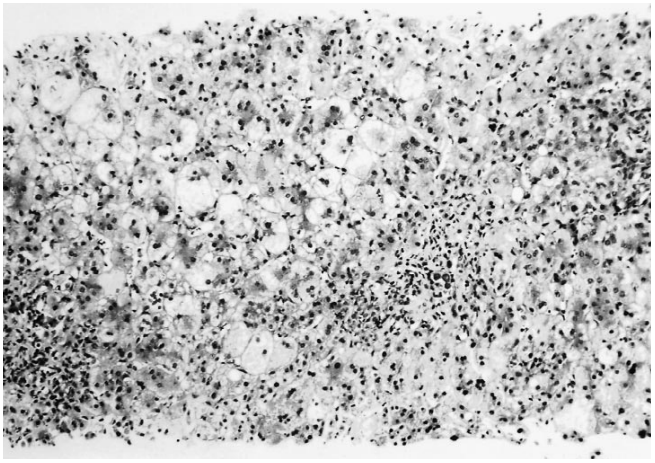

FIGURE 56-3 Light microscopy of a liver biopsy of a patient with parenteral nutrition–associated liver disease showing nonspecific periportal inflammation and mild lobular disarray, with ballooning of hepatocytes, microvesicular steatosis, and focal pseudoacinar arrangement of hepatocytes. Cholestasis is present within canaliculi, hepatocytes, Kupffer cells, and occasional bile ducts. Courtesy of Antonio Perez, MD, Department of Pathology, Children's Hospital, Boston.

biopsy. Mild to moderate periportal inflammation is observed. This is usually a lymphocytic infiltrate, although neutrophils and eosinophils may also be present. With disease progression, hepatocytes become ballooned with lipofuscin granules identified in the periportal region. Kupffer cells are hyperplastic and may also have lipofuscin granules. The lobular architecture becomes disordered with periportal fibrosis observed in most patients. Bile duct proliferation and, less commonly, bridging fibrosis may occur. In infants, extramedullary hematopoiesis is common. If parenteral nutrition administration continues, steatosis and extramedullary hematopoiesis tend to improve, but cholestasis, fibrosis, and progression to cirrhosis can occur.[97] If parenteral nutrition treatment is ceased before the development of cirrhosis, many of the histologic features of liver disease improve.[97] The estimated time from onset of long-term parenteral nutrition to the development of moderate fibrosis (< 50% portal spaces involved) in children with short bowel syndrome is reported to be about 40 months.[96] After the development of fibrosis, there tends to be a more rapid progression to cirrhosis (mean duration 14 months). Hepatocellular carcinoma was reported in a 6-month-old infant dependent on long-term parenteral nutrition.[99]

MANAGEMENT

Cessation of parenteral nutrition is the most effective therapy for the management of PNALD.[4,97,99,100] However, this may not be possible in some patients, and treatment is aimed at minimizing the impact of parenteral nutrition on the liver. This includes the identification of individual risk factors and the development of a multidirected strategy to reduce the adverse impact on the liver. Meehan and Georgeson reported the prevention of liver failure in long-term parenteral nutrition patients using taurine, prevention and aggressive treatment of sepsis, strict catheter care, early parenteral nutrition cycling, "appropriate" enteral feeding, and inhibition of bacterial translocation.[101] The timing of the progression of liver disease is critical in planning which patients may require small bowel or combined liver–small bowel transplant.[4,16,89] In the absence of liver transplant, PNALD can be fatal.[6]

Enteral Feeding

For patients who are unable to discontinue parenteral nutrition, small volumes of enteral nutrition have been shown to reduce the progression of PNALD.[9,102] Minimal or "trophic" enteral feeding is associated with gallbladder contraction, increased bile flow, increased gastrin and glucagon secretion, a reduction in intestinal stasis, and bacterial overgrowth.[4,102] Supplementation of enteral feeds with fish oil rich in Ω-3 long-chain polyunsaturated fatty acids has been advocated in an attempt to limit exposure to Ω-6 polyunsaturated long-chain fatty acids.[103] Excess Ω-6 polyunsaturated long-chain fatty acids have been linked to hepatic inflammation. Supplementation of feeds with Ω-3 long-chain polyunsaturated fatty acids and/or antioxidants (vitamins C and E, *N*-acetylcysteine) has been proposed for the prevention of PNALD.[104]

Prevention of Infection

Meticulous catheter care and prompt and aggressive treatment of infection are important in the prevention of PNALD.[4,6,101] The supervision of central line care and nutrition therapy by a multidisciplinary nutrition support team is associated with a significant benefit in terms of the incidence and age at development of liver disease owing to parenteral nutrition.[105] Routine throat swabs have been used to predict bacteremia in infants receiving parenteral nutrition who have abnormal small intestinal flora.[106] Prompt surgical intervention with possible resection is encouraged in patients with suspected intestinal ischemia in an attempt to minimize hepatic exposure to endotoxin in the neonatal period.[16]

Bacterial Overgrowth

Bacterial overgrowth is a frequent complication of functional and mechanical disorders of the small intestine. The clinical hallmarks of bacterial overgrowth include abdominal distention, vomiting, halitosis, and loose, offensive stool. The diagnosis is established by the quantitative culture of small intestine fluid. A high fasting breath hydrogen level may also be suggestive. Treatment usually involves the use of antibiotics. Metronidazole and the oral nonabsorbable antibiotics gentamicin, kanamycin, neomycin, and polymyxin B have been studied in animals and in limited human trials.[28] Metronidazole prevents PNALD in rats; however, its role in the prevention of human disease is uncertain.[107] In infants receiving parenteral nutrition, intravenous metronidazole was associated with lower serum hepatic transaminase levels but had no effect on the incidence of hyperbilirubinemia.[108] Suppression of bacterial overgrowth may be assisted by avoiding acid-suppressing agents and carbohydrate malabsorption.[16] The use of probiotic microorganisms such as lactobacillus GG and bifidobacteria to suppress the growth of potentially harmful bacteria has been proposed, although the efficacy of probiotics for the prevention of PNALD is yet to be determined.[16,109] Patients with permanent dilatation of a loop of small intestine may benefit from surgical intervention, including resection of a stricture or stenosis or an infolding or tapering procedure.[101]

Modification to Parenteral Nutrition Solution and Administration

Modification of the macronutrient concentrations and balancing their composition in the parenteral nutrition solution may be required in patients with PNALD. Energy should be provided to meet individual needs for growth and activity. Infants receiving energy at 110 kcal/kg/d or greater had a higher incidence of cholestasis compared with infants receiving a lower energy intake.[3] Glucose infusions should be limited to less than or equal to 15 g/kg/d or 12.6 mg/kg/min in premature infants.[66]

Recommendations for intravenous amino acid intakes for premature infants are generally aimed at providing between 2 and 3 g/kg/d.[66] Specialized pediatric amino acid solutions have been developed with the goal of limiting the complications of amino acid imbalance owing to immature

metabolism in the premature and young infant. However, the efficacy of these solutions in preventing or minimizing PNALD has not yet been established.[110,111] Supplementation of parenteral nutrition solutions with taurine has not been shown to reduce serum hepatic enzyme, bilirubin, or bile acid concentrations in premature infants receiving short-term parenteral nutrition.[73–75] Intravenous glutamine supplementation has been shown to improve gut barrier integrity, although its role in the prevention and treatment of PNALD in infants and children requires further study.[112]

Current evidence suggests that in infants and children, lipid emulsions should be limited to < 3 g/kg/d and less than 60% of total daily energy.[19,113] Lipid doses of > 1 g/kg/d were associated with cholestasis and complicated liver disease in adults with intestinal failure receiving home parenteral nutrition. However, this has not yet been confirmed in children.[33] In vitro studies suggest that exposure of lipid emulsion to ultraviolet light results in the production of potentially toxic hydroperoxidases.[114] Therefore, lipid emulsions should be protected from ultraviolet light, particularly during phototherapy. The addition of fat-soluble vitamins to the lipid emulsion may provide some protection from this effect.[115]

In the presence of progressive cholestasis and cirrhosis, modification of the micronutrient composition of the parenteral nutrition solution may include the removal of copper and manganese.[37] This underscores the importance of routine monitoring of micronutrient status in patients receiving long-term parenteral nutrition. Cycling of parenteral nutrition for up to 12 hours a day may help in limiting the progression of PNALD in patients requiring long-term parenteral nutrition.[116,117]

Pharmacologic Management

A number of pharmacologic agents have been proposed for the prevention and treatment of PNALD. Nonsteroidal anti-inflammatory drugs, including acetylsalicylic acid, have been shown to be beneficial in the prevention of PNALD in animal studies.[118,119]

Cholecystokinin-octapetide and the cholecystokinin analog ceruletide stimulate gallbladder contraction and prevent the development of biliary sludge and cholelithiasis in patients receiving parenteral nutrition.[49,50,120,121] The use of these agents in the prevention and treatment of PNALD is encouraging but warrants further clinical investigation.

Ursodeoxycholic acid improves bile flow and reduces serum and liver bilirubin concentrations in piglets with PNALD.[122] In humans, treatment with ursodeoxycholic acid has been associated with a reduction in markers of liver dysfunction, including serum γ-glutamyltransferase, aspartate transaminase, alanine transaminase, alkaline phosphatase, and/or serum bilirubin concentration.[123] A rebound increase in serum γ-glutamyltransferase, alkaline phosphatase, and alanine transaminase concentration was observed in children in whom ursodeoxycholic acid was discontinued in the presence of ongoing parenteral nutrition administration.[123] These patients responded to reintroduction of ursodeoxycholic acid therapy. This raises the question of whether ursodeoxycholic acid reduces serum markers of liver dysfunction in PNALD but does not influence the progression of liver disease. Enteral administration of tauroursodeoxycholic acid was not found to be effective in the prevention of PNALD in neonates.[124]

Other pharmacologic agents, including antibiotics, cholestyramine, rifampin, and phenobarbital, have been studied in the context of management of PNALD.[28] Surgical approaches aimed at improving bile flow, including biliary irrigation, have also been associated with improvement in PNALD in some patients.[125,126]

Liver–Small Bowel Transplant

Most children requiring long-term parenteral nutrition have underlying intestinal disease, either short bowel syndrome or severe intestinal dysfunction. If transition to full enteral nutrition cannot be achieved and parenteral nutrition cannot be discontinued, over time, PNALD may progress to overt liver failure.[4] Small bowel transplant prior to progression to severe liver disease and combined liver–small bowel transplant are therapeutic options for the management of both primary gut disease and the complication of parenteral nutrition–associated liver failure. Because the morbidity and mortality associated with small bowel transplant are probably more favorable compared with combined liver–small bowel transplant, it is important that referral to a transplant center is made before the liver disease becomes irreversible.[16,89,127,128] Elevation of the total serum bilirubin level of > 3 mg/dL for over 3 months in a parenteral nutrition–dependent infant and/or early clinical features of progressive liver disease, including mild splenomegaly, dilatation of abdominal wall veins, and a deteriorating platelet count, are indications for referral.[16,89] Serum hepatic or biliary enzyme levels provide no additional predictive benefit in patients with PNALD.[16] Hypoalbuminemia, coagulopathy, and hypoglycemia during cycling of parenteral nutrition are markers of hepatic synthetic dysfunction. These are considered late features of liver disease and are associated with a poor prognosis.[16] In the setting of progressive PNALD and portal hypertension, severe bleeding may occur from stomas in patients with short bowel syndrome.

CONCLUSION

Infants and children receiving parenteral nutrition are at risk of developing PNALD. No single factor has been shown to be responsible for the development of this potentially fatal complication. Current evidence suggests that the developing liver is particularly sensitive to injury resulting from a range of individual factors, such as infection and intestinal stasis, and that PNALD has a multifactorial etiology that, in part, is determined by the underlying clinical indication for parenteral nutrition administration. Discontinuation of parenteral nutrition is the most effective treatment, but this cannot be achieved in some patients. Treatment strategies that include the identification of risk factors and the development of a multidirected approach to the prevention and treatment of PNALD are required. Although new pharmacologic and

surgical approaches have been reported, the risks and benefits of these therapies still need to be assessed in randomized prospective controlled trials. Small bowel or combined liver–small bowel transplant provides a therapeutic option for long-term parenteral nutrition–dependent patients with PNALD in the presence of short bowel syndrome or severe intestinal dysfunction.

CHAPTER 57

SYSTEMIC CONDITIONS AFFECTING THE LIVER

Mounif El-Youssef, MD
Deborah K. Freese, MD

An understanding of the effects of systemic diseases on hepatobiliary function in infancy and childhood requires an understanding of liver physiology and, in particular, how that physiology changes with increasing maturity. This is described in detail in Chapter 5, "Liver Function and Dysfunction." It is particularly important to recognize that many of the cells that comprise the liver and biliary tract respond to potentially toxic insults differently at different ages and that the process of cell repair and wound healing varies with the insult to the liver and the age of the patient. The liver may be injured as a passive bystander or may actively exacerbate the systemic conditions described below.[1–19] The following discussion is organized by organ system or major categories of systemic disease and is meant to provide a clinical overview of hepatobiliary function during system illnesses.

ACUTE CARDIAC DISEASE

The pediatric hepatologist may be called on to evaluate the infant and child with cardiac disease in several situations. These include (1) the patient with acute liver injury from cardiogenic circulatory compromise, (2) the patient with chronic congestive heart failure or outflow obstruction, and (3) the patient with complex congenital anomalies in which the liver and heart are affected by associated malformations.[20–22]

Acute circulatory failure results in a typical pattern of liver injury that is a result of the unique dual blood supply to the liver and of the heterogeneity of the liver acinus. Two-thirds of the blood supply to the liver is from the portal circulation, and the remainder is from the hepatic artery. The oxygen-rich blood perfuses the liver acinus, creating a gradient of oxygenation, with the maximal concentration of oxygen delivered to the periportal zone 1 of Rappaport and the lowest concentration of oxygen to the pericentral zone 3. Blood flow to the liver is regulated locally by the concentration of adenosine, a vasodilator that is produced by endothelial cells. With poor perfusion, the local concentration of adenosine increases, and vasodilation occurs. This results in increased portal flow that compensates partially for the reduced arterial flow. Outflow resistance may also affect oxygenation of the liver, as in acute cardiogenic shock. Thus, cells in the pericentral zone of the liver are most susceptible to perfusion-related injury.

Clinical Presentation

The infant or child with ischemic hepatic injury is usually critically ill. Cardiac symptoms may predominate, but, occasionally, the cardiac origin may not be recognized, especially when hepatic symptoms predominate and initial attention focuses on liver dysfunction.[19] This is particularly true in cases of noncyanotic heart disease. The liver is uniformly enlarged, and the edge is round and smooth, reflecting generalized engorgement of the organ.[23,24] Jaundice, which is usually a later manifestation of liver disease, may not be apparent in the first few days after the acute event.

Concentrations of hepatic transaminases are increased up to 200 times the upper limit of the reference range. Lactic dehydrogenase is also increased and, if fractionated, is mostly of hepatic origin (Table 57-1). This increase in lactic dehydrogenase, seldom seen in viral hepatitis, may be used to distinguish ischemic hepatic injury from acute viral hepatitis.[25] The dramatic increase in aspartate aminotransferase and alanine aminotransferase reflects the predominant injury to the central zone of the liver.[26–28] Not uncommon is an association with renal hypoperfusion and increases in serum urea nitrogen and serum creatinine. Acute renal tubular necrosis may also occur. The peak concentration of the transaminases occurs in the first 3 days after the insult. The concentrations return to normal in 5 to 7 days except in patients with ongoing liver ischemia. Coagulation is significantly altered, and, typically, the prolongation of the prothrombin time, as indicated by the international normalized ratio, is not corrected by the

TABLE 57-1 THE LIVER IN HEART DISEASE

Hepatomegaly with a smooth rounded edge of the liver
Jaundice and hyperbilirubinemia
Splenomegaly with chronic cardiac insufficiency
Differential elevation of liver-derived enzymes AST > ALT
Coagulopathy unresponsive to vitamin K

ALT = alanine aminotransferase; AST = aspartate aminotransferase.

administration of vitamin K. Jaundice and the increase in bilirubin occur later, usually by the third to fifth day after the original insult. Typically, the degree of hyperbilirubinemia is mild compared with the increase in transaminases and is by no means universal.[29] Cholestasis occurs with a decrease in transaminases. Persistence of cholestasis and coagulopathy with normalizing concentrations of enzymes indicates a poor prognosis and an exhaustion of the hepatocyte mass owing to the acute ischemic event.

A pig model of cardiogenic shock showed that immediately following decreased liver perfusion, there is an increase in messenger ribonucleic acid for acute-phase proteins.[30] Expression of certain heat shock proteins was also demonstrated, with the potential for preservation of cellular integrity. The significance of this expression and its relationship to the degree of liver injury and potential for recovery are unknown.[31]

Histologically, the pericentral area shows variable degrees of parenchymal necrosis and hepatocyte loss directly related to the duration of shock. There is little inflammatory activity, and the necrotic areas are clearly defined. At this stage, cholestasis is not a prominent feature.[32] The differential diagnosis of ischemic hepatic injury is usually not a problem because cardiac signs and symptoms predominate. Patients with other conditions associated with shock and ischemic events, including septic and hypovolemic shock, may present similarly. Protracted seizures and drug-induced hepatitis must be considered as well with this constellation of biochemical and histopathologic features. Patients with severe rhabdomyolysis may present with a marked increase in aspartate aminotransferase that is out of proportion to the concentration of alanine aminotransferase. The presence of muscle pain, easy fatigability, and, occasionally, bulky muscle mass should be sought. The presence of myoglobinuria and an increase in creatinine kinase help in the differential diagnosis.

Therapy for ischemic hepatic injury is directed toward the original insult. Supportive measures include the administration of vitamin K and, if bleeding is a problem, fresh frozen plasma. The injury to zone 3 hepatocytes, the site of xenobiotic and drug metabolism, may increase the susceptibility of the liver to potentially toxic metabolites of medications administered to these patients.

Prognosis

Correction of the original insult results in resolution of the hepatopathy. An ischemic event with a duration of more than 24 hours usually results in severe liver injury and may progress to liver failure. The lack of resolution of the coagulopathy together with a decrease in transaminases and deepening jaundice is ominous. In several adult and pediatric series, the most important prognostic factors for survival were the degree of shock and, most importantly, the duration of the ischemic event. A duration of circulatory disturbance of more than 24 hours is associated with significant morbidity and mortality.[33,34] The cardiac lesions that most commonly result in significant liver involvement are hypoplastic left heart syndrome and coarctation of the aorta.[24]

CHRONIC CARDIAC DISEASE

The liver is vulnerable to a chronic increase in pressure on the right side of the heart. Chronic passive congestion results in sinusoidal dilatation and engorgement, fibrosis, and, eventually, cirrhosis.[34,35]

Clinical Manifestations

Clinically, the liver is enlarged and hard; the edge is usually smooth, but nodularity is apparent in the advanced stages. The increase in liver-derived enzymes is minimal or nonexistent at first. With time, a slow, mild increase in transaminase values, as well as increases in the biliary tract–derived enzymes, is seen. Presumably, the degree of fibrosis is related to the development of microthrombi in the sinusoids and in the hepatic veins. The distribution of fibrosis can be uneven, with the right and left lobes affected to different degrees.

In a series of 150 pediatric patients, the severity and duration of hypoxia correlated with the amount of connective tissue present at autopsy.[35,36] Fibrosis had asymmetrically affected the lobes of the liver. Inhomogeneous liver parenchyma was noted on computed tomography in 24 of 25 patients with congestive heart failure.[36] Other patterns noted included hepatomegaly, enlargement of the inferior vena cava, and early reflux of contrast material into the inferior vena cava. The patient may or may not be jaundiced. The degree of hyperbilirubinemia fluctuates and occasionally results in overt jaundice. In late stages, jaundice in cardiac cirrhosis indicates a poor prognosis.

Histologic Features

Bands of fibrosis and, occasionally, cirrhosis are seen. Sinusoidal engorgement and dilatation are common (Figure 57-1). With chronic congestion, zone 3 hepatocytes atrophy, and the liver grossly resembles a nutmeg because of the association of areas of engorgement and atrophy. In cases of fetal hydrops, the liver congestion is accompanied by hemosiderosis in zone 1 hepatocytes.[37]

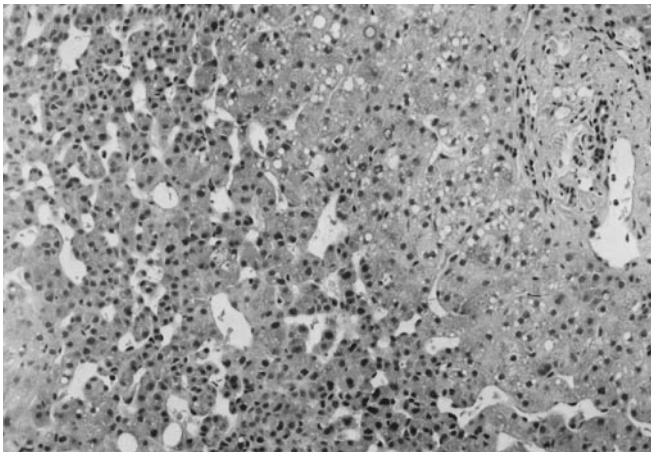

FIGURE 57-1 Venous outflow obstruction of cardiac origin. Note sinusoidal dilatation (hematoxylin and eosin; ×40 original magnification). Courtesy of Dr. L. Burgart, Mayo Clinic and Foundation.

TREATMENT

For children who have a chronic increase in right-sided ventricular pressure from surgical correction of congenital heart disease, definitive correction is not always possible. With advances in medical and surgical care, more of these children are surviving into young adulthood, and cardiac cirrhosis may become the most important factor for their survival. The chronically congested liver is more susceptible to other insults. Animal studies have shown that endotoxemia with congestive heart failure can lead to fulminant hepatic failure.[35]

PROGNOSIS

Prognosis is variable because the distribution of pressure is not uniform throughout the liver, and there may be significant potential for compensated cirrhosis. Correction of the underlying cause is therapeutic in most cases.

OPEN HEART SURGERY

It is not uncommon for patients to have both congenital heart disease and congenital liver disease. The infant with a paucity of bile ducts or biliary atresia may have hemodynamically significant congenital heart disease, and the cardiac surgeon often inquires about the possibility of liver damage during open heart surgery and extracorporeal oxygenation. The infant or child with a paucity of bile ducts is usually jaundiced. The serum concentrations of biliary tract–derived enzymes are markedly increased, but the increases in transaminases are only moderate. In our experience, the prothrombin time is the best indicator of the ability of the patient to avoid fulminant hepatic failure as a result of the operation. Often the cardiac lesion is more serious than the liver lesion in patients with syndromic paucity of intrahepatic bile ducts. The same is not entirely true for the association of biliary atresia, polysplenia, dextrocardia, and congenital heart and vascular lesions. In terms of the liver, the earlier a portoenterostomy is performed, the better the hepatic outcome. If biliary drainage is accomplished and the infant is thriving, the cardiac lesion can be corrected at a later, optimal time. If biliary drainage is not accomplished, the cardiac lesion will be corrected in conjunction with liver transplant to optimize the outcomes of both operations. Once again, the prothrombin time and the degree of cholestasis and growth failure are used to determine the timing of the intervention and the degree of support required during and after the intervention.

Liver abnormalities are not uncommon after open heart surgery.[38,39] The increase in liver-derived enzymes is similar to that in ischemic hepatitis, although much smaller. Hyperbilirubinemia occurs later and is related to the duration of hypothermia and extracorporeal circulation. The infant or child with persistently low cardiac output is most susceptible to the development of liver injury. Blood transfusions during the operation add to the hyperbilirubinemia. The duration of hypoperfusion and the response to inotropic agents are important factors in the degree of liver involvement. Liver failure with encephalopathy has been reported for both adult and pediatric patients.[40–43]

CARDIAC TRANSPLANT

The liver may show evidence of being affected immediately within the first 2 weeks after cardiac transplant or not until the development of chronic liver disease. In the setting of established pulmonary hypertension, after heart transplant, the immediate insult to the liver is due to right-sided heart failure if the transplanted organ fails. This is similar to heart failure from other causes; however, the clinical case may be further complicated by acute rejection and infections. Chronic liver disease after heart transplant may be due to a lymphoproliferative disorder involving the liver or to chronic viral hepatitis acquired after transplant. The infection is due to hepatitis B and C viruses and to non-A–E hepatitis viruses, as well as to de novo infections with cytomegalovirus. Most cases of chronic hepatitis B and C are mild, and fulminant cases are rare except in cases of precore mutants of hepatitis B virus. Immunosuppression may lead to faster progression of liver fibrosis.[44]

SEPSIS

Infants and children with systemic or localized infections may have significant liver involvement.[45–48] One example is the classic description of neonatal cholestasis in the context of a urinary tract infection. Underestimation of liver dysfunction is likely because usually only jaundiced patients are evaluated. Jaundice from septicemia occurs infrequently. In an adult series of 1,150 bacteremic patients, only 7 had jaundice.[46]

The organisms implicated in the development of hepatic dysfunction include gram-negative enteric pathogens, streptococci, and staphylococci. The site of infection varies. For instance, jaundice with septicemia is one such manifestation, and hepatic abscess is known to complicate appendiceal infections. Another example is soft tissue infections leading to hepatopathy.

The onset of jaundice occurs 2 to 5 days after the infection, and the degree of direct hyperbilirubinemia varies from 5 mg/dL to more than 60 mg/dL. Hepatomegaly occurs in about 50% of the cases, and, in this instance, exclusion of hepatic abscess or cholangitis is important in the differential diagnosis.[47,48] The hepatomegaly is due to the activation of the reticuloendothelial system.[46–50]

The increases in the liver- and biliary tract–derived enzymes are only moderate compared with the degree of hyperbilirubinemia, and this dissociation is characteristic of septicemia. However, the increase in alkaline phosphatase may be significant at the onset of jaundice and during the resolution of jaundice.[46,50–52]

The recognition of the polarity of the hepatocyte has shed new light on the transport mechanisms of organic acids and bile salts. Evidence has shown that the cholestasis of septicemia is associated with abnormal regulation of the localization of the multidrug resistance protein 2. This transporter is responsible for the secretion of conjugated bilirubin at the canalicular membrane. The effect of endotoxin on this transporter results in its translocation to the inner cytoplasmic membrane. Thus, the degree of hyper-

bilirubinemia is out of proportion to the degree of hepatocyte damage.[53,54]

Histologically, the liver may show suppurative cholangiolitis without large duct cholangitis, in association with intrahepatic cholestasis (Figure 57-2). The lesion in the context of the clinical findings is characteristic.[48] Cholestasis alone is also common (Figure 57-3).

One important consideration is that septic patients have other confounding factors that may contribute to cholestasis. For example, some patients with multiorgan failure may have received blood products or are receiving total parenteral nutrition (TPN) and various medications. In particular, cephalosporins and biliary sludge may contribute to cholestasis. Evaluation of the patient centers on the exclusion of an hepatic abscess or ascending cholangitis. Treatment of the underlying cause is essential. There are no data on the efficacy of supportive treatment, including bile acid supplementation and early feeding, but their use is common. The prognosis is excellent after the infection is controlled.[47,50]

Characteristic features of certain infections are worth mentioning. For example, the liver may be involved in pneumococcal pneumonia.[46] The right lobe is most commonly affected, and the male-to-female ratio is 10:1.[46,47] There is swelling of hepatocytes and focal necrosis. The increase in serum transaminases may be moderate. Usually, the increase in aspartate aminotransferase is greater than the increase in alanine aminotransferase. Streptococcal infections may be associated with jaundice, and an association with scarlet fever has been described in which the liver may be tender and enlarged. Hepatomegaly and hepatitis with jaundice are not uncommon in ehrlichiosis, a tickborne infection. A history of exposure in endemic areas is helpful, and the typical rash on the palms and soles aids in the diagnosis. Hepatic involvement resolves with antibiotic therapy.[54–56]

A mild hepatitis that is often subclinical is not infrequent with varicella. The increases in serum transaminases are about three times the upper limit of the reference range. The increase is transient, and the hepatitis usually follows a benign course.[46]

CONNECTIVE TISSUE DISEASE

Liver involvement is often considered in the child with connective tissue disease for a number of reasons: (1) the child has a new-onset disease and autoimmune hepatitis is a consideration; (2) the child has connective tissue disease and involvement of the hepatobiliary system, usually evident as increases in transaminases and alkaline phosphatase and hepatosplenomegaly; and (3) the child is receiving medications that may impair liver function and questions arise as to the potential hepatoxicity of these medications.

Juvenile Rheumatoid Arthritis

Hepatosplenomegaly is not uncommon in juvenile rheumatoid arthritis (JRA). Approximately 10 to 15% of the children may have hepatomegaly sometime during the course of the disease. Splenomegaly is usually more prominent and occurs more frequently than hepatomegaly. The occurrence of splenomegaly with neutropenia and active systemic JRA characterizes Felty syndrome.[57] Hepatomegaly and increases in transaminases may occur with systemic JRA.[58,59] The histologic findings are nonspecific, showing Kupffer cell hyperplasia and focal hepatitis.[57–59] The occurrence of a hepatitis exacerbation is sometimes associated with improvement of the arthritis, but the mechanism is unknown.

Long-standing JRA, usually of more than 8 years, can be associated with amyloidosis.[60] The incidence is about 4% in adult series. Hepatosplenomegaly with proteinuria should increase awareness of amyloid deposition in multiple organs, but this complication is rare in pediatric patients.

Another feature is the asymptomatic increase in serum alkaline phosphatase and transaminases. The increase in alkaline phosphatase reported in the adult population is not as prevalent as in the pediatric population.[58] Some of this increase is from multiple sources, and some is from the inflamed synovium. The number of joints involved seems to

correlate with the increase in the alkaline phosphatase. More common, however, is the increase in transaminases, which has a dose-dependent association with aspirin therapy.[61] The patient with JRA who is receiving aspirin therapy is more susceptible to the development of Reye syndrome.[61–64] One may speculate about the existence of subtle mitochondrial fatty acid oxidation genetic defects that are triggered by particular environmental factors in this population. With the discovery of more mitochondrial errors of metabolism, it is possible that concomitant administration of toxic medications may unmask these conditions.

The use of aspirin has been largely replaced by the use of nonsteroidal anti-inflammatory drugs that are less toxic to the liver. However, the potential for an idiosyncratic reaction in the form of fulminant hepatic failure is possible.[65,66] Gold toxicity manifests as cholestasis; histologically, the liver shows cholestasis and deposits of gold particles in Kupffer cells. The liver may have a brown-black pigmentation. Fulminant hepatic failure has been reported with the use of gold compounds, but the use of this treatment is uncommon in the pediatric age group.

Methotrexate is increasingly used for JRA. Two patterns of liver involvement occur. One is a mild increase in liver enzymes, about three to four times the upper limit of the reference range, that occurs in 15% of patients.[67,68] The other is progressive fibrosis that may be clinically silent. The progression to fibrosis seems to be related to a cumulative methotrexate dose of more than 1.5 g. In pediatrics, our experience and the experience of others with small series is that fibrosis is not common, even when methotrexate doses exceed 1.5 g. In adults, the toxicity of methotrexate is significantly increased with obesity and alcohol consumption.[67–71]

Systemic Lupus Erythematosus

The liver is involved in up to 40% of patients with systemic lupus erythematosus (SLE). Hepatomegaly occurs in about one-third of the patients sometime during the illness. Increases in liver-derived enzymes occur in two contexts: with use of hepatotoxic medications and with use of aspirin, the most important culprit.[72–81] In addition, the use of corticosteroids may be involved with steatosis and the use of azathioprine with cholestasis.

The association of SLE and autoimmune hepatitis is well described in detail elsewhere.[73,74] The presence of autoimmune markers common to both diseases is not uncommon, and the liver lesion of SLE is indistinguishable from classic autoimmune hepatitis. This spectrum of liver disease fits into the overlap syndrome seen in adult patients who have features of autoimmune hepatitis and primary sclerosing cholangitis. The liver enzyme concentrations and the histologic changes improve rapidly with immunosuppression therapy.

The presence of a hypercoagulable state may lead to vaso-occlusive disease (VOD) of the liver or to Budd-Chiari syndrome. The association with lupus anticoagulant and anticardiolipin antibodies is well described.[78–82]

The liver may be involved in the transient abnormalities of neonatal SLE.[82,83] This occurs because of the transplacental transfer of antibodies from the mother to the fetus and is associated with anti-Ro and anti-La antibodies. The characteristic pattern is congenital heart block, dermatitis, and hematologic abnormalities. Cholestasis that resolves by 6 months of age has been described and is associated with portal fibrosis, bile duct obstruction, and inflammation. Any infant with a combination of cardiac arrhythmias and cholestasis should be evaluated for SLE, especially because the maternal disease may be asymptomatic and unrecognized.

Juvenile Dermatomyositis

The liver is seldom involved in juvenile dermatomyositis. However, the increase in the aspartate aminotransferase from muscular origin can masquerade as hepatitis early in the disease. Hepatosplenomegaly is not uncommon in the severe form of the disease. The use of methotrexate may be associated with increases in liver-derived enzymes, and the long-term consequences are often of concern.[66,72–74] The use of nonsteroidal anti-inflammatory drugs can add to the concern for hepatotoxicity.

Miscellaneous Connective Tissue Disease

The liver and spleen may be involved in mixed connective tissue disease, an overlap syndrome with features of SLE, scleroderma, and polymyositis.[82] The involvement is from generalized vasculitis, and usually there is hepatosplenomegaly. The vasculitis involves medium-size vessels, with intimal thickening and inflammation in the periportal areas.[84]

Hydrops of the gallbladder and increases in the liver enzymes occur in Kawasaki disease.[83] Hepatomegaly and increases in the liver enzymes occur in about one-third of the patients. The use of high doses of aspirin causes dose-dependent toxicity in the liver, which has occasionally led to severe hepatitis. Histologically, Kupffer cell hyperplasia, bile duct inflammation, and gallbladder wall thickening have been reported. Interestingly, hydrops of the gallbladder may respond to therapy with low doses of nonsteroidal anti-inflammatory drugs.

HEMATOLOGIC DISORDERS

Sickle Cell Disease

Depending on the definition and the diagnostic methods used, the incidence of liver disease in sickle cell (SC) disease varies. If one uses abnormal concentrations of liver-derived enzymes as an indicator, liver disease may be present in up to 65% of the patients. If histologic criteria are used at autopsy, the liver is universally involved in SC disease.[84,85]

Several issues are often considered in patients with SC disease: (1) the distinction of acute crises from acute gallbladder disease, (2) the contribution of cardiac dysfunction to acute SC disease crises, (3) the chronic overload of iron and bilirubin in the liver and in other organs, and (4) the association of chronic hepatitis from contaminated blood products in patients with SC disease.

Any of the following factors lead to liver injury: (1) the increased hemolysis adds to the development of unconju-

gated hyperbilirubinemia[85]; (2) the increased concentrations of bilirubin and turnover lead to increased risk of pigment gallstones and acute and chronic gallbladder disease; (3) the additional transfusions increase the risk of bloodborne infections and contribute to the iron overload; iron overload with or without anemia may lead to cardiac dysfunction and secondary liver congestion; and (4) the liver may have repeated episodes of ischemic crises; the reticuloendothelial system is the first to be affected by the iron overload, and the hepatocytes are affected later. In severe cases, brown pigmentation of the hepatocytes is seen with hematoxylin and eosin stain.[84,86]

Acute Hepatic Crisis

The liver is involved in an acute hepatic crisis in about 10 to 15% of patients with SC disease.[87,88] Pain in the right upper quadrant of the abdomen, tender hepatomegaly, increases in serum transaminases, and conjugated hyperbilirubinemia develop. Fever is common. The results of coagulation studies are normal. The distinction of SC hepatopathy from acute cholecystitis may be difficult. The biliary tract–derived enzymes and serum transaminases may be equally increased. Conjugated hyperbilirubinemia is common, and concentrations may vary from 15 to 50 mg/dL. The transaminases are increased up to 10 times the upper limit of the reference range. An increase in lactic dehydrogenase is common and reflects ongoing hemolysis. Imaging of the intrahepatic and extrahepatic bile ducts is important and may help in the differential diagnosis. The difficulty arises when there is a hepatic crisis with incidental cholelithiasis. Careful observation and supportive therapy may lead to a rapid resolution of liver abnormalities, and a lack of dilated bile ducts and normal concentrations of pancreatic enzymes help in determining the course of the disease. Occasionally, a liver biopsy is indicated. The classic sinusoidal congestion, sickling, Kupffer cell hyperplasia, and erythrophagocytosis are characteristic of SC hepatopathy.

Acute and Chronic Cholecystitis

Acute cholecystitis and choledocholithiasis in SC patients are similar to those conditions in other patients.[87,89–95] The triad of abdominal pain and tenderness in the right upper quadrant, fever, and increased serum biochemical biliary tract inflammatory markers helps in the diagnosis. Imaging studies show dilatation of the biliary tree in some patients. Others with hepatic crisis improve rapidly.

The most difficult diagnostic decisions involve conditions without a clear cause. Intrahepatic or endoscopic imaging of the biliary tree is then essential. Endoscopic imaging can be coupled with therapeutic maneuvers and may obviate the need for operative intervention. Endoscopic treatment of complications should be considered in centers with expertise in therapeutic endoscopic retrograde cholangiopancreatography.

Chronic pigment gallstones occur in 70 to 80% of patients with SC disease.[87,89–95] The incidence increases with age and is related to the increased concentrations of bilirubin from hemolysis. The consultant is often asked to consider whether an incidental cholelithiasis needs to be addressed. If the child is well and there are no significant symptoms or increases in liver enzymes, careful observation and awareness of the finding are important if pancreatitis or choledocholithiasis occurs.

CHRONIC IRON OVERLOAD

Repeated transfusions result in chronic iron overload (Table 57-2). Iron overload is most common in thalassemia.[85,96] The identification of genetic markers for hemochromatosis is challenging because the development of iron toxicity in this population is variable and occurs at a later stage in life. When thalassemia and hemochromatosis occur in the same patient, it can be difficult to determine the best method of following iron overload. There are no known reports of associated diseases (Figures 57-4 and 57-5). However, hepatitis correlated with the accumulation of more than 300 μg of iron per gram of liver tissue, presumably as a result of oxidative injury.[97] Therefore, in patients with multiple transfusions, increases in the liver enzymes may be a manifestation of iron overload, requiring measurement of ferritin and histologic confirmation with iron stains of the liver. This would also exclude other infections and vascular hepatic insults.

Chronic Viral Hepatitis Complicating Iron Overload States

Chronic viral hepatitis occurs in about 25 to 30% of patients with SC disease.[94,98] Screening for hepatitis C virus has reduced the risk of transfusion-associated infection. In a series of 99 patients, 23% had evidence of hepatitis C virus infection.[94] The risk of infection is related to the frequency of blood transfusions, and multiple transfusions may result in repeated infections with different genotypes. The frequency of transfusions, combined with chronic liver disease, may complicate the response to treatment. There are no reports that clarify the optimal antiviral therapy and the response to therapy for this population.

Thalassemia

The transfusion requirements of patients with thalassemia lead to iron overload and eventually to liver fibrosis and cirrhosis. The risk of viral infection is high in this patient population, and the patients who received transfusions before the availability of screening for hepatitis C virus have a high incidence of infection. Histologic findings in the liver are nonspecific and may show the characteristic features of hepatitis C infection.[94,98]

TABLE 57-2 CHRONIC IRON OVERLOAD

Infection with hepatitis C virus constitutes an important cause of morbidity in patients with β-thalassemia.[99] The patient may be infected more than once and with more than one strain of the virus. The combination of iron overload and viral burden may accelerate the progression to fibrosis.

Coagulation Disorders

The use of contaminated blood products, especially before 1990, has resulted in a high incidence of hepatitis C infection in patients with hemophilia.[94,98] In this population, the liver is commonly involved, and increases in the liver-derived enzymes are not unusual. Because the patients have had multiple transfusions, infection may have occurred through more than one genotype. The results of therapeutic trials in this population are pending at this time.

Budd-Chiari Syndrome

Budd-Chiari syndrome can be a manifestation of either coagulation disorders or vascular diseases affecting the liver (Table 57-3). Because coagulation disorders are associated with this syndrome, it is another example of how the liver is involved in hematologic diseases. Yet, worldwide, membranous obstruction of the hepatic veins is the most frequent cause of this syndrome.[100]

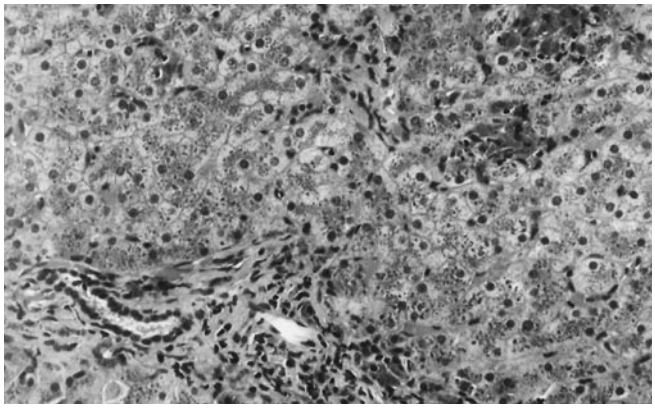

FIGURE 57-5 Severe hemosiderosis with sickle cell disease (hematoxylin and eosin; ×40 original magnification). Courtesy of Dr. L. Burgart, Mayo Clinic and Foundation.

The acute form is characterized by the sudden onset of abdominal pain in the right upper quadrant, tender hepatomegaly, and ascites. The acute event leads to mild increases in the liver enzymes, and in a similar fashion to cardiac congestion, the increases in enzymes reflect zone 3 involvement. Prolongation of the prothrombin time is common, but this finding may be confusing if a hypercoagulable state is present.[101,102]

Acute events may result from thrombosis of the hepatic veins as a result of protein C deficiency, antithrombin III deficiency, mutations in the genes for factor V Leiden and thrombin, polycythemia vera, primary lymphoproliferative disorders, inflammatory bowel disease, paroxysmal nocturnal hemoglobinuria, Behçet syndrome, and collagen vascular diseases, including those associated with anticardiolipin antibodies and lupus anticoagulant.

Acute obstructive lesions are usually due to tumor invasion from adrenal and renal cancers. Occasionally, patients who have hepatic tumors that have spread beyond the liver may present with acute Budd-Chiari syndrome.

Chronic Budd-Chiari syndrome is usually due to membranous obstruction of the hepatic veins, a condition common in developing countries. The lesion may be congenital or, perhaps more commonly, due to thrombosis. Thrombosis is often found histologically, but it is difficult to know whether it is a consequence of congenital occlusion. The increases in the liver-derived enzymes are mild, and coagulation is normal. Progression of the disease leads to manifestations of portal hypertension and liver failure, including ascites, hepatic encephalopathy, and variceal bleeding. Treatment of membranous occlusion is by invasive radiologic techniques. Advanced liver disease can be corrected with transplant, although recurrence of disease in the transplanted liver is possible, especially when polycythemia or primary thrombotic conditions are present.[100–120]

The diagnosis of Budd-Chiari syndrome is made with the use of several types of imaging techniques, from Doppler ultrasonography to magnetic resonance imaging. Hypertrophy of the caudate lobe is a peculiar feature found on technetium uptake because of the differential drainage of this lobe. The caudate lobe drains directly into the inferior vena cava and is enlarged because of hypertrophy from portal hypertension in Budd-Chiari syndrome.[104,118,121–124]

A dual approach is used to manage Budd-Chiari syndrome: identify the original insult and treat the present

condition. Diagnosis of hypercoagulable states should be sought and the evaluation for polycythemia pursued vigorously to prevent recurrence of vascular compromise. If the liver shows only congestion and the response to diuretic therapy is good, anticoagulation may be attempted. If a subsequent liver biopsy shows persistent congestion, only then can medical therapy be continued. If severe necrosis is present, surgical shunting is offered. If fibrosis is present, medical therapy and evaluation for liver transplant are initiated.[112–115,121]

Vascular Diseases

The dual supply of blood to the liver is a fundamental difference between it and other organs.[116,117,125] Development of a liver infarct requires that occlusion to both the arterial and the venous supplies occurs simultaneously. Occasionally, occlusion of the hepatic and portal veins occurs, leading initially to loss of hepatocytes and subsequently to bridging fibrosis. After atrophy of the hepatocyte mass has occurred, compensatory hypertrophy occurs in the remaining liver tissue.[126] Depending on the location and the extent of vascular compromise and the reparative adaptation of the liver, several clinicopathologic entities may occur. In noncirrhotic portal hypertension, reactive nodular hyperplasia and idiopathic portal hypertension accompany the liver cell atrophy. The liver function is normal,[126–135] and the liver is characteristically normal in size.

Nodular hyperplasia of the liver occurs with systemic diseases (Table 57-4). The hyperplasia occurs in different forms, depending on the extent of vascular compromise. In large nodular hyperplasia, extensive areas of the liver are affected, and several large nodules are present. In regenerative nodular hyperplasia, the liver has many small nodules affecting multiple areas of the liver. Large nodules are not accompanied by portal hypertension unless they become numerous. These large lesions occur with congenital anomalies of the portal vein, such as absence of the portal vein, patent ductus venosus, or large arteriovenous shunts. A recent report of focal nodular hyperplasia mentions its association with multiple clonal chromosomal aberrations.[136] The patient presents with silent hepatomegaly owing to focal nodular hyperplasia, and the diagnosis is established by imaging studies and analysis for clonal abnormalities in the mesenchymal origin of the vascular stroma.

When the vascular supply is severely impaired, leading to significant and mainly venous injury, cirrhosis may be the end result. This leads to the loss of hepatocyte function, marginal blood supply, capillarization of sinusoids, and various degrees of cholestasis.

The involvement of hepatic arteries in systemic conditions is not uncommon. The dual supply of the liver is protective for the most part; however, arterial compromise affects the large intrahepatic bile ducts, and stricture formation secondary to biliary necrosis is a well-recognized complication of hepatic artery injury, whether surgical or thrombotic.

One report describes ischemic necrosis of bile ducts complicating Henoch-Schönlein purpura owing to hepatic vasculitis. The vasculitis affected the integrity of the biliary system and resulted in biliary cirrhosis, requiring transplant.[137]

Research into the biology of the endothelial cell has led to several conceptual advances: (1) the identification of endothelin, a potent vasoactive peptide; (2) the identification of overproduction of endothelin in the injured liver; and (3) the elucidation of the synthesis and function of nitric oxide.[13–18] The recognition that endothelin and nitric oxide are produced by endothelial cells and that they have dramatic effects on the surrounding stellate cells and on the microvasculature is shedding new light on the function of these cells in the development of portal hypertension. The recognition of the importance of the endothelial cell during ischemic liver injury and its targeting by host lymphocytes during organ rejection has become critical to our understanding of the cellular and molecular events in liver transplant and disease.[10–17]

MALIGNANCIES

Leukemia

Hepatosplenomegaly is common in leukemia. About one-third of patients with leukemia have clinical and biochemical abnormalities sometime during their illness. One rare presentation of neonatal leukemia is liver failure, and biopsy results are usually needed for the diagnosis. The response to chemotherapy is dramatic. The histologic finding is leukemic infiltration of the liver by malignant cells (Figure 57-6).[138]

Increases in liver-derived enzymes occur often, especially during therapy, but the increase is transient. In our experience, several patients continued to have abnormal serum concentrations of liver enzymes while they received low-dose maintenance therapy with azathioprine. The increases in liver enzymes correlated with the metabolic activity of thiopurine methyltransferase.

Neutropenia predisposes the patient to opportunistic infections, and severe hepatitis from adenoviral infection has been reported in this population. More ominous is fungal infection, for which the only clues may be hepatomegaly, increases in liver enzymes, and fever.[139,140]

Hodgkin Lymphoma

The extent of liver involvement in Hodgkin disease varies with the timing of the evaluation.[141–146] Whereas the liver is clinically involved in about 5% of the patients at pre-

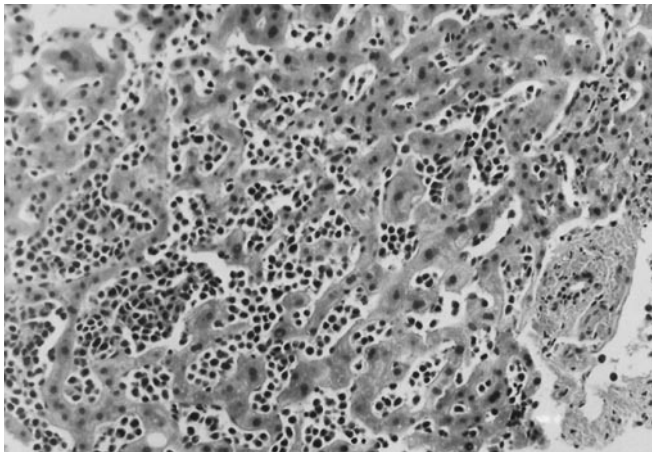

FIGURE 57-6 Liver involvement by leukemia (hematoxylin and eosin; ×40 original magnification). Courtesy of Dr. L. Burgart, Mayo Clinic and Foundation.

sentation, evidence of liver involvement is found in 50% at autopsy.

Histologic findings show either direct involvement of the liver or nonspecific inflammation and infiltration and noncaseating granulomas. Reed-Sternberg cells are found in about 25% of the cases. More commonly, nonspecific liver inflammation is found in about 50% of the cases. The detection rate of Reed-Sternberg cells is higher with laparoscopic biopsy than with percutaneous biopsy. Noncaseating granulomas, found in about 25% of the cases, are not considered to be part of the direct involvement of the liver in Hodgkin disease.

The most commonly increased biliary tract enzyme in the adult population is alkaline phosphatase, showing a correlation with disease stage. The fact that this enzyme is often elevated owing to normal bone growth in healthy children makes it a less useful indicator in pediatric patients than in adults.

Jaundice occurs with direct liver involvement. Obstructive lesions of the biliary tree are much less common. There are reports of vanishing bile duct syndrome occurring in patients with Hodgkin lymphoma. Whether this syndrome represents a variant of Hodgkin presentation or coincidental occurrence of primary sclerosing cholangitis is not clear.

Langerhans Cell Histiocytosis

The liver is involved in two large groups of disorders of histiocytes. Langerhans cell histiocytosis (LCH) refers to the group that includes eosinophilic granuloma, Letterer-Siwe disease, Hand-Schüller-Christian syndrome, Hashimoto-Pritzker syndrome, and histiocytosis X.[147,148]

This group of disorders is characterized by abnormal infiltration of various tissues with phagocytic mononuclear histiocytes with particular markers. These markers indicate the dendritic lineage of the Langerhans cells that infiltrate various organs. The definitive diagnosis is determined by the presence of Birbeck granules on electron microscopy. The demonstration of T-6 antigens on the surface of cells with tissue involvement is also diagnostic. In addition, the finding of CD1a antigen on the surface of histiocytes is a relatively easy way to demonstrate the cell lineage in paraffin-embedded tissue specimens. Although the presence of the CD1a marker is not 100% specific for LCH, the procedure is rapid and easy.[149]

The other group of disorders that involve histiocytes but not of the Langerhans cell type includes the familial hemophagocytic lymphohistiocytosis and the infection-associated hemophagocytic syndromes.[149–152]

Depending on the degree of organ involvement, LCH is categorized as involving either one site or multiple sites in a single system or as being multisystemic. In multisystemic LCH, patients are classified as having either organ involvement alone or organ involvement with dysfunction.[149]

Liver involvement in LCH is mostly a manifestation of multisystemic disease. The patient may have the characteristic skin lesion with diaper dermatitis, drainage from the external auditory canal, or hepatosplenomegaly. Other presentations include gastrointestinal tract bleeding and protein-losing enteropathy. The liver is almost universally involved with gut disease and is involved in up to 30% of patients with LCH. The spectrum of liver disease includes acute hepatitis, severe biliary cholestatic liver disease, and silent hepatomegaly with incidental increases in serum liver enzymes. The histologic findings vary from liver infiltration with histiocytes to destructive sclerosing cholangitis, in which the biliary enzymes are often increased, but jaundice is not prominent. The progression of the liver lesion does not parallel the response of the skin and other organs to chemotherapy. Cirrhosis may also be the presenting manifestation, especially when the disease progresses silently.[147–153] The progression to biliary cirrhosis is rapid compared with other causes of biliary cirrhosis, such as primary sclerosing cholangitis. Liver disease in LCH is progressive despite successful treatment of skin and bone lesions. After cirrhosis develops, the progression appears to be relentless.

The important point to remember is that patients with LCH require careful monitoring of liver involvement. A false sense of security should be avoided when the extrahepatic manifestations of the disease are controlled.

In a review at a single center, 75% of the neonatal patients with LCH presented with multisystemic involvement.[148] The characteristic skin lesion and the extent of the skin lesions did not correlate with systemic disease, and mortality was higher in this age group than in older children. Overall, the liver is involved in 30% of patients with LCH, but it is involved in 50% of patients with multisystemic disease. In patients with liver disease, only 25% have jaundice.[154] The others have hepatomegaly with or without increases in the liver enzymes. In a few patients, the onset of liver disease occurs well after successful treatment of skin and extrahepatic disease.

As expected, the outcome of LCH is dependent on the extent of disease at presentation. However, the progression of histiocytic infiltration of organs and the response to therapy in individual cases cannot always be predicted. A report has shown a clear association between the level of soluble interleukin-2 receptor and the extent of LCH. This association may be useful for monitoring a patient's

progress and possibly monitoring the response to chemotherapy. Interestingly, there seems to be activation of the tumor necrosis factor pathway in tissues with histiocytic infiltration, and one report showed a good response to the use of tumor necrosis factor receptor:Fc-fusion protein with regression of multisystemic invasion.[149] If confirmed in more cases, this report may pave the way for treatment of disease before pathologic changes in the liver become irreversible and the only option is liver transplant.

A key feature of the management of LCH is close cooperation between hematologists and hepatologists. The patient should have frequent and focused examinations for hepatomegaly and for screening laboratory values of hepatic and biliary enzymes. The use of magnetic resonance imaging of the liver and the biliary tree seems to be promising for identifying liver disease and biliary destruction. However, changes that are detectable by this technique may be indicative of late infiltration rather than early infiltration. Therefore, histologic examination of tissue remains an important tool for confirming and analyzing liver involvement.

Liver transplant has been successful for treatment of this disease. However, a review of the transplant experience in LCH patients has shown some that there is an increased risk of lymphoproliferative disease developing post-transplant,[155] perhaps owing to an altered immune status. This speculation is based on the demonstration of increased levels of interleukin-1, tumor necrosis factor, granulocyte-macrophage colony-stimulating factor, and soluble interleukin-2 receptor. Recurrence of LCH in the transplanted organ and extrahepatic sites is reported to occur in up to 33% of the patients. Only recently has it been shown that the graft is susceptible to LCH invasion.[155] Despite chemotherapy, the disease seems to be progressive in transplants, as well as in native livers. Finally, acute rejection is nearly universal among patients who receive transplants for LCH. Patients with certain liver conditions characterized by altered immune status, such as LCH and primary sclerosing cholangitis, who undergo liver transplant may require a different immunosuppressive regimen or may develop significant morbidity later, such as post-transplant lymphoproliferative disease or exacerbation of concomitant inflammatory bowel disease.[156,157]

Hemophagocytic Syndrome

Hemophagocytic syndrome (also called hemophagocytic lymphohistiocytosis), is a rare disease affecting infants and children. The hallmark of the disease is the accumulation in the reticuloendothelial system of lymphohistiocytes with features of hemophagocytosis. The diagnosis is based on a set of clinical and laboratory criteria (Table 57-5).

The liver is often involved in both infection-induced and familial hemophagocytic syndromes.[147–150] The sporadic form is a reactive proliferation of the lymphohistiocytic lineage, affecting multiple organs in reaction to a viral, bacterial, or fungal infection. The activated lymphocytes are benign, and there is evidence of hemophagocytosis. The most frequently associated infection is related to Epstein-Barr virus. The immune systems in children with hemophagocytic lymphohistiocytosis seem to lack the ability to control infections; they react with an uncontrolled inflammatory response with sustained activation of macrophages and T lymphocytes. Evidence of proliferation is present in the peripheral blood and numerous organs. Fever and hepatomegaly and other organomegaly are present. Concentrations of serum liver enzymes are abnormal in 80% of the patients. The lesion resolves with prompt resolution of the original infection in sporadic cases. The familial form is almost universally fatal without stem cell transplant.

The inheritance of the familial form is autosomal recessive. The condition occurs in the first 3 months of life and has a poor prognosis. The infant has hepatosplenomegaly, fever, and weight loss. Anemia, thrombocytopenia, hyperlipidemia, and low concentrations of fibrinogen are features of this disease as well. Neurologic involvement may also be present, manifesting as irritability, convulsions, meningitis, and altered consciousness.[158]

The liver and other organs are infiltrated with malignant histiocytes. The best area for the documentation of the diagnosis is the bone marrow because the liver lesion may show a nondiagnostic lymphocytic hepatitis without phagocytosis. Hyperlipidemia is an important feature of this condition and may help in the diagnosis. Acute fulminant hepatic failure mimicking neonatal hemochromatosis has been reported in two cases. In patients with hemophagocytic syndrome, the ferritin level may be increased, so the disease may be confused with neonatal iron storage disease. Ultrasonographic findings show hepatomegaly, thickening of the gallbladder wall, and increased periportal echogenicity. There is a report of one case successfully treated with intravenous administration of cyclosporine.[159] In one report, a deficiency in perforin, an important mediator of lymphocyte cytotoxicity, was shown to be present in familial hemophagocytic syndrome.[157]

Whereas the sporadic form occurs as a result of immunologic overactivity, as in Epstein-Barr virus–related hemophagocytic lymphohistiocytosis, the familial form is due to malignant transformation. Therefore, in the sporadic form, immunosuppression is the mainstay of therapy, whereas in the familial form, immunomodulation and immunosuppression of T-lymphocyte activation are performed in preparation for stem cell transplant as the definitive treatment.[160]

The gene encoding for perforin has been mapped to 10q22 and is mutated in familial LCH.[155] Perforin is a protein expressed in lymphocytes, macrophages, and bone marrow precursors. Its main role is the formation of pores

TABLE 57-5 CLINICAL AND LABORATORY CRITERIA FOR THE DIAGNOSIS OF HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Absence of malignancy

in target cells. After this occurs, the disrupted membrane of the target cell allows the entry of granzymes that trigger apoptosis. Perforin-deficient mice cannot lyse target cells and have an impaired defense against cancer and intracellular pathogens.[161] In combination with the defective aspect of antigen-presenting cells lacking perforin, this leads to several disrupted immune pathways that combine to cause the clinical manifestations of the disease.

The familial form is autosomal recessive, with an incidence estimated at 0.12 per 100,000 children.[154] Despite the classic description of sporadic cases occurring with an infection, 50 of 122 children reported to the registry for hemophagocytic lymphohistiocytosis had evidence of infection; of those, 25 had a positive family history and characteristics that were similar to those of the other 25 sporadic and nonfamilial cases.

Finally, Griscelli syndrome, a rare condition characterized by partial albinism and immunodeficiency, is also associated with perforin mutation; therefore, patients may present with hemophagocytosis with liver involvement.[162]

Bone Marrow Transplant

The liver is involved in several ways in patients undergoing bone marrow transplant. Chronologically, liver involvement occurs during the conditioning regimen; during the period of marrow ablation and pancytopenia, immediately after engraftment; and 6 months after transplant.

When malignancy recurs, the liver may be affected by the original condition that led to the transplant. The liver may become one of the sites of opportunistic infections, or it may be injured by various medications. Prolonged fasting and the use of TPN may contribute significantly to the pathophysiology of liver disease in bone marrow transplant patients.

The hepatopathy of bone marrow transplant varies from fulminant failure owing to viral infections, such as herpes simplex and adenovirus, to chronic cholestasis from graft-versus-host disease (GVHD) and prolonged nutritional support (see Table 57-4).

Veno-occlusive Disease

The triad of hepatomegaly, increased liver enzymes, and ascites describes VOD owing to obstruction of the terminal hepatic venules. Originally, VOD was described in patients exposed to pyrrolizine alkaloids (Table 57-6). VOD of the liver occurs in about 20 to 25% of the patients undergoing bone marrow transplant.[152,153,157] The condition is more likely to occur with allogeneic transplants than with autologous transplants. It is more common in patients who undergo transplant for malignancies, such as leukemia, than for aplastic anemia. Preexisting liver disease, total-body irradiation, and the intensity of the conditioning regimen contribute to the endothelial injury and the development of VOD. Low levels of pseudocholinesterase, a marker of hepatic synthetic function, correlate positively with the development of liver disease, and levels of proteins C, S, and antithrombin III correlate inversely with the development of VOD.[155,163,164]

Diagnostic criteria for VOD include onset within 20 days after transplant, weight gain of 2 to 10%, hepatomegaly, ascites, and a serum concentration of bilirubin greater than 2 mg/dL. Using these criteria, the frequency of VOD after bone marrow transplant ranges from 1 to 50%, with a mortality rate of 3 to 50%. Poor outcome is correlated with the severity of hyperbilirubinemia and the presence of multiorgan failure.[165–167]

The pathophysiologic process of VOD is presumed to be direct injury to the endothelium of the central hepatic veins. The injury is often associated with zone 3 necrosis from irradiation. The propensity of zone 3 hepatocytes to injury is multifactorial and is related to the relatively low oxygen tension in this area and the concentration of drug metabolism pathways. Glutathione depletion in this area leads to increased injury, a process that may be prevented by administration of glutamine. The combination of radiation injury and tissue hypoxia seems to involve the endothelial cells of the terminal hepatic venules and to initiate local thrombosis that potentiates congestion and hypoxia. Eventually, significant fibrosis and collagen deposition around occluded central veins lead to the clinical triad of weight gain, jaundice, and hepatomegaly that manifests between the second and sixth week after transplant. There is considerable evidence to implicate intravascular thrombosis in the early events leading to VOD.[168] The hypothesis is that reactive compounds are produced by zone 3 hepatocytes that are directly toxic to the endothelial cell. The endothelial cell injury leads to intravascular thrombosis, thereby potentiating the initial insult and leading to activation of the stellate cell. Persistent activation of the stellate cell, the principal fibrogenic cell in the liver responsible for the accumulation of collagen, is also evident from studies of autopsy cases.

VOD is characterized by fibrous intimal thickening or occlusion of hepatic venules less than 0.3 mm in diameter.[169–171] Occasionally, lesions and significant congestion are seen in larger veins (Figures 57-7 and 57-8).

Treatment for moderate and severe VOD consists of infusion of tissue plasminogen activator and transjugular intrahepatic portosystemic shunting, which may be beneficial in the early stages of the disease. In uncontrolled studies, heparin showed some efficacy.[172] Early detection is crucial. Abdominal girth measurement and twice-daily measurement of body weight are essential for the initiation of therapy. Jaundice and frank ascites are ominous signs. In about 50% of the patients, the disease resolves slowly. Fatal

outcome is not uncommon, and liver transplant for VOD has been attempted.[171]

Graft-versus-Host Disease

Chronic GVHD occurs in up to 70% of the patients after bone marrow transplant. The disease most commonly affects the skin, liver, and gastrointestinal tract, but other organs and organ systems are affected as well. Isolated involvement of one organ system, such as the liver, is not uncommon. Chronic GVHD, by definition, occurs 100 days after transplant.[173,174] The disease may occur earlier, and in about one-third of the patients, it occurs after acute GVHD. The predisposing factors to GVHD include acute GVHD and the degree of human leukocyte antigen (HLA) mismatch.[173–182] The portal tracts are enlarged, and there is variable lymphocytic infiltration. Long-standing GVHD results in the vanishing bile duct syndrome and eventually may lead to cirrhosis. Treatment consists of administration of immunosuppressive medication, ursodeoxycholic acid, and thalidomide (Figures 57-9 and 57-10).

Acute GVHD may occur when an immunocompromised host receives immunocompetent T cells.[183] The condition has been described in patients after solid organ or stem cell transplant, in immunocompromised patients receiving unirradiated blood, and in newborns with hemolytic disease after exchange transfusion.[184,185] Acute GVHD, which occurs 3 to 6 weeks after the transplant, is characterized by anorexia, nausea, vomiting, and, occasionally, profuse diarrhea. A maculopapular rash is also common. Hepatocyte injury and cholestasis are common; however, severe insufficiency is rare. Histologically, the liver shows segmental destruction of small bile ducts in association with mononuclear infiltration. Rectal and skin biopsy findings may help in the diagnosis and the exclusion of hepatotoxicity and viral infections. Immunosuppression is the treatment of choice.

NUTRITIONAL DISORDERS

Malnutrition

The liver is affected in all forms of malnutrition.[186–189] Chronic starvation results in depletion of glycogen stores,

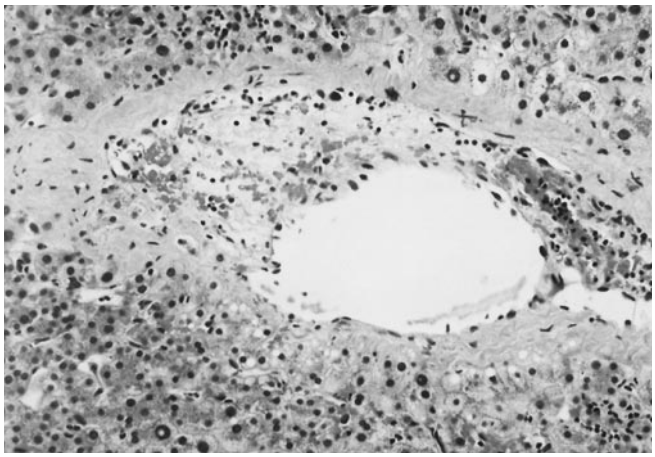

FIGURE 57-8 Idiopathic veno-occlusive disease of the liver (hematoxylin and eosin; ×40 original magnification). Courtesy of Dr. L. Burgart, Mayo Clinic and Foundation.

reduced neoglycogenesis owing to reduced protein stores, and production of ketones as fuel for cardiac muscle and the central nervous system.

Chronic malnutrition leads to the mobilization of free fatty acids even when the intake of carbohydrates is small. The free fatty acids are mobilized from the periphery and are not oxidized effectively in the liver; eventually, fat accumulates in the hepatocytes with resultant macrovesicular steatosis. Kwashiorkor, in particular, is associated with severe steatosis, whereas marasmus is associated less often. The livers of patients in prolonged starvation have decreased numbers of peroxisomes, and their carnitine stores are depleted, which are two factors that contribute to lipid metabolic abnormalities.[188–190]

Deficiencies of trace metals, such as zinc and selenium, may contribute to liver injury. Zinc is a cofactor in several enzymatic reactions and is considered to be an antioxidant. Selenium may function as an antioxidant as well.

Among children who have undergone starvation, chronic infections and bacterial overgrowth are often present and are presumed to contribute to liver disease in some way. In developing countries, the association of parasitic infestations, such as ascariasis, that may invade the biliary tree is well known.

Fatty Liver, Obesity, and Nonalcoholic Steatohepatitis

Fatty liver occurs with obesity, diabetes mellitus (especially type 2), jejunoileal bypass, hypertriglyceridemia, and certain metabolic diseases, such as galactosemia, tyrosinemia, and hereditary fructose intolerance (Table 57-7). Mitochondrial fatty acid oxidation defects and peroxisomal disorders also cause fatty liver. Rare causes of fatty liver include cholesterol ester storage disease and neutral lipid storage disease. Fatty liver can also be a feature of drug toxicity because the drugs undergo phase I metabolism through the cytochrome P-450 enzyme system. In cases of drug toxicity, mitochondrial function is presumably affected, resulting in microvesicular steatosis. Except for the known metabolic causes of fatty liver, nonalcoholic steatohepatitis (NASH) is considered to be the most severe form of nonalcoholic fatty liver.[190–210]

The normal liver is 5% fat by weight, in the form of triglycerides, cholesterol, cholesterol esters, and fatty acids. In steatosis, the liver may be 40% fat. The metabolism of fat depends on various factors, including the presence of fed or fasting states and the hormonal conditions, such as insulin and glucagon balance, adrenergic tone, and concentrations of thyroid hormones. During the fed state, the combination of triglycerides from chylomicrons and insulin and the activation of the parasympathetic system contribute to the accumulation of lipids in the adipose tissue and liver. During the fasting state, glucagon is released in response to the sympathetic nervous system, resulting in the increased formation of free fatty acids, which are released into the circulation as fuel for muscle and the brain.

The liver is crucial not only in energy metabolism but also in hormonal homeostasis. During excessive food intake, the liver stores fats, and steatosis may develop. During chronic starvation, fats are mobilized from the periphery, but oxidation in the liver is lacking, and steatosis is a hallmark of kwashiorkor, as previously mentioned. The same processes that occur during chronic starvation occur with prolonged use of TPN, especially if the administration of nutrients is continuous. In diabetic patients who have newly diagnosed diabetes, who are noncompliant, or whose diabetes is poorly controlled, accumulation of fat in the liver is common. The use of corticosteroids likewise affects the metabolism of fats, and steatosis is a common occurrence during prolonged administration.

Many metabolic disorders are associated with steatosis.[201–205,208,209] Classic Reye syndrome and severe steatosis occur with mitochondrial fatty acid oxidation defects. The presence of steatosis is also common in hereditary fructose intolerance, galactosemia, and tyrosinemia. Cholesterol ester storage disease produces a peculiar orange-colored liver and is also associated with steatosis. Certain medications, such as tetracycline, colchicine, and asparaginase, cause steatosis.[199]

Chronic intake of vitamin A leads to steatosis and to stellate cell hyperplasia. Long-term intake may lead to perisinusoidal fibrosis, presumably from activation of the stellate cell by accumulation of retinyl esters.[199–203]

The number of children with a body mass index (BMI) greater than the 95th percentile for age and sex has doubled since 1976.[211] About 15% of obese children have NASH, characterized by increases in serum liver enzymes that are associated with inflammatory changes and with occasional bridging fibrosis on liver biopsy. Pure macrovesicular steatosis without increases in liver enzymes is very common in obesity and reflects the accumulation of fat in the liver and in other organs.

The reason why increases in transaminases (usually four times the upper limit of the reference range) occur in certain children is unknown. Often the only clue to liver disease is an incidental finding of increased serum liver-derived enzymes on routine testing. The biliary tract–derived enzymes may be mildly increased as well. Occasionally, ultrasonography shows increased echogenic-

ity of the liver parenchyma as an indicator of steatosis. However, many patients with NASH have minimal changes on ultrasonography. A more accurate, quantifiable measure of liver steatosis can be determined with magnetic resonance imaging of the liver.

All of the cases of NASH identified at the Armed Forces Institute of Pathology during a 5-year period were reviewed; 71% of the patients were obese.[199] Therefore, the association of obesity and NASH is strong in the adult population. Nevertheless, one-third of the patients were not obese. The relationship between a nonobese BMI and the development of NASH is not known, and the prevalence of NASH in the obese population is not known. Normalization of the increases in liver enzymes may occur with a decrease in the BMI. Whether this is accompanied by a decrease in the frequency of liver fibrosis in patients with NASH is unknown. Ultrasonographic echogenicity and the absence of other causes help in the determination of the diagnosis. Reports of fatty liver in adult patients followed up for 18 years showed that the group at highest risk of progression to cirrhosis is the one with fibrosis, Mallory hyaline, and significant histologic inflammation on liver biopsy.[203,204] There are no comparable data for children.

The generally benign nature of this condition and the slow progression to cirrhosis outweigh the risks involved in a biopsy. The steatosis in this condition is usually macrovesicular and occasionally microvesicular (Figures 57-11 and 57-12). There are anecdotal reports of familial NASH, although diabetes and the illicit use of alcohol are confounding variables. The familial forms seem to be associated with mild obesity. Whether there are subgroups of patients with a metabolic basis for their microvesicular steatosis is unknown.[212,213] Proposed explanations include abnormalities of lipid oxidation, chronic endotoxemia, iron overload, and concurrent infection with hepatitis C virus.

The association of type 2 diabetes and NASH is well known in adults. Whether similar changes occur in juvenile diabetes is not entirely clear.[202–208] It is well known that about 5% of patients with type 1 diabetes have associated celiac disease. Left undiagnosed, this may lead to significant malnutrition and subsequent steatosis.

Short-Bowel Syndrome

The liver is affected in short-bowel syndrome in several ways: malnutrition and vitamin and trace element deficiencies may be present,[214–216] TPN may contribute to liver injury, intra-abdominal infections may result in liver abscesses, and bacterial overgrowth may affect the development of liver inflammation and injury. The early institution of enteral feeding and the cycling of nutritional supplementation have decreased the incidence of liver injury. The recognition of the contribution of bacterial overgrowth to the malabsorption of nutrients has led to the aggressive use of antibiotics, which has a beneficial effect on the liver (see Chapter 39, "Gastrointestinal Manifestations of Immunodeficiency").

Total Parenteral Nutrition

TPN is the best characterized cause of nutrition-related liver disease. Cholestatic liver disease predominates in premature and young infants and steatohepatitis in older children and adolescents.[217–229] Clinical cholestasis develops in about 25% of premature infants receiving TPN.[220] The severity of the cholestasis depends on the duration of nutritional support, and cholestasis usually resolves after the cessation of parenteral support. Associated sepsis, severe lung disease, congenital heart disease, and short-bowel syndrome add to the liver insult. Amino acid and glucose concentrations may be the primary culprits in the development of liver disease, although this remains controversial. The effect of fat emulsions is not entirely clear.[220–225]

The composition of the current amino acid formula results in a serum amino acid profile that is similar to that of breastfed babies. This formulation has resulted in a decreased incidence of cholestatic liver disease. The decreased concentration of carbohydrates in the formula seems to be beneficial as well. The early institution of oral

feeding and the cycling of TPN to nighttime feeding alone has also helped restore the natural process of gallbladder emptying and has protected the liver from injury.

The earliest biochemical abnormality is an increase in serum bile acids.[228] Hyperbilirubinemia and increases in serum alkaline phosphatase and γ-glutamyltransferase occur later. Usually, there is associated hepatomegaly. Ultrasonographic findings may show evidence of steatosis.[230] More commonly, biliary sludge and cholelithiasis can be seen, especially in premature infants who have received diuretic therapy. The development of sludge (calcium bilirubinate) occurs in 100% of infants receiving TPN for more than 6 weeks. However, gallstones develop in only a small proportion of patients. Among those patients, incidental ultrasonographic findings may be all that are documented; other patients have clear evidence of cholelithiasis and choledocholithiasis, with cholecystitis, pancreatitis, or both.

Early pathologic features consist of lobular cholestasis.[222–226] Portal inflammation and bile duct proliferation suggestive of obstruction may be present. Canalicular and cytoplasmic bile stasis, a common feature, occurs later. Giant cell transformation, indicative of a regenerative response, may occur. The lesion progresses to fibrosis and micronodular cirrhosis in a minority of patients (Figure 57-13).

The exact mechanism of TPN-related liver disease is unknown. The most important aspect of this cholestasis seems to be an exacerbation of the physiologically poor enterohepatic bile circulation already present in infants and children.

The physiologic immaturity of the enterohepatic circulation of bile is accompanied by an immaturity of the bile acid metabolism. For example, the gradient of bile acid synthesis that exists in the liver of the adult does not exist in the liver of the infant.[228] The physiologic concentration of serum bile acid in infants is clearly in the pathologic range for the adult. The result is a decreased bile acid pool, decreased circulation, increased concentration of serum bile acids, and decreased concentration of canalicular bile acid.

In animal studies, intravenous infusion of amino acids results in decreased output of bile. Infusion of large quantities of protein results in earlier and more severe cholestasis.[229] The combination of enteral starvation and parenteral nutrition results in the decrease or cessation of several hormonal stimulatory activities that are essential for proper enterohepatic circulation of bile. The lack of cholecystokinin, glucagon, insulin, and secretion affects not only cholestasis but also the formation of extrahepatic biliary sludge.

The short-bowel syndrome is associated with loss of surface area and interruption of the bile acid enterohepatic circulation. Moreover, loss of the ileocecal valve results in bacterial overgrowth, which is accompanied by increased translocation of bacteria into the bloodstream and increased incidence of septic episodes. Sepsis, especially with gram-negative enteric bacteria, can lead to dysregulation of the multidrug resistance protein 2 transport protein. The dependency of certain children on TPN for survival has led to the development of intestinal transplant as a lifesaving procedure. Occasionally, a combined liver–small bowel transplant is needed simply because of the development of end-stage liver disease from a combination of factors, including TPN.

The antioxidant role of vitamin E, selenium, and zinc in protecting the parenchyma and preventing chronic inflammation is not known.

Steatosis occurs with increased caloric intake in the form of glucose. There is a direct correlation between the amount of glucose given and the development of steatosis. The condition is usually asymptomatic, but mild increases in serum transaminases are not unusual (Figure 57-14).

Herbal Therapy and the Liver

The use of herbal medicines has increased during the past few years. Clinicians should ask patients whether they use herbal supplements or traditional remedies because herbal therapy may be associated with liver abnormalities.

A definition of *herb* is "a plant or plant part valued for its medicinal, savory, or aromatic qualities."[231] This broad definition includes plants and trees and their products or parts as possible sources of herbal products. Herbal products are also considered to be nutritional supplements

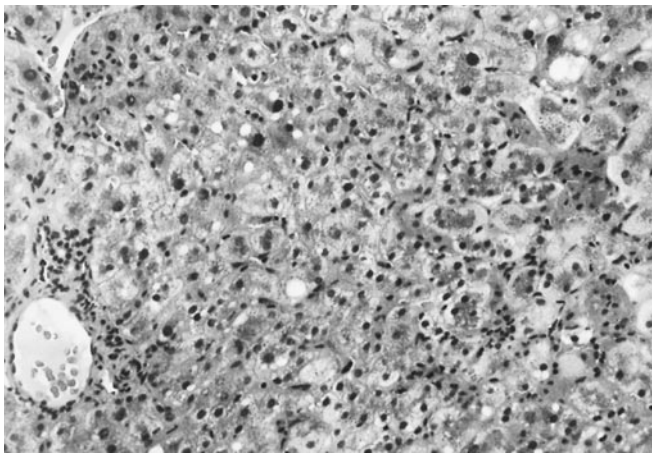

FIGURE 57-13 Total parenteral nutrition cholestasis (hematoxylin and eosin; ×40 original magnification). Courtesy of Dr. L. Burgart, Mayo Clinic and Foundation.

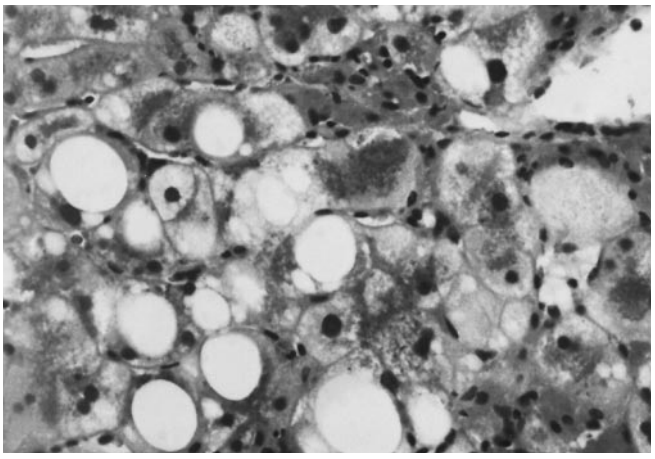

FIGURE 57-14 Total parenteral nutrition–associated steatosis (hematoxylin and eosin; ×100 original magnification). Courtesy of Dr. L. Burgart, Mayo Clinic and Foundation.

because they may contain a vitamin, an amino acid, or a trace element.

The classification of herbs and nutritional supplements as dietary supplements by the Dietary Supplement Health and Education Act of 1994 is outside the jurisdiction of many of the safety and regulatory rules that cover these categories. The purity and composition of products, as well as the consistency of dosages on labels, have varied. Some products were found to contain unlabeled compounds, and others were found to have significant heavy metal (lead) content. Table 57-8 shows the documented cases of hepatotoxicity associated with the use of herbal medicines.

Celiac Disease

The liver is involved in celiac disease in several forms.[232–236] Chronic malnutrition may lead to hepatic steatosis and fatty liver that is indistinguishable from the condition in kwashiorkor. Similar mechanisms of fatty acid mobilization occur in celiac disease and kwashiorkor (see Chapter 44.1, "Celiac Disease")

A few patients with celiac disease present with increases in liver enzymes. Concentrations of serum transaminases are usually increased two to five times the upper limit of the reference range. The patient may have subtle signs of malabsorption, such as iron or folate deficiency, or only growth failure. Overt symptoms, such as diarrhea, muscle wasting, and irritability, may also be present. The increases in enzymes resolve with the elimination of gluten from the diet. The exact pathogenesis of the liver involvement in celiac disease is not known but is presumed to be autoimmune.

Histologic evaluation shows nonspecific hepatitis, chronic active hepatitis, and, rarely, cryptogenic cirrhosis. A few reports of an association with primary sclerosing cholangitis show that the liver lesion does not improve with a gluten-free diet.

Celiac disease occurs with other autoimmune diseases, such as diabetes mellitus and Hashimoto thyroiditis, and in patients with Down syndrome. The association of diabetes and celiac disease may result in both steatosis from poorly controlled diabetes and chronic malnutrition. Awareness of these associations is important in the consideration of associated liver disease.

Celiac disease has also been associated with sarcoidosis. Therefore, the liver may be secondarily affected by granulomatous changes as well.

ENDOCRINE DISEASE

Hypopituitarism

The constellation of hypoglycemia, nystagmus, and cholestasis should prompt evaluation for hypopituitarism.[237,238] Hypopituitarism occurs in association with the absence of the septum pellucidum and septo-optic dysplasia. The lack of thyroid hormones and cortisol affects the bile acid–independent fraction of bile flow in the liver, with resultant cholestasis. In male infants, a micropenis may be evident. The cholestasis is similar to the cholestasis from other neonatal causes and can be associated with acholic stools. Acholic stools occur in obstructive lesions and hepatocellular disorders such as idiopathic neonatal hepatitis and α_1-antitrypsin deficiency. Hepatomegaly may be present.

Histologic cholestasis and neonatal hepatitis have been associated with hypopituitarism. The findings are nonspecific. The jaundice is initially due to an indirect hyperbilirubinemia, and it eventually develops into a mixed hyperbilirubinemia. Treatment is aimed at the underlying disorder, and rapid correction of the cholestasis occurs with initiation of thyroid and adrenal hormone replacement therapy.

Hypothyroidism

The association of neonatal hypothyroidism and jaundice is well described.[239–242] About 20% of infants with hypothyroidism have jaundice, which is due to indirect hyperbilirubinemia and presumably to the lack of maturation of the conjugation enzymes. Abnormal bile flow may also be present.

In older children and adolescents, liver and thyroid disease are associated with autoimmune disease. The association of Hashimoto thyroiditis with hypergammaglobulinemia occurs in about 70% of the patients. The association of autoimmune chronic active hepatitis and autoimmune thyroid disease is well known. Thyroid disease may precede or follow the development of liver disease.[243]

Diabetes Mellitus

In patients with diabetes mellitus, the liver may be involved in several ways.[243–247] The aforementioned association between celiac disease, chronic active hepatitis, and diabetes may result in chronic liver inflammation, steatosis, or even steatohepatitis, also seen in children with diabetes alone who have poor glycemic control. Poor glycemic control results in the accumulation of glycogen in the liver and hepatomegaly. The degree of hepatomegaly correlates with the amount of glycogen deposited and hence with the duration and severity of the diabetes.

There is also an association between diabetes and the development of cholelithiasis.

TABLE 57-8 HERBAL MEDICINES ASSOCIATED WITH DOCUMENTED CASES OF HEPATOTOXICITY

Soy phytoestrogens
Green tea leaf
Pyrrolizidine alkaloids and Jamaican tea preparations
Anthronoids

Autoimmune Polyglandular Syndrome Type 1

The association of autoimmune disease and its effect on the parathyroid glands, adrenal glands, and ovaries constitutes autoimmune polyglandular syndrome type 1,[248] which includes an association of mucocutaneous candidiasis and autoimmune hepatitis. The autoimmune hepatitis (type 2) is liver, kidney, and microsomal antibody positive. Liver disease occurs after the earlier manifestations in other organs. Hypocalcemia is common and is often exacerbated by the administration of corticosteroids for control of the liver lesion. Screening for the development of autoimmune hepatitis, with at least yearly serum liver enzyme determinations, is essential (see Chapter 48, "Systemic Endocrinopathies").

RENAL DISEASE

The association of liver and renal disease is well recognized.[249–256] Renal and hepatic disease occur concomittantly in both hepatitis C and B and in patients on dialysis. Liver abnormalities can occur in cases of glomerulonephritis and in hemolytic uremic syndrome as well. Some anomalies, such as autosomal recessive polycystic kidney disease and congenital hepatic fibrosis, affect both organs, but the degree of disease in the liver and kidney can be variable. In the infantile form of polycystic kidney disease, early renal failure predominates, whereas in Caroli disease, the liver lesion is predominant. Both entities are covered in detail elsewhere in this textbook. When hepatopathy is present in the dialysis or renal transplant patient, the liver involvement is usually attributed to viral infections, immunosuppressive medications, opportunistic infections, or iron overload.

GENETIC SYNDROMES WITH LIVER INVOLVEMENT

Liver disease is a component of many genetic syndromes (Table 57-9). Three recently reported syndromes with concomitant liver involvement are described below.

Hereditary Fetal Growth Retardation with Aminoaciduria, Cholestasis, Iron Overload, and Lactic Acidosis

This new genetic disease was recently described in 17 newborns from Finland. The characteristic findings are growth retardation with Fanconi-like aminoaciduria, cholestasis, and iron overload. The patients have increased serum ferritin concentrations and hypotransferrinemia. The acronym GRACILE is used to summarize the findings. Treatment in two cases with apotransferrin and exchange transfusion resulted in prolonged survival and growth. The disease locus was assigned to 2q33-37.[257]

Familial Progressive Tubulointerstitial Nephropathy and Cholestatic Liver Disease

This recently described entity is characterized by tubular nephropathy and sclerosed glomeruli with intrahepatic biliary ductular irregularities akin to primary sclerosing cholangitis. Histologically, the liver shows fibrosis with enlarged portal areas and biliary ductular proliferation. Serum concentrations of liver-derived enzymes are moderately increased.[258]

Renal Hepatic Pancreatic Dysplasia with Multiple Congenital Anomalies

Syndromes of renal hepatic pancreatic dysplasias may be grouped together as dysplastic syndromes of several organs. The association of renal, hepatic, and pancreatic abnormalities is a constant feature.[259]

MISCELLANEOUS DISORDERS

Amyloidosis

Amyloid is an amorphous protein, and amyloidosis is the resultant end-organ damage from deposition of amyloid protein.[260–264] The two major amyloid proteins are designated "AL" for primary amyloid and "AA" for secondary amyloid. Primary amyloid consists of the light chain of immunoglobulin. Secondary amyloid or serum amyloid is associated with chronic inflammation. It appears to be secreted by the liver as an acute-phase reactant. Amyloid is deposited in the gastrointestinal tract, liver, and renal tissue as the result of chronic inflammation. The condition is rare in children younger than 15 years. Cystic fibrosis is the most common association, with reports of up to one-third of the patients having amyloidosis at autopsy. The association has been reported in familial Mediterranean fever, JRA, and tuberculosis as well. The association of hepatomegaly and proteinuria with a chronic inflammatory condition should prompt the search for amyloid in rectal and renal tissue. Also, a liver biopsy may be the first diagnostic test performed when a patient has silent hepatomegaly (Figures 57-15 and 57-16). There is no correlation between the degree of amyloidosis and the increases in liver enzymes.[265,266]

Sarcoidosis

Sarcoidosis is a multisystemic chronic granulomatous disease of unknown cause.[267–270] It is associated with Crohn disease, celiac disease, lymphoma, Addison disease, thyroiditis, and the use of various drugs. The lung is the organ involved most often. Hepatomegaly is a late phenomenon, occurring in about one-third of the patients. The differential diagnosis centers on the association of other granulomatous diseases, such as chronic drug therapy, cat-scratch disease, and immunodeficiency (Table 57-10). Long-standing sarcoidosis leads to portal hypertension, with minimal increases in liver enzymes, and eventually to fibrosis and micronodular cirrhosis. Treatment with corticosteroids and, eventually, methotrexate is advocated in reports of adult patients.

Behçet Syndrome

Behçet syndrome is a multisystemic disorder characterized by ocular, mucocutaneous, articular, vascular, gastrointestinal tract, and neurologic abnormalities.[60,271–274] The clinical syndrome consists of recurrent oral, genital, and gastrointestinal tract ulcers. The association with uveitis, arthritis, and renal amyloidosis is well known. The association of

TABLE 57-9 CHARACTERISTIC FEATURES OF GENETIC DISEASES WITH LIVER INVOLVEMENT

DIAGNOSIS	AGE AT ONSET*	FEATURES
Galactosemia, tyrosinemia, neonatal iron storage disease	Neonate; infant	Jaundice, ascites, edema, coagulopathy, lethargy, sepsis, hypogylcemia, hyperammonemia, hepatitis, growth retardation, lactic acidosis, cholestasis, hypotransferrinemia
Fructosemia	Infant, with introduction of fructose	Jaundice, ascites, coagulopathy, lethargy, hypoglycemia, acidosis, hyperammonemia, phosphorus abnormalities, hepatitis
Neonatal iron storage disease	48 h	Cholestasis, coagulopathy, and liver failure (prominent); hepatitis (mild)
Inborn error of bile acid synthesis	48 h	Similar to neonatal iron storage disease; normal GGT
Ataxia telangiectasia	Infant; child	Features of ataxia telangiectasia, immunodeficiency, autoimmune markers, mild hepatitis, and steatohepatitis
SYNDROMES WITH CHOLESTASIS AND HEPATOMEGALY		
Inborn errors of bile acid metabolism	Neonatal	Mild hepatitis, normal or low GGT
Familial cholestasis	Infant; child	PFIC 1: family history features; PFIC 1 and 2: low GGT, paucity of bile ducts; PFIC 3: proliferation of bile ducts; family history of gallstones; cholestasis during pregnancy
α_1-Antitrypsin deficiency	Neonate; infant	Acholic stools, hepatomegaly
Galactosemia	As above	As above
Tyrosinemia	As above	As above
Fructosemia	As above	As above
Niemann-Pick type C	Neonate; infant	Jaundice, neurologic signs
Peroxisomal disorders	Neonate; infant	Hypotonia; low or normal GGT; varied presentations: neurologic, renal, hepatic
Adrenoleukodystrophy, Zellweger syndrome, pipecolic acidemia	Infant	As in peroxisomal disorders; hypotonia with poor sucking and retinal pigmentation, fibrosis and cirrhosis, abnormal very-long-chain fatty acids, normal GGT
Tubular nephropathy and cholestasis	Child	PSC-like with tubular nephropathy, familial pattern
Cystic fibrosis	Infant	Meconium ileus equivalent
SYNDROMES WITH HEPATOMEGALY		
Glycogenosis, types I and III; Wolman disease; familial adenomatous polyposis	Infant; 1 mo to first years	Hypoglycemia; variable clinical and metabolic features; liver with normal consistency; splenomegaly (unlike glycogenosis, type I); Wolman disease: diarrhea, vomiting, organomegaly, foam cells in the marrow, lysosomal acid lipase deficiency with storage of triglycerides and cholesterol esters, adrenal calcifications (a hallmark); familial adenomatous polyposis associated with hepatoblastoma
Glutaricaciduria, type II	Neonate	Respiratory and cardiac failure at birth with hepatomegaly
Mucopolysaccharidosis, types I and II; α-mannosidosis; fucosidosis	Neonate; infant	Progressive neurologic deterioration, splenomegaly
α_1-Antitrypsin deficiency; congenital hepatic fibrosis; glycogenosis, type IV; carbohydrate-deficient glycoprotein; fibrosis	0–6 yr	With or without splenomegaly, hard liver, portal hypertension, carbohydrate-deficient glycoprotein syndromes with intractable diarrhea and developmental delay
Cystic fibrosis, congenital hepatic fibrosis, α_1-antitrypsin deficiency, Wilson disease	Variable: 3–6 yr or later	Portal hypertension, varices, cirrhosis, typical features of biliary ectasia with fibrosis
Sialidosis, type II; mucolipidosis; Gaucher disease; mucolipidosis, type II	Early infant	Coarse features, ocular symptoms, bone changes, vacuolated lymphocytes

GGT = γ-glutamyltransferase; PFIC = progressive familial intrahepatic cholestasis; PSC = primary sclerosing cholangitis.
*Age categories: neonate, 0–4 weeks; infant, 0–12 months; child, 1 year to puberty.

hepatic vein thrombosis and Behçet syndrome was described in a report of four cases, with a review of 17 previously published cases. There was a male preponderance; the inferior vena cava was thrombosed in 90% of the patients, and the thrombosis was acute in one-third of the patients.[273]

CONCLUSION

The liver is a frequent target in systemic diseases because of its complexity and its central role in homeostasis, xenobiotic metabolism, defense against endogenous and exogenous insults, and regulation of the vascular space.

In this chapter, cellular and molecular events were linked to pathophysiologic and clinical correlates of disease. However, to cover every aspect of liver involvement in these disorders is beyond the scope of this chapter, and many subjects are covered in detail elsewhere in this textbook.

ACKNOWLEDGMENTS

We are indebted to Dr. Lawrence J. Burgart in the Department of Laboratory Medicine and Pathology, Mayo Clinic, for providing the pathology slides and to Nick A. Hegg for secretarial assistance.

CHAPTER 58

ACUTE LIVER FAILURE

Sanjay Bansal, MD, MRCP
Anil Dhawan, MD, FRCPCH

Acute liver failure (ALF), a clinically heterogeneous and complex multisystem disorder, is a rare but devastating sequel of an insult to the liver. The liver damage, within a few days to weeks, can cause encephalopathy and multiorgan failure. Different underlying etiologies, the age of the patient, and the duration of time over which the disease evolves contribute to the heterogeneity of this disorder. The mortality is high without liver transplant. ALF is the indication for liver transplant in about 10 to 20% of pediatric recipients in major transplant centers, with a 1-year survival rate of 60 to 75%. Auxiliary liver transplant offers the opportunity for the native liver to regenerate with the possibility of withdrawal of immunosuppression. Liver assist devices (cleansing systems and biologic systems) are being evaluated as newer treatment options. Management requires early appreciation of the severity of the illness, treatment, and prevention of complications, and if the spontaneous recovery is doubtful, emergency liver transplant before the irreversible brain damage occurs. This involves an integrated, multidisciplinary approach involving hepatologists, intensivists, and transplant surgeons; therefore, this condition should ideally be managed in a specialist center.

DEFINITION

Although the occurrence of fatal hepatitis as a consequence of epidemic hepatitis was first reported in 1946,[1] the first attempt at a formal definition was made only in 1970 by Trey and Davidson.[2] Fulminant hepatic failure (FHF) was described as "a potentially reversible condition, the consequence of severe liver injury, in which the onset of hepatic encephalopathy was within eight weeks of the first symptoms of illness, and in the absence of pre-existing liver disease."[2] In 1989, the term "late-onset hepatic failure" was used on the basis of development of hepatic encephalopathy (HE) between 8 and 24 weeks from the onset of jaundice.[3] Bernuau and Benhamou described FHF as the onset of encephalopathy within 2 weeks of the onset of jaundice (rather than other symptoms); it was subfulminant hepatic failure if encephalopathy developed between 2 and 12 weeks from the first appearance of jaundice.[4] Subsequently, O'Grady and colleagues proposed a new classification based on a retrospective study of 539 adult patients. They suggested use of the terms hyperacute, acute, and subacute failure, depending on the interval between jaundice and onset of encephalopathy, less than 1 week, 1 to 4 weeks, and 5 to 12 weeks, respectively.[5] They also suggested that the lack of preexisting liver disease is not mandatory if it remained asymptomatic, for example, Wilson disease, autoimmune hepatitis, delta virus superinfection, and hepatitis B reactivation.

These definitions do not satisfactorily encompass the complexity of the condition in the pediatric population. The early stages of encephalopathy are very difficult to detect in infants and small children. Also, in children, particularly during infancy, encephalopathy may appear very late, if ever, and ALF may be the first manifestation of an underlying metabolic disease associated with a variable degree of chronic liver damage. The first pediatric definition was suggested by Bhaduri and Mieli-Vergani as "a rare multisystem disorder in which severe impairment of liver function, with or without encephalopathy, occurs in association with hepatocellular necrosis in a patient with no recognised underlying chronic liver disease."[6] This definition has addressed the issues relevant to the pediatric population.

ETIOLOGY

ALF is the final common pathway of a variety of insults to the liver. There is considerable variation in the etiologies around the world, with acute viral hepatitis and drugs accounting for the majority of cases. The frequency of ALF in all age groups in the United States is 17 cases per 100,000 population per year, but the frequency in the pediatric age group only is unknown.[7] The overall incidence of ALF complicating acute hepatitis in the United States is 0.9%, and it causes about 2,000 deaths annually, with non-A–E hepatitis being the most common cause.[8] In children, acute viral hepatitis is the most common identified cause in most of the series, but there is a lot of geographic variation, with hepatitis A being the most common cause in Asia, whereas in Europe and North America, it is seronegative hepatitis. The etiology of ALF as seen in a tertiary pediatric liver center is shown in Table 58-1.

INFECTIVE

Viruses. Infection with the hepatotropic viruses is probably the most identifiable cause of ALF. Patients usually present with icterus and markedly raised serum transaminase

TABLE 58-1 ETIOLOGIES OF ACUTE LIVER FAILURE IN NEONATES AND CHILDREN (KING'S COLLEGE HOSPITAL, 1991–2000)

levels. The magnitude of transaminase elevation and the rate of decline do not predict prognosis. In patients who spontaneously recover, serum bilirubin, international normalized ratio (INR), and serum transaminases gradually decline, whereas a continued rise in bilirubin levels and INR, despite declining serum transaminase levels, indicates massive hepatocyte necrosis and a poor prognosis.

The risk of developing liver failure in acute hepatitis A virus (HAV) infection is 0.1 to 0.4%.[9–12] A higher incidence of ALF is suggested when HAV infection occurs in patients with underlying chronic liver disease. Very high mortality is reported in an Italian study in which 7 of 17 children with chronic hepatitis C infection with superadded HAV infection developed ALF, and only 1 child survived.[13] The diagnosis of acute hepatitis A is made by the detection of the anti-HAV immunoglobulin (Ig)M antibody in serum. In 95% of cases, anti-HAV IgM antibody is present at the time of presentation, and the remaining 5% become positive on repeat testing.

The incidence of ALF owing to hepatitis B virus (HBV) is 1 to 4%.[8] The liver failure can present at (1) the time of acute infection, (2) reactivation of chronic HBV infection in immunocompromised patients, (3) superinfection or coinfection with hepatitis D virus, or (4) seroconversion from a hepatitis B e antigen–positive to a hepatitis B e antibody (HBeAb)-positive state. Infants born to HBeAb-positive mothers are a special group that can present with ALF around 3 weeks to 3 months of age.[14,15]

There is a theoretic risk of developing ALF after hepatitis C virus (HCV) infection, but in a large follow-up study of children with post-transfusion HCV infection, ALF was not observed.[16]

Hepatitis E virus (HEV) infection, a waterborne infection like hepatitis A and a well-recognized cause of ALF, is common in the Indian subcontinent and Africa. The risk of developing ALF in adult males is 0.6 to 2.8%, but the risk increases significantly in pregnant women, especially in the third trimester, with the case-fatality ratio of around 25%.[17] HEV infection may be responsible for up to 8% of cases, which would have been attributed to seronegative hepatitis. A history of travel to an endemic area is not always present. A study from northern India reported that 7 of 44 children with ALF had isolated HEV infection, whereas another 16 of 44 had mixed HEV and HAV infection. HEV infection is diagnosed by the presence of anti-HEV antibody in the serum.[18] Despite identification of hepatitis G (a flavivirus) virus in ALF of unknown etiology, it does not appear to cause ALF.[19] Similarly, TT virus (transfusion-transmitted virus), a single-stranded deoxyribonucleic acid (DNA) virus, was discovered in 1997 from the sera of non-A, non-B (NANB) hepatitis patients but has also not been shown conclusively to cause ALF.[20]

Non-A–E hepatitis (seronegative hepatitis) is the most common cause of ALF in the Western world. In our series, of 100 cases of ALF, 45 were due to non-A–E hepatitis.[21] Similar experience was reported from Chicago, with 26 of 42 children with ALF who were diagnosed with non-A–E hepatitis.[22] The diagnosis is one of exclusion in which other causes of ALF are eliminated with appropriate laboratory investigations and clinical examination. Non-A–E hepatitis is characterized by its propensity to cause severe hepatitis, a high fatality rate (low spontaneous remission) without liver transplant, and its association with bone marrow failure in up to 10% of patients.[23] Bone marrow failure can develop even a few weeks after the onset of symptoms of ALF.

Other Hepatotropic Viruses. Herpes simplex virus, cytomegalovirus, Epstein-Barr virus, and varicella-zoster virus, members of the herpesvirus family, can cause severe hepatic necrosis, particularly in immunocompromised patients and neonates. Herpes simplex infection–induced ALF in the neonatal period has a very high case-fatality ratio. The diagnosis is suspected in an unwell neonate with or without a vesicular lesion along with remarkably raised serum transaminases and coagulopathy. Maternal history suggestive of herpes simplex infection and/or positive serology is helpful in establishing the diagnosis. Viral studies (immunofluorescence or polymerase chain reaction) of vesicular fluid are diagnostic. Association of cytomegalovirus with ALF is not reported, although Epstein-Barr virus has been, rarely, associated with ALF.[24]

Parvovirus B19 infection can cause severe hepatitis, ALF, and, rarely, bone marrow failure in children. A retrospective study of 6 patients with ALF with peritransplant aplastic anemia owing to presumed NANB hepatitis showed the presence of parvovirus B19 DNA in 4 of 6 explanted livers, but all 6 patients had IgG antibodies against parvovirus.[25] In our experience, parvovirus infection as the cause of ALF was recognized in 2 of 8 children who had bone marrow aplasia with ALF.[23]

Echovirus (type 20) and coxsackieviruses have been reported to cause ALF, especially in neonates.[26,27] In an adult study, Toga virus–like particles were isolated in explanted livers in 7 of 18 patients who had liver transplant for ALF owing to NANB hepatitis but none in 26 explanted livers available for study after liver transplant owing to other causes. ALF, characterized by severe hemorrhagic

necrosis on histology, developed 7 days after transplant in 5 patients, all in the NANB group with Toga virus–like particles in native liver. Further analysis revealed no identifiable epidemiologic factors between these and the other NANB hepatitis–induced ALF patients.[28]

Nonviral Infections. Nonviral infective agents have been implicated in the pathogenesis of ALF, although rarely. Acute liver dysfunction is well recognized in severe sepsis. Bacterial infections, especially gram-negative infections (*Salmonella*, *Shigella*, *Escherichia coli*, and *Pseudomonas*), miliary tuberculosis, brucellosis, and Q fever (owing to *Coxiella burnetii*), have been reported to cause ALF. Spirochetal infections, particularly leptospirosis, can present with severe hepatitis or ALF. The clinical picture is predominated by high fever and renal failure. In endemic areas, there have been reports of ALF following plasmodium falciparum infection.[29]

Hepatic dysfunction in sepsis is the result of decreased hepatic perfusion, hypoxia, and lactic acidosis. Bacterial cell wall products (endotoxin and lipoteichoic acid) and cytokines (tumor necrosis factor, interleukin-1β, and interferons) induce the production of nitric oxide. The elevated levels of inducible nitric oxide are toxic to liver cells.[30]

Drugs and Toxins

Drugs and toxins are well known to cause liver failure in children. In general, the risk factors for drug-induced hepatotoxicity are age (very young or adolescents), abnormal renal function, concurrent use of other hepatotoxic agents, drug interactions, and preexisting liver diseases. Drug-induced hepatoxicity can be a dose-dependent response, an idiosyncratic reaction, or a synergistic reaction (Table 58-2).

Estimates of the risk of developing ALF as a result of an idiosyncratic reaction range from 0.001% for nonsteroidal anti-inflammatory drugs to 1% for the isoniazid-rifampicin combination. Drug toxicity produces a distinctive pattern of liver injury. The most common liver injury pattern owing to drugs is hepatitic (hepatocellular necrosis), accounting for about 90% of cases. Others could be cholestatic (biliary damage), mixed (both hepatitic and cholestatic), or steatosis.[31] Sodium valproate is known to unmask underlying mitochondrial cytopathies; hence, detailed investigations to exclude mitochondrial hepatopathies should be undertaken before injury is ascribed to sodium valproate. Use of antiretroviral drugs has also been associated with ALF. Ecstasy (3,4-methylenedioxymethamphetamine), a synthetic amphetamine, has been associated with a range of clinical syndromes ranging

from asymptomatic hepatic liver function tests or subacute liver failure to rapidly progressive ALF.[32]

Acetaminophen, the most common drug associated with ALF, is safe when used in therapeutic doses in healthy individuals. It is normally a dose-dependent hepatotoxic agent. The hepatocyte necrosis is caused by accumulation of the *N*-acetylparabenzoquine amide, which is a toxic intermediate compound.[33] When cytochrome P-450 enzymes are induced either owing to drugs such as antiepilepsy drugs or chronic alcohol consumption, hepatic glutathione stores are depleted. Consequently, even therapeutic doses of acetaminophen can lead to accumulation of *N*-acetylparabenzoquine amide, causing ALF. Inadvertent administration of higher doses of acetaminophen can lead to ALF in children. A detailed history of exposure to acetaminophen is helpful. In 1995, a series of young children were reported with ALF without any identifiable cause but with minimal jaundice. All of these children had a history of exposure to acetaminophen, although in therapeutic doses. Fifty percent of these patients survived, and the histopathology was characterized by a varying degree of centrilobular necrosis, which is a characteristic lesion of acetaminophen toxicity, suggesting the possible role of toxicity owing to therapeutic doses of acetaminophen in the development of ALF.[34] Serum acetaminophen levels after 4 hours of ingestion are useful in identifying high-risk patients but are not informative in patients in whom toxicity is secondary to chronic administration.

Mushroom (*Amanita phalloides*) poisoning leading to ALF is mainly reported from Europe (France and eastern Europe), the west coast of the United States, and South Africa. Cases of poisoning peak in autumn, when mushrooms are plentiful. α-Amantin is a heat-stable toxin that is not destroyed by cooking. The usual presentation is severe diarrhea with or without vomiting commencing about 5 or more hours after ingestion. Liver failure is usually followed 3 to 4 days later. Other hepatotoxins include carbon tetrachloride, herbal medicines, and aflatoxins.

Autoimmune Hepatitis

Autoimmune hepatitis can present as ALF, most of these patients being liver-kidney microsomal antibody positive. The diagnosis may be difficult because some cases may not show an antibody response at presentation. Some reports have suggested a good response to steroids and azathioprine or cyclosporine.[35,36] In our experience, children with autoimmune hepatitis presenting with ALF along with encephalopathy do not respond to any form of immunosuppression and need urgent liver transplant.

Metabolic Diseases

Inherited disorders of metabolism merit special attention as a differential diagnosis while investigating ALF in pediatric patients, in particular newborn babies. Although all of these patients have variable degrees of liver damage before clinical presentation as ALF, overt signs and stigmata of chronic liver disease are usually absent. A high index of suspicion is important because urgent intervention such as dietary manipulation or disease-specific treatment may be lifesaving. Conditions that are common to the neonatal age group are listed in Table 58-3.

Galactosemia is usually associated with hypoglycemia and gram-negative septicemia. Immediate exclusion of galactose (from the diet and the medications) usually provides a quick recovery, but some cases do progress to liver failure. Tyrosinemia presents with severe coagulopathy, mild jaundice, and rickets. Hereditary fructose intolerance is rare, but a history of administration of fructose, as in fruits, sugar, or honey, may coincide with clinical symptoms.

Neonatal hemochromatosis (NH) is a disorder of iron handling of antenatal onset with excess iron deposition in the nonreticuloendothelial system. Liver failure usually presents in the first few days of life, but liver disease is generally present at birth. Maternal viral infection in the antenatal period or metabolic disease in the fetus is suggested as an underlying cause. Although an underlying genetic basis for NH has been suspected, no test is available for predictive analysis in at-risk pregnancies. In a systematic study of the mode of transmission of this disorder in a total of 40 infants born to 27 families, four pedigrees showed clear evidence of maternal infection associated with NH. One pedigree showed transmission of maternal antinuclear factor and ribonucleoprotein antibodies to the affected infants, and two families with possible matrilineal inheritance of disease in maternal half-siblings, but the large subgroup of the affected pedigrees points to the inheritance of an autosomal recessive trait. This included 14 pedigrees with affected and unaffected infants and a single pedigree in which all four affected infants were the sole offspring of consanguineous but otherwise healthy parents.[37] It can occur sporadically or recurrently, without an overt cause, in siblings. The diagnosis should be considered in every case of neonatal liver failure. Elevation of ferritin as a diagnostic test is sensitive but not specific because elevation of ferritin is commonly observed in sick babies. Hypersaturation of transferrin with relative hypotransferrinemia may be a valuable finding. Magnetic resonance imaging of the liver or pancreas to demonstrate iron is not usually rewarding, but a punch biopsy specimen of buccal mucosa is a useful diagnostic tool. Documentation of iron in salivary glands in buccal mucosa is diagnostic of NH. To ensure the presence of salivary glands in the buccal mucosal biopsy specimen, a frozen section examination is advisable. Most of the time, the biopsy can be performed safely after correction of coagulopathy with blood products. Iron chelation and antioxidant cocktail therapy (Table 58-4) for NH

TABLE 58-3 CAUSES OF NEONATAL LIVER FAILURE

Severe birth asphyxia

has shown variable results.[38,39] Recently, successful fetal outcome following antenatal intravenous immunoglobulin therapy of pregnant mothers considered to have a high risk of carrying an affected fetus has been reported. In six pregnancies in five mothers, intravenous immunoglobulin was administered weekly at a dose of 1 g/kg body weight from the eighteenth week until the end of gestation. Four pregnancies progressed to term; one had spontaneous delivery at 36 weeks, and one had an induced birth at 32 weeks. All six were live births and were medically stable, with evidence of liver involvement. Four of six required an antioxidant or a chelation cocktail.[40]

Wilson disease, an autosomal recessive disorder, may present as ALF in an older child. The acute hepatic presentation is characterized by the presence of liver failure, Coombs-negative hemolytic anemia, and low alkaline phosphatase. Demonstration of Kayser-Fleischer rings is diagnostic of Wilson disease in a patient who presents with ALF. Serum ceruloplasmin is usually but not invariably low, and serum free copper concentration can be increased or normal. A serum alkaline phosphatase to total bilirubin ratio of < 2.0 has also been suggested as a diagnostic tool to discriminate Wilson disease from other causes of ALF.

Mitochondrial Disorders

In recent years, mitochondrial respiratory chain disorders have been implicated in the etiology of ALF in children.[41–43] This group of disorders encompasses a wide variety of diseases, including Pearson syndrome, mitochondrial DNA depletion syndrome, nuclear DNA defect, Alpers disease, and intestinal pseudo-obstruction with liver disease. Presenting symptoms could be hypoglycemia, vomiting, coagulopathy, acidosis, and increased lactate with or without neurologic symptoms. The presence of high serum lactate in the mother and a history of sibling deaths are suggestive of this condition. Diagnosis involves quantitative assessment of the respiratory chain enzyme complexes in the affected tissues (muscle, liver, skin fibroblast culture). Isolated hepatic involvement with successful liver transplant has been reported; however, the follow-up of these patients is not long enough to rule out future neurologic deterioration. Rarely, fatty acid oxidation defects and inborn errors of bile acid synthesis, especially Δ^4-3-oxosteroid 5β-reductase enzyme deficiency, can present as ALF.[44,45]

TABLE 58-4 DISEASE-SPECIFIC THERAPIES

Acetaminophen toxicity: *N*-acetylcysteine (100 mg/kg/d) until INR is < 1.5
Hereditary tyrosinemia: NTBC[93]
Neonatal hemochromatosis: iron chelation and antioxidant cocktail
N-Acetylcysteine (100 mg/kg/d IV infusion)
Selenium (3 µg/kg/d IV)
Desferrioxamine (30 mg/kg/d IV)
Prostaglandin E_1 (0.4–0.6 µg/kg/h IV)
Vitamin E (25 U/kg/d IV/PO)
Mushroom poisoning: benzylpenicillin (1,000,000 U/kg/d) or thiotic acid (300 mg/kg/d)

INR = international normalized ratio; IV = intravenously; NTBC = 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione; PO = orally.

Vascular/Ischemic Causes

Any condition causing obstruction of hepatic venous outflow (eg, Budd Chiari syndrome, veno-occlusive disease, cardiomyopathies, and acute heart failure) can present with ALF. A detailed cardiovascular examination, including an echocardiogram, is essential to exclude cardiac causes. Diagnostic clues include soft hepatomegaly and ascites.

Malignancies

Hemophagocytic lymphohistiocytosis is a spectrum of inherited and acquired conditions with disturbed immunoregulation and encompasses two main conditions that have common clinical and pathobiologic characteristics: familial (primary) hemophagocytic lymphohistiocytosis and secondary hemophagocytic lymphohistiocytosis. Familial hemophagocytic lymphohistiocytosis is an invariably fatal inherited disease seen mostly in infancy and early childhood,[46] but secondary hemophagocytic lymphohistiocytosis can affect people at any age and may subside spontaneously. The annual childhood incidence of familial hemophagocytic lymphohistiocytosis has been estimated (in Sweden) at 1.2 cases per 1,000,000, corresponding to 1 in 50,000 births.[47] Clinical presentations include fever, hepatosplenomegaly, and pancytopenia. There is reduced cytotoxic T- and natural killer cell activity, as well as a widespread accumulation of T lymphocytes and macrophages, some of which may engage in hemophagocytosis.[46–48] Biochemically, it is characterized by high serum triglycerides and low fibrinogen. Usually, patients with hemophagocytic lymphohistiocytosis bleed disproportionately from venepuncture sites because of the coagulation abnormalities present.

A varied form of hematologic malignancies (eg, leukemia[49] or lymphoma) can present with ALF. Diagnostic clues include high fever, hepatosplenomegaly, high alkaline phosphatase, high lactate dehydrogenase, and abnormalities on peripheral blood film. Bone marrow examination is diagnostic.

PATHOPHYSIOLOGY OF THE CLINICAL SYNDROME

ALF is a syndrome of multiorgan involvement. Most patients are jaundiced at presentation, except those with hyperacute liver failure, in whom jaundice follows encephalopathy. Peripheral stigmata of liver cell failure may be seen occasionally. A rapid decrease in liver span is usually seen, but patients with hematologic malignancies or cardiac failure have hepatomegaly.

Encephalopathy

The pathogenesis of encephalopathy is not clearly understood and probably is multifactorial. The most widely studied factor is ammonia (Figure 58-1). Ammonia is produced from the breakdown of proteins, amino acids, purines, and pyrimidines. Half of the ammonia in the intestine is produced by bacteria; the remainder is from the breakdown of dietary protein and glutamine. Ammonia is cleared in the liver by urea cycle enzymes. In brain, urea cycle enzymes

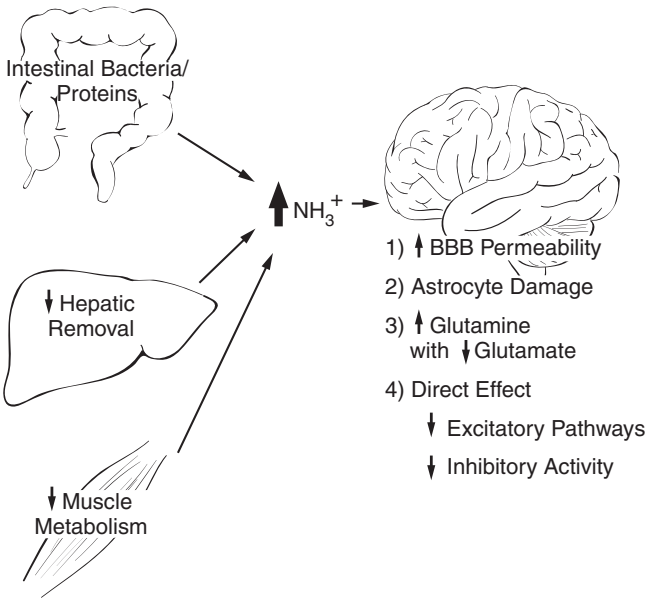

FIGURE 58-1 Summary of the role of ammonia in hepatic encephalopathy.

are absent; hence, ammonia is cleared by the formation of glutamine by enzyme glutamate synthetase. High concentration of glutamine in brain has been demonstrated by magnetic resonance spectroscopy.[50] Ammonia has a direct effect on the neural membranes and also causes postsynaptic inhibition.[50] Although the role of hyperammonemia in HE appears logical, 10% of patients with HE have normal serum ammonia levels.

γ-Aminobutyric acid (GABA), a principal inhibitory neurotransmitter in the brain, is increased in ALF.[51] GABA can act directly or in synergy with the benzodiazepine receptors. In addition to elevated blood levels, increased GABA receptor density and increased sensitivity have been shown in animal studies.

Intestinal decarboxylation of amino acids in the colon lead to the formation of β-phenylethanolamine, tyramine, and octopamine. These products inhibit dopamine- and catecholamine-mediated cerebral transmission by acting as false neurotransmitters.[52]There is also an imbalance in the ratio of plasma and intracerebral branched-chain and aromatic amino acids. Other toxins, such as mercaptans, phenols, fatty acids, and middle-molecular-weight substances, have all been implicated as causative agents. These toxins suppress neural energy metabolism and alter blood-brain barrier permeability.

Encephalopathy of variable degree is often present in patients with ALF, but early encephalopathy is difficult to recognize in children. Traditionally, the encephalopathy is believed to progress over four stages in adults. The symptomatology of stages 3 and 4 is similar in adults and children, but the following modifications could be applied to pediatric patients:

- Stage 1: Mild confusion/anxiety, disturbed or reversal of sleep rhythm, shortened attention span, slowing of ability to perform mental tasks (simple addition or subtraction). In young children, irritability, altered sleep pattern, unexplained bursts of excessive crying.
- Stage 2: Drowsiness, confusion, mood swings with personality changes, inappropriate behavior, intermittent disorientation of time and place, gross deficit in ability to perform mental tasks. In young children, excessive sleepiness, inability to interact with or recognize parents, lack of interest in favorite toys or activities.
- Stage 3: Pronounced confusion, delirious but arousable, persistent disorientation of time and place, hyperreflexia with a positive Babinski sign.
- Stage 4: Comatose with or without decerebrate or decorticate posturing, response to pain present (IVa) or no response to pain (IVb).

Electroencephalographic changes present in HE, although not very specific, may be useful in diagnosis and in assessment of treatment. These changes occur very early, even before the onset of psychological or biochemical disturbances. Initially, there is slowing of the alpha rhythm down to the delta range. Altering stimuli such as opening eyes may fail to reduce the background rhythmic activity. Usually, changes start in the frontal or central region and then progress posteriorly. In deeper coma, there is generalized slowing, and synchronous low-amplitude waves are recorded. It is still unclear whether routine electroencephalographic monitoring provides any advantage over clinical assessment alone except in patients who are ventilated and paralyzed, in whom it may reveal seizure activity.

Intracranial Hypertension and Cerebral Edema

Intracranial hypertension is uncommon in stages 1 and 2 but is invariably present in grade 4 encephalopathy. Raised intracerebral pressure can lead to brainstem herniation, which is the most common cause of death observed on autopsy in 80% of fatal cases.[53] Increased intracranial hypertension more commonly occurs in hyperacute liver failure (70%) rather than ALF (55%). The pathophysiology and clinical events related to it could be divided into three phases:

- Phase 1: Episodic increase in intracranial pressure (ICP) either spontaneously or in response to stimuli involved in the routine care of the patient. An intact Cushing reflex at this stage can maintain cerebral perfusion by increasing mean arterial pressure. Although the cerebral oxygenation is preserved at this stage but life-threatening, brainstem herniation can occur.
- Phase 2: At this stage, mean arterial pressure does not increase with further surges in ICP, leading to neuronal hypoxic injury.
- Phase 3: This phase is dominated by poor cerebral perfusion either owing to very high ICP or low mean arterial pressure, leading to hypoxic brain injury.

Factors responsible for encephalopathy cause cerebral edema, leading to an increase in ICP. This increase in ICP can lead to a cycle of poor cerebral perfusion, anoxic injury, and further worsening of cerebral edema. The clinical features vary depending on the severity of intracranial

hypertension. The factors and mechanisms that may lead to increased ICP are shown in Figure 58-2.

The mechanism leading to increased ICP could be broadly considered under two headings: the direct toxicity of neuronal cells and vasogenic. The neuronal toxicity leads to osmotic imbalance and an increase in intracellular water, whereas disruption of the blood-brain barrier leading to plasma seepage into the cerebrospinal fluid is of vasogenic origin. Circulating endotoxin from superimposed infections,[54] fluid overload, hypoglycemia,[55] and gastrointestinal bleeding all add to further worsening of intracranial hypertension (Table 58-5).

Gastrointestinal bleeding

Renal Failure

Renal failure occurs in about 55% of all ALF patients referred to specialist centers.[56] A variable degree of renal dysfunction is invariably present in patients with acetaminophen-related ALF. In the pediatric population, the incidence of renal failure is lower (10–15%) than in the adult population.[57] Functional renal failure (hepatorenal syndrome) usually progresses to tubular damage as the encephalopathy advances. Avid sodium retention (urinary sodium < 20 mmol/L) and normal urine sediment may help to differentiate between functional renal failure and tubular damage. The hepatorenal syndrome recovers rapidly after liver transplant, whereas established tubular damage requires prolonged renal replacement therapy.

Renal failure could be due either to the direct toxic effect on kidneys, as in acetaminophen overdose, or to a complex mechanism such as hepatorenal syndrome or acute tubular necrosis secondary to complications of ALF (sepsis, bleeding, and/or hypotension). In hepatorenal syndrome, there is a hyperdynamic circulation with a decrease in renal perfusion pressure, leading to activation of the sympathetic nervous system and rendering the kidneys more susceptible to decreases in the renal perfusion pressure and increased synthesis of several vasoactive mediators such as renin, angiotensin, adrenaline, eicosanoids, and endothelins.[58] These vasoactive mediators not only cause vasoconstriction leading to a rise in renal vascular resistance but also a decrease in glomerular capillary ultrafiltration coefficient leading to a fall in the glomerular filtration rate over and above that caused by the vasoconstrictors alone.

Blood urea estimation is unreliable as a marker of renal dysfunction because gastrointestinal hemorrhage may increase urea disproportionately. Serum creatinine is a better indicator of kidney function.

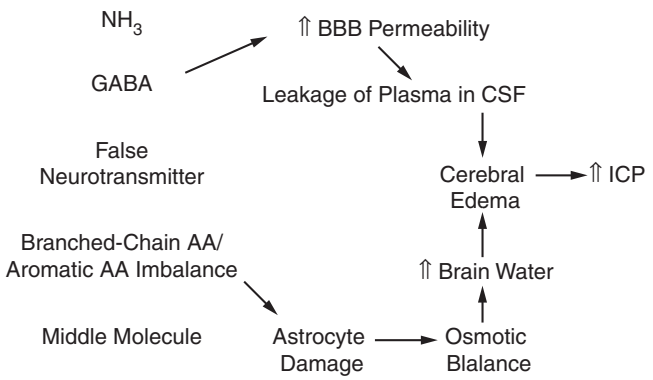

FIGURE 58-2 Schematic diagram of the pathophysiology of cerebral edema. AA = amino acid; BBB = blood-brain barrier; CSF = cerebrospinal fluid; GABA = γ-aminobutyric acid; ICP = intracranial pressure; NH_3 = ammonia.

Metabolic Derangements

Hypoglycemia is present in 40% of patients with ALF. This is due to increased plasma insulin levels owing to reduced hepatic uptake and reduced gluconeogenesis. The classic signs and symptoms of hypoglycemia are often masked, and regular blood glucose monitoring is mandatory because hypoglycemia can worsen HE and cause rapid neurologic deterioration.

Acid-base imbalance is common. Metabolic acidosis is present in about 30% of patients with acetaminophen-induced ALF and is a bad prognostic marker, with greater than 90% mortality if the arterial pH is less than 7.3 on or after the second day of overdose in adequately hydrated patients. This acidosis is independent of renal function and usually precedes the onset of encephalopathy, whereas in ALF owing to other etiologies, metabolic acidosis is present in only 5% of cases, occurs late in the disease process, and is associated with a poor outcome. Lactic acidosis develops in about 50% of patients, reaching grade 3 or 4 encephalopathy, and is related to inadequate tissue perfusion owing to hypotension or hypoxemia resulting from the impaired oxygen extraction owing to microvascular shunting of blood from actively respiring tissue. Sometimes respiratory alkalosis can be present owing to hyperventilation, probably related to direct stimulation of respiratory center by unknown toxic agents. Respiratory acidosis can be caused by pulmonary complications or by respiratory depression in association with increased ICP.

Hypokalemia is common and is due to excessive urinary potassium loss with inadequate replacement. Hyponatremia may be dilutional owing to excessive antidiuretic hormone secretion, or it may represent a true sodium-depleted state in patients who are vomiting. Hypophosphatemia is most commonly associated with acetaminophen-induced ALF when renal function is preserved. Other electrolyte disturbances include hypocalcemia and hypomagnesemia.

Hemodynamic Abnormalities

The early hemodynamic changes in ALF patients reflect a state of hyperdynamic circulation with decreased systemic peripheral vascular resistance and increased cardiac out-

put. These changes are similar to the one seen in systemic inflammatory response syndrome.[59] Profound vasodilatation, probably mediated by increased prostaglandin or nitric oxide, causes hypovolemia. Invasive monitoring is required to determine the adequacy of intravascular volume and appropriate fluid regimens. As the disease progresses, it can lead to circulatory failure either due to falling cardiac output or the inability to maintain an adequate mean arterial pressure despite inotropic support or depression of brainstem function as a result of cerebral edema. Cardiac arrhythmias of most types may occur in the later stages and are usually caused by electrolyte disturbances (eg, hypo- or hyperkalemia, acidosis, hypoxia, or cardiac irritation by a central venous catheter).

Pulmonary Complications

Pulmonary complications are common and are usually present in about 50% of patients. Aspiration of gastric contents is a significant early complication, particularly in encephalopathic patients who are vomiting; hence, early elective ventilation to protect the airway is critical in these patients. Other complications include atelectasis, infection, intrapulmonary hemorrhage, respiratory depression, or pulmonary edema. In a series of 100 patients with FHF, 52 had radiologic changes and 37 of 52 had pulmonary edema.[60]

Coagulopathy

The liver synthesizes not only the coagulation factors (except factor VIII) but also inhibitors of coagulation and factors involved in the fibrinolytic system. ALF is characterized by decreased synthesis of clotting factors (factors II, V, VII, IX, and X), accelerated fibrinolysis, and impaired hepatic clearance of activated clotting factors and fibrin degradation products. The prothrombin time expressed as an INR is markedly elevated and is used as an indicator of the severity of the liver damage. Factors V and VII have the shortest half-lives of all of the coagulation factors and are theoretically more sensitive markers than INR of hepatic synthetic function. Significant disseminated intravascular coagulation is unusual in ALF. Thrombocytopenia may develop rapidly, and a platelet count of less than 100×10^9/L has been reported in about two-thirds of the patients. Causes include increased immune-mediated platelet destruction and decreased hepatic synthesis of factors necessary for platelet maturation and release into the peripheral blood. Also, abnormalities of platelet morphology and function have been reported.

Clinically, significant bleeding tends to be less severe compared with the degree of INR prolongation, although the risk of hemorrhage correlates with thrombocytopenia. Common sites of internal hemorrhage include the gastrointestinal tract, nasopharynx, lungs, and retroperitoneum. Intracranial hemorrhage is uncommon. The incidence of gastrointestinal hemorrhage has declined since the use of histamine$_2$ blockers in the management of ALF. A mild degree of hemophagocytosis (hemophagocytic lymphohistiocytosis) is commonly observed and contributes to coagulation abnormalities. The presence of significant disseminated intravascular coagulation usually indicates sepsis or secondary hemophagocytic lymphohistiocytosis.

Infections

Patients with ALF are at increased risk of bacterial infections because of poor host defenses. There is impaired Kupffer cell and polymorphonuclear function and reduced levels of factors such as fibronectin, opsonins, and chemoattractants, including components of the complement system. The additional predisposing factors are poor respiratory effort and cough reflex and the presence of an endotracheal tube, urinary catheters, and central venous and arterial lines.

Infection can lead to development and progression of multiorgan failure. An active uncontrolled infection also can render potential candidates disqualified for emergency liver transplant. It is very difficult to detect infection in the setting of ALF because there is a poor correlation between infection and normal indicators of infection, such as leukocyte count and fever. The risk factors for infections include coexisting renal failure, cholestasis, treatment with thiopental, and liver transplant. The presence of encephalopathy (grade 2 or above) has been shown to be associated with bacterial infection in about 80% of cases and fungal infections in about 32% of cases.[61] The sources of positive cultures include blood, urine, sputum, and catheter tips. More than two-thirds of bacterial infections are due to gram-positive bacteria, usually *Staphylococcus aureus*, but streptococci or gram-negative organisms such as coliforms are also isolated. *Candida* spp are the most common fungal infections. These are often unrecognized and ominous. Deterioration of HE after initial improvement, a markedly raised leukocyte count, pyrexia unresponsive to antibiotics, and established renal failure are strong indicators of fungal infection.

Acute Pancreatitis

Mild elevation of serum amylase is not uncommon, but clinically significant pancreatitis is unusual. It should be suspected in patients who complain of abdominal pain or have hypocalcemia. Etiologic factors include causative virus, hemorrhage into or around the pancreas, sodium valproate–related ALF, or shock.

Adrenal Hyporesponsiveness

In a recent adult study, 62% of patients with ALF had a poor response to a short synacthen test and showed significant improvement of hemodynamic parameters after administration of replacement therapy with hydrocortisone.[62] No pediatric data are available, but corticosteroid replacement could be considered in patients with intractable hypotension unresponsive to conventional therapy.

PROGNOSIS

The prognosis of ALF varies greatly with the underlying etiology. In an adult series from King's College Hospital, London, 50% of patients survived following acetaminophen overdose, whereas the survival rate was only 12.5% following halothane-induced ALF—66% for hepatitis A and 39% for hepatitis B.[63]

Prothrombin time is the best indicator of survival.[64] Bhaduri and Mieli-Vergani have shown that the maximum INR reached during the course of illness was the most sen-

sitive predictor of the outcome, with 73% of children with an INR less than 4 surviving compared with only 4 of 24 (16.6%) with an INR greater than 4.[6]

Factor V concentration has been used as a prognostic marker, especially in association with encephalopathy (Clichy criteria). In children, a factor V concentration of less than 25% of normal suggests a poor outcome, and in many French centers, this criterion is used for listing for liver transplant.[65]

Liver biopsy is rarely helpful in ALF and is usually contraindicated because of the presence of coagulopathy. However, it can be done using a transjugular approach. Hepatic parenchymal necrosis of more than 50% is associated with a reduced survival,[66] but the potential for sampling error is considerable. A biopsy taken from an area of complete collapse will show very few viable hepatocytes, indicating a poor prognosis. On the other hand, a biopsy specimen taken from a regenerative nodule may falsely give a good prognosis (Figure 58-3). These limitations and difficulty in performing a liver biopsy in patients with ALF have limited its value as a prognostic test.

A small liver or, more particularly, a rapidly shrinking liver is an indictor of a poor prognosis. Computed tomographic volumetry of the liver has been used to assess both the size of the liver and its functional reserve.[66]

Fulminant Wilson disease is invariably fatal, and emergency liver transplant is the only effective treatment.[67,68] Predicting the outcome of decompensated Wilson disease presenting as ALF is usually difficult. In our experience, a prognostic score has been useful in identifying the patients who carry a high risk of mortality without liver transplant (Table 58-6). It incorporates bilirubin, INR, aspartate transaminase, white blood cell count, and albumin at presentation. A score of 11 or more indicates high mortality, with 93% sensitivity and 96% specificity.

Survival depends on the ability of the liver to recover from the ensuing insult, but it is very difficult to predict the potential of recovery. There are no single criteria that can predict the outcome with absolute certainty and be universally applicable for all patients with ALF with different etiologies. However, prediction of a low level of survival (chance of < 20%) is clinically useful to decide to list the patient for orthotopic liver transplant (OLT), which has a 1-year survival rate of 75%.[69]

MANAGEMENT

An initial contact with a specialist center at diagnosis should be made to establish a management plan. Depending on the local facilities and expertise, the timing of referral to hepatology and liver transplant centers may vary, but an early transfer is always recommended. Liver transplant has undoubtedly improved the survival of this group of patients, but better intensive care monitoring and early and better management of complications can sometimes avoid transplant or death. Also, monitoring of these patients is a continuous process of assessing the clinical status so that a child who is not considered for liver transplant initially may change his/her status. Likewise, a child who has been listed for liver transplant may show signs of unexpected improvement, hence not requiring transplant operation, or may develop complications that contraindicate it.

Initial Assessment

A careful and detailed history should include the mode of onset of illness, family history of liver disease, consanguinity, and exposure to drugs and toxins. Clinical examination

could give diagnostic clues such as the presence of any herpetic vesicles, signs of underlying chronic liver disease, and the presence of Kayser-Fleischer rings on slit lamp examination. All children with ALF require elaborate investigations to establish the underlying cause (Tables 58-7 and 58-8).

General Measures

All children with ALF should be nursed in a quiet environment with as little stimulation as possible to minimize acute increase in the ICP. Children with encephalopathy or an INR greater than 4 (without encephalopathy) should be admitted to an intensive care unit for continuous monitoring. Sedation is contraindicated unless the patient is to be mechanically ventilated because of the possibility of aggravating the encephalopathy or precipitating respiratory failure.

Monitoring of nonventilated ALF patients should include the following:

- Continuous oxygen saturation monitoring
- 6-hourly urine output
- 6-hourly vital signs including blood pressure, neurologic observations, and blood glucose estimation
- 12-hourly electrolyte and coagulation studies (INR)
- Daily full blood count along with surveillance blood and urine cultures

In addition, patients on assisted ventilation have an arterial line for invasive blood pressure monitoring and frequent blood sampling. Blood gas analysis is performed every 4 hours, and electrolytes and prothrombin time are measured every 8 hours. Sedation in these ventilated patients is maintained by a morphine and midazolam infusion in our unit. The use of benzodiazepines for sedation in ALF is only recommended once a decision has been taken to ventilate the patient (management of specific complications is discussed later). Controlled trials in adults have failed to substantiate any beneficial effect of corticosteroids, interferon, insulin and glucose, prostaglandin E_1, bowel decontamination, and charcoal hemoperfusion in patients with ALF. The use of enemas and cathartics in patients who are not constipated is usually counterproductive, not only by increasing their nursing need but also by triggering surges of ICP. Hypoglycemia should be avoided by use of intravenous glucose infusion or by ensuring adequate enteral intake. Total fluid intake is restricted to two-thirds maintenance if there is no evidence of dehydration, with the idea of decreasing the possibility of development of cerebral edema. The idea of protein restriction to limit the possibility of HE has now been disregarded, and adequate calories should be provided. Oral or nasogastric feeding is usually well tolerated. Prophylactic broad-spectrum antibi-

TABLE 58-7 DIAGNOSTIC TESTS OF THE CAUSES OF ACUTE LIVER FAILURE

CAUSE	TEST
Hepatitis A infection	Anti-HAV antibody (IgM)
Hepatitis B infection	
Acute infection/seroconversion	Anti–core antibody (IgM)/HBV profile
Increased replication	Full HBV profile
Hepatitis D infection	Anti-HDV antibody (IgM)
Parvovirus, adenovirus, EBV	Viral serology/antigen tests, PCR
Seronegative hepatitis	Diagnosis of exclusion (all tests)
Acetaminophen	History, drug level in blood
Mushroom poisoning	History, diarrhea
Autoimmune hepatitis	Autoantibodies, immunoglobulins
Wilson disease	Urinary copper, Kayser-Fleischer rings, Coombs-negative hemolytic anemia
Galactosemia	Galactose-1-phosphate uridyl transferase level in blood
Tyrosinemia	Urinary succinylacetone
Neonatal hemochromatosis	Buccal mucosal biopsy, raised ferritin, high transferrin saturation
Hemophagocytic lymphohistiocytosis	Bone marrow aspiration (typical cells)
Mitochondrial hepatopathies	Muscle and liver biopsies for quantitative assay of respiratory chain enzyme
Veno-occlusive disease	Doppler ultrasonography/venography
Malignancies	Imaging (CT/MRI) and histology
Idiosyncratic drug reactions	History, eosinophil count

CT = computed tomography; EBV = Epstein-Barr virus; HAV = hepatitis A virus; HBV = hepatitis B virus; HDV = hepatitis D virus; IgM = immunoglobulin M; MRI = magnetic resonance imaging; PCR = polymerase chain reaction.

TABLE 58-8 INVESTIGATIONS IN INFANTS AND CHILDREN WITH ACUTE LIVER FAILURE

- Biochemical tests
  - Liver function tests (total and direct bilirubin, AST, ALT, GGT, ALP, albumin)
  - Blood sugar
  - Serum electrolytes
  - Serum calcium, phosphorus
  - Serum magnesium
  - Uric acid
  - Cholesterol
  - Triglyceride
  - Amylase
  - α_1-Antitrypsin phenotype
  - Galactose-1-phosphate uridyl transferase (in infants and neonates)
  - Serum copper and ceruloplasmin (in children > 3 yr old)
  - Serum amino acids
  - Plasma acylcarnitines
  - Blood gas analysis
- Hematologic tests
  - Full blood count
  - Reticulocyte count
  - Prothrombin time or INR
  - Blood for grouping and crossmatching
  - Direct Coombs test
  - Bone marrow examination (in seronegative hepatitis or if hematologic malignancy or HLH is suspected)
- Ultrasound scan of abdomen, especially liver, portal and hepatic veins, inferior vena cava, biliary system, and spleen
- Microbiologic tests
  - Bacterial cultures: blood, urine, stool, throat swab, sputum, skin lesion if present, ascitic fluid if present
  - Viral culture of urine and skin lesion if present
- Serologic tests
  - Viral hepatitis: anti-HAV IgM antibody, HBsAg, HBcAg, hepatitis D antigen and antibody, anti–hepatitis C antibody, anti–hepatitis E antibody
  - Cytomegalovirus
  - Epstein-Barr virus
  - Human immunodeficiency virus (HIV)
  - Measles
  - Varicella
  - Herpes simplex virus
  - Adenovirus
  - Echovirus
  - Others: toxoplasmosis, leptospirosis, and listeriosis
- Immunologic tests
  - Immunoglobulins(IgG, IgA, and IgM)
  - Tissue antibodies (anti-SMA, GPC, mitochondrial, liver-kidney microsomal and antinuclear antibodies)
  - Complement C3 and C4
- Ascitic fluid or cerebrospinal fluid cytospin for evidence of hemophagocytosis
- Urine
  - Toxicology
  - Chemical analysis, osmolality, and electrolytes
  - Organic acids
  - Succinyl acetone
  - 24-h urinary copper prepenicillamine and postpenicillamine (2 doses of 500 mg 12 h apart)
  - (5 mL of serum and aliquot of initial urine for possible subsequent investigations)
- Tissue studies
  - Buccal mucosal biopsy
  - Muscle biopsy
  - Skin fibroblast culture
  - Transjugular liver biopsy

ALP = alkaline phosphatase; ALT = alanine transaminase; AST = aspartate transaminase; GGT = γ-glutamyl transferase; GPC = gastric parietal cell; HAV = hepatitis A virus; HBcAg = hepatitis B core antigen; HBsAg = hepatitis B surface antigen; HLH = hemophagocytic lymphohistiocytosis; INR = international normalized ratio; SMA = smooth muscle antibody.

otics[70] and antifungals[71] significantly reduce the incidence of infective episodes. In neonatal liver failure, intravenous acyclovir should be commenced.

MANAGEMENT OF SPECIFIC COMPLICATIONS

Neurologic Complications

The most important neurologic complications are HE and cerebral edema. Management options for the treatment of HE are limited. Ammonia-lowering measures such as dietary protein restriction, bowel decontamination, or lactulose are of limited or no value in rapidly advancing encephalopathy. The use of branched-chain amino acids, flumazenil, and extracorporeal circuits has only shown transient improvement in encephalopathy, without any survival benefit in larger studies.

Cerebral edema has been documented at the time of postmortem in about 30 to 40% of all patients with fatal ALF. Typical features of raised ICP include systemic hypertension, hypertonia, hyperreflexia, decerebration, hyperventilation, dysconjugate eye movements, or squint. In infants, the anterior fontanel may be tense. If uncontrolled, the clinical features progress to loss of pupillary reflexes and, ultimately, impairment of brainstem reflexes. Despite severely increased ICP, papilledema is a rare sign. Systemic hypertension is a good surrogate marker for increased ICP in the initial stages but is absent in later stages.

To date, the opinion is divided toward the risk-to-benefit ratio of using ICP monitoring devices for early detection of increased ICP. Proponents of the use of ICP monitors argue that these devices allow early and accurate detection of changes in ICP, especially in ventilated and sedated patients, in whom the clinical signs are usually masked. It also helps in accurate monitoring of ICP during interventions such as central line insertions, tracheal suctioning, and hemodialysis or hemodiafiltration. Keays and colleagues have shown that ICP monitoring identified rises in ICP unaccompanied by clinical signs, and, as a consequence, treatment was given to the monitored patients more often than the nonmonitored group. The duration of survival from the onset of grade 4 encephalopathy was significantly greater in the ICP-monitored group, although the overall survival rate was unchanged. Monitoring also provided important prognostic information because the peak ICP was higher in nonsurvivors than in survivors.[72] The group that was not enthusiastic about invasive ICP monitoring argued that the procedure is associated with a high incidence of intracranial bleeding and is never proven

to improve patient survival. Epidural transducers are associated with a lower complication rate (3.8%) compared with subdural devices that carry a 22% risk of intracranial complications.[8,73] High ICP at the time of insertion of the device has been shown to be a major risk factor for the development of intracranial hemorrhage. Our practice is to insert a subdural bolt in children older than 2 years who have clinical signs of increased ICP and are awaiting liver transplant.

The aim of ICP monitoring is to maintain cerebral perfusion pressure (mean arterial blood pressure – ICP) at more than 50 mm Hg. If the cerebral perfusion pressure falls below 50 mm Hg, the adequacy of sedation and paralysis should be checked, along with $PaCO_2$ levels (in ventilated patients, $PaCO_2$ should be kept between 4 and 4.5 kPa). If the $PaCO_2$ is more than 4.5 kPa, then hyperventilation may be helpful. Excessive hyperventilation should be avoided because it may paradoxically compromise the cerebral perfusion pressure. A care pathway for the management of raised intracranial pressure is shown in Figure 58-4.

Mannitol remains the mainstay of treatment for increased ICP because of its property as an osmotic diuretic. It has also been suggested that a therapeutic response is due to the increase in cerebral blood flow, and the rapidity of action of mannitol is more consistent with this function. A rapid bolus of 0.5 g/kg as a 20% solution over a 15-minute period is recommended, and the dose can be repeated if the serum osmolarity is less than 320 mOsm/L. In anuric patients, a diuresis is simulated by ultrafitrating three times the administered volume over the next half hour.

Uncontrolled studies have shown sodium thiopental to be an effective agent in controlling mannitol-resistant cerebral edema.[74] A bolus dose of 2 to 4 mg/kg over 15 minutes is followed by a slow intravenous infusion of between 1 and 2 mg/kg/h. There has been no controlled trial of the use of sodium thiopental in lowering ICP. Major concerns are hemodynamic instability and increased incidence of infective complications following its administration. Hypothermia (core body temperature of 32°C) has been shown to be effective in the management of severe intracranial hypertension with lowering of ICP and improvement of cerebral perfusion pressure in adults.[75] Subclinical seizure activity also has been suggested as a contributing factor for the development of cerebral edema. In a study of 42 adult patients, Ellis and colleagues demonstrated a significant reduction in the seizure activity in the group treated with phenytoin infusion. Incidence of cerebral edema was also significantly less in the phenytoin-treated group compared with the control group.[76]

In severe unresponsive cerebral edema, the emphasis of management shifts toward preservation of cerebral perfusion pressure, increased oxygen delivery to the brain, and manipulation of the neuronal microcirculation to promote cerebral oxygen extraction. In this situation, inotropic agents can be used to increase the mean arterial pressure, consequently improving cerebral perfusion pressure. Normally, at this stage, spontaneous recovery is unlikely without liver transplant.

Hepatectomy with a portacaval shunt has been shown to stabilize the patients hemodynamically with reduction of ICP up to 48 hours followed by successful liver transplant. *N*-Acetylcysteine has been shown to increase the cerebral blood flow and cerebral metabolic rate, thereby improving the microcirculatory stability.

Infections

Bacterial and fungal infections have been documented in about 82 and 34% of patients with ALF, respectively.[61] About 60% of deaths in ALF have been attributed to sepsis.[77] Prophylactic intravenous antibiotics have been shown to reduce the incidence of culture-positive bacterial infection from 61.3 to 32.1%. The respiratory tract is the most common site (47%), followed by the urinary tract (23%).[77] A high index of suspicion, along with early and frequent bacteriologic investigations, is necessary for early diagnosis. Gram-positive bacteria are the most common organism isolated in about 70% of cases, 35% of these isolates being *S. aureus*.[77]

Topical antifungal prophylaxis has been used in combination with intravenous antibiotics. The efficacy of systemic antifungals as prophylaxis has not been studied systematically. Systemic fungal infection is very difficult to diagnose, but renal failure, severe cholestasis, previous or concomitant thiopental therapy, concomitant immunosuppressive therapy, and worsening coagulopathy are the high-risk factors. The choice of systemic antifungal agents is determined by the local experience. In our unit, fluconazole is the preferred agent because *Candida* spp. account for most of the fungal infections.

Hemodynamic Instability

Circulatory failure is a common mode of death in patients with ALF, often complicating sepsis or multiorgan failure. Invasive hemodynamic monitoring may provide early evidence of circulatory failure. Despite the presence of edema, frequently these patients have intravascular volume depletion and need an appropriate combination of colloids, crystalloids, or blood products. In the presence of persistent hypotension despite normal filling, pressure vasopressors such as noradrenaline and adrenaline are inotropic agents of choice. *N*-Acetylcysteine has been shown to improve the

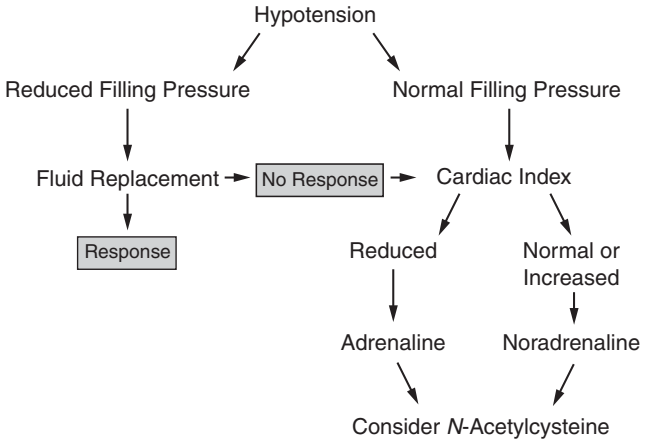

FIGURE 58-4 Care pathway for the management of hypotension.

parameters of oxygen metabolism. A combination of prostacycline and *N*-acetylcysteine has been found to be more beneficial for oxygen metabolism than either drug alone. In our experience, newer monitoring devices such as pulse contour cardiac output (PiCCO) and lithium dilutional cardiac output (LiDCO) monitoring, which can measure various body water compartments, are good devices to rationalize fluid management and the choice of vasopressors. The PiCCO method is a combination of transpulmonary thermodilution technique and arterial pulse contour analysis. It requires a central venous line and an arterial thermodilution catheter placed in either a femoral or an axillary artery. A bolus of cold saline is injected in the central venous line, and the thermodilution is detected from the special arterial catheter. It measures cardiac ouput (by thermodilution), continuous cardiac output using the pulse contour method, intrathoracic blood volume, and extravascular lung water.[78] LiDCO monitoring involves a bolus indicator dilutional technique for measuring cardiac output using isotonic lithium chloride as an injectate.[79] A care pathway for the management of hypotension is shown in Figure 58-5.

Renal Failure

Renal failure with severe oliguria often develops in ALF, especially in later stages. Although the mechanism of renal failure is not clear, it is essential to correct intravascular hypovolemia. Recent studies have shown that low-dose dopamine is not only ineffective[80] but can have deleterious effects,[81] especially in the setting of profound vasodilatation, which is seen typically in ALF. Extracorporeal renal support was required in 75% of cases with acetaminophen-induced ALF and in 30% of patients with other etiologies of ALF. Hemodiafiltration and hemodialysis should be instituted when the urine output is less than 1 mL/kg/h. Continuous filtration or dialysis systems are associated with less hemodynamic instability and consequently less risk of aggravating latent or established encephalopathy than intermittent hemodialysis. In spite of the presence of coagulopathy, heparin requirements have been shown to be increased. Recently, prostacycline infusion at a rate of 5 ng/kg/min has been found to be superior to heparin anticoagulation with respect to functional duration of the filters and the hemorrhagic complications.[82]

Coagulopathy

Bleeding diathesis, although always present in ALF, differs in severity from patient to patient. Normally, disseminated intravascular coagulation is not a feature of ALF but is usually an indicator of sepsis. The possible advantage of reduced bleeding by repletion of coagulation factors with fresh frozen plasma has not been established by clinical studies. Because coagulopathy is a very good tool for assessment of prognosis and monitoring of disease progression, correction of coagulopathy is indicated only if the patient is already listed for transplant or prior to an invasive procedure such as insertion of a central line or ICP monitors. This also carries a further disadvantage of volume overload and hyperviscosity. There has been a poor correlation between the severity of prolongation of prothrombin time and bleeding tendencies, but associated thrombocytopenia is an important risk factor for hemorrhage; hence, the platelet count should be maintained above 50×10^9/dL.

The most common site of bleeding is the gastrointestinal tract. Prophylactic ranitidine (histamine$_2$ blocker) or proton pump inhibitors have been shown to decrease the incidence of gastric bleeding.[83] A study comparing antacid with histamine$_2$ blockers showed equal efficacy if the gastric pH was kept above 3.5 by frequent administration of antacid. There is increased risk of gastric colonization with use of histamine$_2$ blockers or proton pump inhibitors. Sucralfate has the potential advantage of reducing gastric colonization and pulmonary infection by maintaining gastric acidity, but its efficacy in ALF has not been assessed.

Ventilatory Management

Ventilatory support in the form of mechanical ventilation is instituted when grade 3 encephalopathy develops or when patients in grade 1 or 2 encephalopathy require sedation. Inducing agents such as suxamethonium and fentanyl are generally safe. Sedation could be maintained with a combination of an opiate such as morphine or fentanyl and a hypnotic such as midazolam. There are no special ventilatory requirements in patients with ALF; however, a peak end-expiratory pressure above 8 cm of water should be avoided because it may increase ICP.

Initially, adult respiratory distress syndrome (ARDS) is unusual, and ventilation is easy. The most severe ventilatory problems arise when liver function is improving or the patient had liver transplant when there is a chance of developing ARDS. In patients with unresponsive ARDS, nitric oxide inhalation or intravenous prostacycline may be tried, although their role has not been properly assessed in ALF.

Liver Assist Devices

In ALF, pathophysiologic changes are due to impairment of synthetic, detoxifying, and biotransformatory activity resulting from the loss of functioning hepatocytes and Kupffer cells. The severity and duration of these changes also depend on the rate and extent of liver regeneration. There has been increasing interest in the possibility of providing an extracorporeal liver support system either as a bridge to liver transplant or, ideally, to obviate the need for it by supporting liver function while the native liver regenerates. Liver support devices could be either cleansing devices or a bioartificial liver support system (Table 58-9). Cleansing devices perform only the detoxifying function of the liver, whereas bioartificial liver support systems have a theoretic advantage of providing the synthetic and detoxifying properties.

Charcoal hemoperfusion was extensively assessed in an initial study of 76 adults and suggested an increase in survival in patients with grade 3 HE,[84] but a subsequent controlled trial did not show any significant difference in outcome.[63]

Recently developed cleansing devices such as Biologic-DT and the molecular adsorbent recirculating system (MARS) attempt to remove protein-bound toxins by perfusion over resins or albumin. The MARS uses an albumin-impregnated dialysis membrane and dialysate containing 5% human albumin solution. This dialysate is perfused to remove water-soluble toxins, including ammonia. Preliminary studies in adults showed a survival rate of 69%, with hemodynamic stabilization, improvement in mental status, and HE.[85] More information is required before this device can be recommended universally.

The bioartificial liver support system uses bioreactors containing hepatocytes in columns. Of three bioartificial liver support devices, the bioartificial liver and the Berlin Extracorporeal Liver Support System use primary porcine hepatocytes, whereas the extracorporeal liver assist device uses the hepatoblastoma cell line. Anticoagulated whole blood or plasma is passed through a device, allowing metabolic transfer between perfusate and hepatocytes. Although preliminary results were encouraging, a controlled pilot study of the ELAD did not show any significant benefit.[86] The bioartificial liver system has shown statistical improvement in the level of consciousness, an increase in ICP, and an increase in cerebral perfusion pressure.[87] These devices appear to be promising, but pediatric experience is limited and anecdotal.

TABLE 58-9 TYPES OF LIVER ASSIST DEVICES

CLEANSING DEVICES	BIOARTIFICIAL LIVER SUPPORT SYSTEMS
Charcoal hemoperfusion	Bioartificial liver
Biologic-DT	Extracorporeal liver assist device
Plasmapheresis	Berlin Extracorporeal Liver Support System
Molecular adsorbent recirculating system	

Liver Transplant

Liver transplant is the only proven treatment that has improved the outcome of ALF. Taking into account all age groups, ALF accounts for 5 to 7% of all liver transplants in the United States[88] and about 11% in Europe.[89] Reports from Europe and the United States have shown that about 45 to 50% of cases with ALF undergo liver transplant, whereas in 13 to 27% of cases, it was contraindicated at the time of admission. About 6 to 18% of cases were removed from the waiting list because of development of a contraindication or the improvement in the clinical and prognostic status or died before a donor liver became available.[8]

Because of the scarcity of donor organs, optimal use of donor livers is essential. This entails proper selection of the patients as well as timing of the operation. In adults, the King's College Hospital criteria have been extensively used for listing for liver transplant (Tables 58-10 and 58-11).[64]

Contraindications for liver transplant are fixed and dilated pupils, uncontrolled sepsis, and severe respiratory failure (ARDS). Relative contraindications are accelerating inotropic requirements, infection under treatment, cerebral perfusion pressure of less than 40 mm Hg for more than 2 hours, and a history of progressive or severe neurologic problems in which the ultimate neurologic outcome may not be acceptable.

After successful transplant, cerebral edema can persist for 12 hours, and cerebral autoregulation is restored within 48 hours. In contrast, the hemodynamic and the neurologic parameters improve during the anhepatic phase of the operation. Extending this advantage, there have been reports of using a two-stage procedure in very unstable patients with hepatectomy followed by liver transplant as soon as the donor liver is available. The longest time of the anhepatic phase preceding OLT has been 48 hours in our experience. Ringe and Pichlmayr reported the largest series of this two-stage procedure, but only 59% of patients received liver transplant[90]

Auxiliary Liver Transplant

The rationale behind this technique is that the allograft provides liver function while the native liver regenerates.

TABLE 58-10 INDICATORS OF A POOR PROGNOSIS IN ACETAMINOPHEN-INDUCED ACUTE LIVER FAILURE

PARAMETER	SENSITIVITY (%)	SPECIFICITY (%)	POSITIVE PREDICTIVE VALUE (%)
Arterial pH < 7.3	49	99	81
All 3 of the following:	45	94	67
Prothrombin time > 100 s or INR > 6.5			
Creatinine > 300 µmol/L (2.3 mg/dL)			
Grade 3–4 encephalopathy			

INR = international normalized ratio.

TABLE 58-11 INDICATORS OF A POOR PROGNOSIS IN NONACETAMINOPHEN ETIOLOGIES OF ACUTE LIVER FAILURE

PARAMETER	SENSITIVITY (%)	SPECIFICITY (%)	POSITIVE PREDICTIVE VALUE (%)
Prothrombin time > 100 s or INR > 6.7	34	100	46
Any 3 of the following:	93	90	92
Unfavorable etiology (seronegative hepatitis or drug reaction)			
Age < 10 yr or > 40 yr			
Acute or subacute categories			
Serum bilirubin > 300 μmol/L (2.3 mg/dL)			
Prothrombin time > 50 s or INR > 3.5			

INR = international normalized ratio.

Once the native liver shows signs of recovery, immunosuppression can be weaned and eventually stopped. Auxiliary liver transplant could be heterotopic (the donor graft is placed alongside the native liver in the right upper quadrant) or orthotopic (part of the native liver is resected and replaced with a reduced-size graft), replacing the right lobe, left lobe, or left lateral segment. Auxiliary partial OLT is preferred over heterotopic. In our center, all patients who undergo auxiliary liver transplant undergo elective liver biopsies at day 7, 6 months, and 1 year, along with computed tomographic volumetry (to assess the volume of native liver and graft) and radionucleotide scan (diisopropyl iminodiacetic acid to assess the relative function of the native liver and the graft). Once the native liver has returned to normal morphology and function, immunosuppression is gradually weaned off. The donor liver is supposed to atrophy with time. In our experience, 12 of 14 children who had auxiliary liver transplant survived, and 7 of them have been able to stop immunosuppression after a median post-transplant interval of 9 months (M. Rela, unpublished data, 2003).

Because auxiliary partial OLT is technically demanding, the choice of this operation is ideally left to the local surgical team.There have been no universally accepted indications for auxiliary liver transplant in the setting of ALF.

Hepatocyte Transplant

Taking the success of auxiliary liver transplant further, hepatocyte transplant has been tried in experimental animals with improved survival. In a small number of clinical studies, variable improvement in encephalopathy, coagulopathy, and hyperammonemia has been reported. The procedure has shown some encouraging results as a bridge to transplant, and in one child, liver transplant was avoided; however, the technique remains experimental.[91,92]

CONCLUSION

ALF is a multisystem disorder with a very high mortality rate. In children, seronegative hepatitis is the most common cause of ALF in Western countries. Despite improvement in intensive care support, liver transplant is the only effective treatment. Liver assist devices and hepatocyte transplant hold a great potential of providing a bridge to transplant or avoiding it while the native liver regenerates. The condition should ideally be managed in a liver center with facilities for liver transplant.

CHAPTER 59

TREATMENT OF END-STAGE LIVER DISEASE

Suzanne V. McDiarmid, MB, CHB

The challenges of treating children with end-stage liver disease are considerable. As liver function deteriorates, a cascade of complications ensues, involving every major organ system. The pivotal role of the liver as the body's biochemical "brain" becomes even more evident as liver function is lost. As well, the liver is positioned at the interface of the splanchnic and systemic circulations and has a profound influence on hemodynamics.

The many diverse causes of chronic liver disease in children are discussed elsewhere, but all share a similar final common pathway as chronic liver failure evolves. Although the spectrum of complications resulting from chronic liver disease is similar in children and adults, children are more vulnerable to the profound effects of the failing liver on growth, development, and nutrition. As well, the management of portal hypertension and bleeding varices is made more technically difficult in small children because therapeutic interventions are often limited by the diminutive size of the patient and their vasculature.

The success of liver transplant over the last two decades has given the pediatric hepatologist a new perspective on managing end-stage liver disease. Because many of these children are transplant candidates, medical care has changed dramatically from the pre-1980s philosophy of supportive, palliative treatment preceding inevitable death to anticipatory management that will maintain the child in the best possible condition until transplant. One of the most effective means that the pediatric hepatologist has to ensure survival after liver transplant is to prevent the child from becoming critically ill before transplant. Keeping this in mind, this chapter reviews the management of the major complications of end-stage liver disease in children.

NUTRITIONAL SUPPORT

Cholestatic liver diseases are the most important etiology of end-stage liver disease in children. Biliary atresia is the most common, followed by the intrahepatic cholestasis syndromes. Irrespective of the cause of cholestasis, all share an increased risk of malnutrition. Because most of these children are candidates for liver transplant and malnutrition is a known factor that adversely affects morbidity and mortality after transplant (Figure 59-1),[1–3] early recognition and timely intervention are essential.

The cause of malnutrition is multifactorial (Table 59-1).[4,5] Fat malabsorption is inevitable because of the dependence of long-chain fatty acids, the most important component of dietary fat, on the micellar action of bile acids in the intestinal lumen for absorption.[6] Compounding the risk, most children afflicted with cholestatic liver disease are infants, with high caloric requirements for growth and development. As well, increased intra-abdominal pressure, either secondary to ascites or organomegaly, is a frequent complication causing early satiety, diminished oral intake,

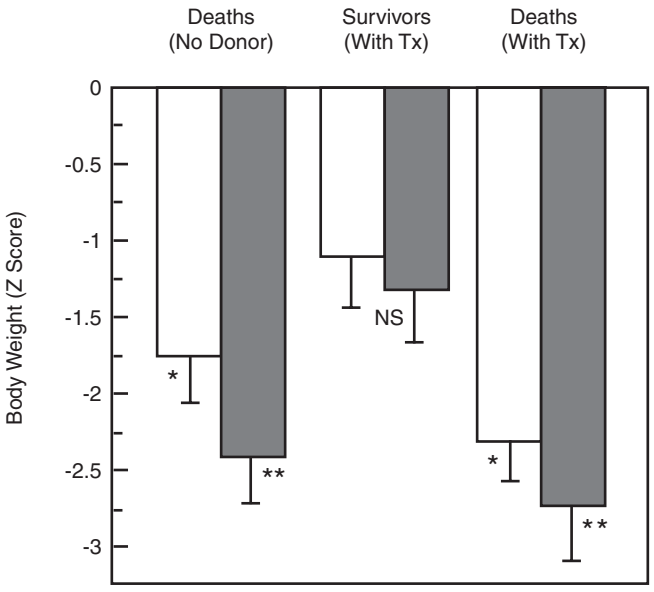

FIGURE 59-1 Z-scores for weight at the time of referral and at the time of transplant or death without a donor in three outcome groups of children with end-stage liver disease accepted for liver transplant. Open bars are scores at referral; black bars are scores at transplant or death. Deaths (no donor), $n = 8$; survivors, $n = 23$. Deaths (with transplant [Tx]), $n = 6$; $p < .05$ for deaths. *$p < .02$ versus survivors; **$p < .02$ versus survivors. NS = not significant. Reproduced with permission from Shepherd RW et al.[1]

TABLE 59-1 FACTORS CONTRIBUTING TO MALNUTRITION IN END-STAGE LIVER DISEASE

Fat malabsorption 2° to cholestasis
Diminished oral intake 2° to ↑ abdominal girth
Ascites

↑ Abdominal pressure → ↑ emesis
Peripheral resistance to anabolic effects of growth hormone
Anorexia 2° to chronic disease
↑ Catabolic rate
Intercurrent infection
Complications

and an increased risk of postprandial emesis. These infants are often debilitated by the anorexia of chronic disease, which is further exacerbated when the complications of end-stage liver disease supervene. Oral intake further decreases at a time when catabolic stresses are increased, resulting in a widening discrepancy between caloric requirement and intake. As the cycle of cholestasis-induced malabsorption and inadequate calorie and protein intake intensifies, these small children rapidly decompensate to clinically evident protein-energy malnutrition. First, subcutaneous tissue stores are depleted (evidenced by decreasing triceps skinfold thickness), followed by loss of muscle mass (measured by decreases in midarm circumference). Eventually, if left untreated, these severely cholestatic infants will present emaciated, hypotonic, dehydrated, and in need of emergency medical care.

Important metabolic and endocrine derangements are associated with chronic liver disease, further intensifying protein-energy malnutrition. Peripheral insulin resistance causing increased gluconeogenesis depletes muscle protein stores. The ratio of aromatic amino acids to branched-chain amino acids (BCAAs) (leucine, isoleucine, valine) in the peripheral blood increases, secondary to increased use of BCAAs by peripheral muscle.[7] BCAAs have important anticatabolic effects and a role in optimizing nitrogen use. As well, caloric requirements are increased above normal estimates for age, as demonstrated by studies in which children failed to show improvement in nutritional status, unless they received in excess of 1.5 to 2 times the estimated caloric requirements for age.[4,8]

Of particular importance in children are the now well-described abnormalities in the growth hormone (GH) and insulin growth factor (IGF) axis in cholestatic liver disease.[9,10] GH mediates most of its anabolic effects through IGF-1. The IGF-binding proteins (IGFBPs), especially IGFBP-3, regulate the transport of IGF to the tissues. Although IGF-1 and IGFBP-3 are produced in a variety of tissues, the most important site of synthesis is the hepatocyte for IGF-1 and the Kupffer cell for IGFBP-3. In children without liver disease but with protein-energy malnutrition, IGF-1 levels fall, suggesting an important link between nutritional status and growth.[11] In children with cholestatic liver disease, including both biliary atresia and Alagille syndrome, several authors have shown that not only are GH levels increased above normal, but IGF-1 levels are decreased, suggesting peripheral resistance to GH. In a study of children with chronic liver disease, short stature, and increased GH levels, Bucuvalas showed that the expected effects of high GH levels, lypolysis, and decreased insulin sensitivity did not occur.[12] As well, several authors have shown that despite adequate protein calorie intake, GH supplementation of children with biliary atresia or Alagille syndrome had no beneficial effect on growth, anthropometric measurements, or body composition.[10,13] In addition, circulating IGF-1 and IGFBP-3 levels were unaffected.[14] This resistance to exogenous GH in the face of low levels of IGF-1 raises the possibility that these growth-retarded children may benefit from IGF-1 treatment.[10,14]

The assessment of nutritional status in children with chronic liver disease is complicated by the effects of fluid retention, ascites, and often massive hepatosplenomegaly, making changes in weight, or weight-for-height ratios, unreliable. Although height z-scores are more useful, a falloff in linear growth is a relatively late consequence of malnutrition. To accurately assess the earlier stages of protein-energy malnutrition and to follow the effects of nutritional interventions, anthropometric measurements are essential. Midarm circumference correlates with lean body mass (protein stores) and triceps or subscapular skinfold thickness with body adipose stores. More sophisticated estimates of body cell mass measure total-body potassium content. Because more than 90% of body potassium is intracellular, its measurement is not affected by fluid shifts between the intra- and extracellular compartments.[15] These principles are well demonstrated by a study that evaluated 56 children with chronic liver disease. Mean height z-scores were decreased, whereas mean weight and mean weight-for-height z-scores were close to normal.[16] Moreover, triceps skinfold z-scores were the most depressed, compared with either height or weight z-scores. Midarm circumference was also depressed but not as markedly as triceps skinfold thickness, suggesting that lean body mass was not as severely depleted as body adipose tissue reserves. This study demonstrates the important principle that children with chronic liver disease have evidence of both chronic malnutrition, as evidenced by stunted growth (decreased height z-scores), as well as acute malnutrition, characterized by depressed adipose reserves and lean body mass.

Improving nutritional status in children with chronic liver disease is challenging (Table 59-2).[17,18] Anorexia, increased abdominal girth, and intervening complications often severely limit the child's voluntary enteral intake. As well, the sodium and fluid restrictions required to manage ascites may sabotage efforts to increase caloric intake. Specialized formulas high in medium-chain triglycerides, which are not dependent on bile for absorption, are useful adjuvants. Caloric density may be further increased by the addition of medium-chain triglyceride and glucose.

However, these measures are often insufficient, necessitating supplemental nasogastic or jejunal feeds[19] or, failing this, parenteral nutritional support. Nocturnal drip feedings appear to be the best tolerated and can allow high caloric intakes without the rise in serum ammonia that might be anticipated with the increased protein intake.[8,20]

TABLE 59-2 ESCALATING LEVELS OF NUTRITIONAL SUPPORT

Change to specialized formula
Low Na
Enriched MCT content
Supplement vitamins A, D, K, and E
↑ Caloric density of voluntary enteral formula intake
24.27 cal/oz
Addition of MCT oil or polycose
Supplement voluntary enteral intake
Continuous nocturnal NG or NJ feeds
Parenteral nutritional support
If fails to grow on maximum enteral feed or unable to tolerate ↑ enteral feeds
Intralipid supplementation only
Intralipid + glucose/amino acid solutions + parenteral vitamins

MCT = medium-chain triglyceride; NG = nasogastric; NJ = nasojejunal.

The usefulness of supplementing enteral feeds with BCAA remains somewhat controversial. In one randomized study, infants receiving BCAA supplementation showed an increase in total-body potassium and improved anthropometric measurements compared with control infants fed an isocaloric formula.[15]

Supplemental enteral feeds fail in many infants because of the inability to tolerate the volumes required. Emesis and increased stool output often negate the hoped for benefits, and parenteral nutrition is the only remaining option. However, parenteral nutrition should not be viewed as a last resort but rather instituted at the first signs of failure of enteral support. Calories provided can be increased easily and weight-for-height z-scores improved[21] by using concentrated glucose solutions supplemented with intravenous lipids.[22] In addition, free water and sodium can be carefully controlled and trace element and vitamin deficiencies more effectively treated.[17,23] Although central venous catheter sepsis is always a concern, careful training of caregivers can greatly decrease this risk.[24]

Fat-Soluble Vitamin Supplementation (Vitamins A, D, E, and K)

Supplementation of the fat-soluble vitamins A, D, E, and K is especially important in children with cholestatic liver disease.[25] The decrease in intraluminal bile acids leading to malabsorption of fat, and therefore the fat-soluble vitamins, is the mechanism of these deficiencies.[26] Vitamin K deficiency, manifested by coagulopathy, is treated with oral vitamin K_1 (Mephyton, Merck & Co, Inc, West Point, PA) at a dose of 5 to 10 mg/d. Vitamin K_1 is virtually nontoxic, compared with vitamin K_3, which, although water soluble, is associated with hemolysis in large doses. The vitamin K–dependent coagulation factors are II, VII, IX, and X. Vitamin K deficiency decreases factor VII levels first so that monitoring prothrombin time is the most useful measure to assess the response to vitamin K therapy. However, as end-stage liver disease becomes more severe, decreased production of all of the coagulation factors produced in the liver occurs, even when vitamin K supplementation is adequate, with consequent prolongation of both prothrombin time and partial thromboplastin time. Occasionally, severely cholestatic children will be unable to adequately absorb oral vitamin K supplements, but the prothrombin time often normalizes after intramuscular vitamin K.

Vitamin E deficiency is a particular concern in children because of vitamin E's role in central nervous system development. Infants who develop cholestasis in the first weeks of life will have low vitamin E levels by about 4 months of age.[27] The first signs of vitamin E deficiency are a symmetric decrease in peripheral stretch reflexes. Left untreated, vitamin E deficiency will progress to cerebellar ataxia, posterior column dysfunction, and peripheral neuropathy.[28] Early recognition is therefore essential but is made more difficult by the unreliability of monitoring only serum vitamin E levels. Normal serum vitamin E levels range between 5 and 15 mg/dL. However, the most accurate evaluation of vitamin E status is the ratio of serum vitamin E to total serum lipids. In children < 12 years of age, the vitamin E–to–total serum lipid (sum of fasting cholesterol, triglycerides, and phospholipids) ratio should be > 0.6 mg/g.[29] No fully water-soluble vitamin E supplement is currently available, making effective vitamin E supplementation often difficult. The free form of vitamin E, available as an over-the-counter preparation, is most often used, but doses as high as 400 to 800 IU/d may be needed. The response to therapy is best evaluated by sequential neurologic evaluations and monitoring of serum vitamin E–to–total lipid ratios.

In those children who do not respond to supplementation of vitamin E by traditional methods, oral administration of a water-soluble form of vitamin E–α-tocopheryl polyethylene glycol–1,000 succinate (α-TPGS) has been found to correct biochemical vitamin E deficiency in doses of 15 to 25 IU/kg/d. In truly refractory cases, an admixture of all fat-soluble vitamins with TPGS may be more beneficial than administration of the supplement alone.

The familiar consequences of vitamin D deficiency—rickets and osteoporosis—can be avoided by early vitamin D supplementation. Although the liver is the site of 25-hydroxylation of vitamin D—a key step in the initiation of activation of vitamin D—malabsorption is the most important cause of vitamin D deficiency in cholestatic children.[30] 25-Hydroxyvitamin D is the major circulating form of vitamin D and, in normal children, has a serum concentration of between 25 and 30 ng/mL.[31] Orally administered 25-hydroxyvitamin D (Caderol, Orggnon Inc, West Orange, NJ) is superior to vitamin D_2 (Drisdol, Sanofi Pharmaceuticals, New York, NY). A dose of 25 to 50 µg/d or 5 to 7 µg/kg/d is adequate. Serum 25-hydroxy levels should be measured and maintained within the normal range. The 1,25-hydroxy form of vitamin D (Rocaltrol, Roche, Nutley, NJ) may be used in a dose of 0.1 to 0.2 µg/kg/d but is not superior to the 25-hydroxy form because kidney conversion of 25-hydroxy to 1,25-hydroxyvitamin D remains intact.

Vitamin A deficiency, characterized by conjunctival and corneal dryness (xerosis) and night blindness, occurs when serum levels fall below 100 to 200 mg/L. Vitamin A can be supplemented with a water-miscible form, such as Aquasol A, at a dose of 5,000 to 15,000 IU/d. Vitamin A

serum concentrations should be monitored both before and during therapy to avoid vitamin A toxicity.

PORTAL HYPERTENSION

Variceal bleeding as a consequence of portal hypertension is one of the most dramatic and life-threatening complications seen in pediatric liver disease. Aggressive management begins with cardiovascular resuscitation and requires knowledge of the full range of medical, pharmacologic, and surgical therapies available (Figure 59-2).

The pathophysiology of portal hypertension is described in detail in Chapter 5.2, "Fibrogenesis and Cirrhosis." In brief, the level of portal vein obstruction can be presinusoidal, sinusodial, or postsinusoidal.[32] Presinusoidal portal hypertension can be extrahepatic or intrahepatic. Extrahepatic portal vein obstruction used to be the most frequently recognized cause of portal hypertension in children and was most often secondary to instrumentation of the umbilical vein in neonates, omphalitis, congenital malformations, blunt trauma, or intra-abdominal infections. Intrahepatic presinusoidal portal hypertension is associated with congenital hepatic fibrosis and schistosomiasis and is relatively less common than extrahepatic or other intrahepatic postsinusoidal causes of portal hypertension in children. Cirrhosis, now the most common cause of portal hypertension in children, results in complex derangements of portal flow within the liver at all three levels but particularly within the sinusoids (reflected by an increased wedge hepatic pressure) and in the postsinusoidal space. Budd-Chiari syndrome, webs in the suprahepatic vena cava, veno-occlusive disease, and cardiac disease are some of the causes of postsinusoidal portal hypertension. The critical difference affecting management of the three levels of portal vein obstruction is that liver functional reserve is almost always normal with extrahepatic and presinusoidal obstruction but may be profoundly impaired in children with sinusoidal and postsinusoidal obstruction secondary to cirrhosis. In such children, coexistent ascites and coagulopathy make the management of variceal bleeding even more challenging.

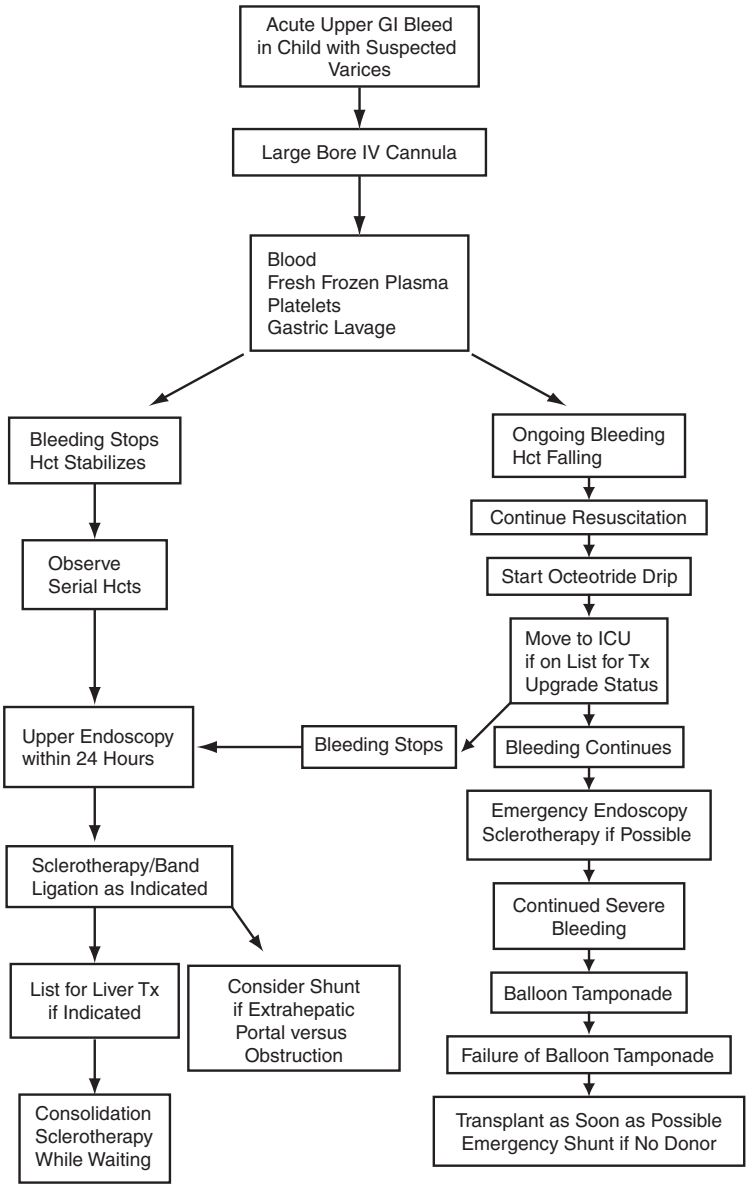

FIGURE 59-2 A management algorithm for the child with suspected bleeding. GI = gastrointestinal; Hcts = hematocrits; ICU = intensive care unit; IV = intravenous; Tx = transplant.

Definition, Diagnosis, and Prediction of Variceal Bleeding

Portal hypertension is defined as portal vein pressure > 5 mm Hg or a portal vein to hepatic vein gradient of > 10 mm Hg.[33]

Portal hypertension can frequently be diagnosed by physical examination. The spleen is usually palpable and sometimes massively enlarged, although it must be remembered that in biliary atresia, one of the most common causes of portal hypertension in children, there may be associated asplenia, polysplenia, or situs inversus, making this physical sign not always reliable. Ascites is generally only present when portal hypertension is at the sinusoidal level. The four main portal to systemic vein collateral systems that become prominent in portal hypertension can all be readily examined. Increased pressure in the paraumbilical venous network is manifested by engorged superficial abdominal wall veins radiating from the umbilicus—the caput medusa. With overfilling of the perirectal collateral venous system, hemorrhoids appear. When abdominal organs become adherent to the abdominal wall, the collaterals formed result in visible varices seen within the stomas[34] sometimes used in biliary drainage procedures or seen in old laparotomy scars.

Esophageal varices are best examined by endoscopy. Newer, less invasive radiologic techniques are being increasingly used. In a recent study, magnetic resonance angiography had a sensitivity of 100% and a specificity of 93% compared with endoscopy for detecting collateral vessels in children with biliary atresia after portoenterostomy.[35] In a study of 50 children, intravenous computed tomography (CT) using a helical CT scanner identified changes in the esophageal and gastric vasculature earlier than endoscopy.[36]

The size of the liver is generally not especially helpful. In older children with cirrhosis, the liver is frequently small and shrunken, whereas in younger children with biliary atresia, the liver may be moderately enlarged, hard, and with an irregular edge. In children with Budd-Chiari syndrome or congenital hepatic fibrosis, the liver may be massively enlarged and firm.

Ultrasonography, particularly when enhanced by duplex sonography, is very useful in the evaluation of portal hypertension.[37] In extrahepatic causes of portal vein obstruction, the characteristic absence of the portal vein signal is replaced by the findings of multiple dilated collateral veins (cavernous transformation). The echogenicity of the liver itself is normal. Not only can the presence or absence of the portal vein be determined, but the direction of flow can also be assessed. Hepatofugal flow (ie, away from the liver) is associated with severe portal hypertension. The ultrasonographer can also provide details of increased flow in the portal collateral circulation and may be able to demonstrate findings such as enlarged coronary veins or paraesophageal veins. Evaluation of the splenic vein is also important, particularly to look for splenic aneurysms, which are found in 8 to 14.7% of patients with portal hypertension.[38,39] Once portal hypertension is suspected on clinical or ultrasound findings, elective upper endoscopy can give useful information. The size of the varices and the presence or absence of portal hypertensive gastropathy help determine the medical management.

As variceal bleeding is the most serious complication of portal hypertension, with a 30 to 50% mortality and a high risk of rebleeding,[40] several studies have addressed the issue of whether the risk of bleeding can be predicted (Table 59-3). Although most of this information is obtained from adult patients, several observations also relevant to children can be made. First, variceal bleeding rarely occurs if the portal vein to hepatic vein gradient is < 12 mm Hg.[41,42] However, in patients with a portal vein to hepatic vein gradient > 12 mm Hg, only about one-third will bleed. Second, the risk of bleeding is related to the cause of portal vein obstruction. In the Bicêtre experience of 389 children with portal hypertension, 80% of children with extrahepatic portal vein obstruction bled compared with 46% of children with congenital fibrosis and 32% of children with cirrhosis. Moreover, 41% of children with portal vein obstruction bled before the age of 3 years. Children with Budd-Chiari syndrome had a very low incidence of variceal bleeding (Figure 59-3).[43] Third, the endoscopic appearance of the varices provides some estimate of the risk of bleeding.[44,45] Large, tense varices that do not flatten with insufflation of air are more likely to bleed than small, decompressed varices. Although large varices bleed more easily, the size of the varices is not related to the measured portal hypertension.[46] Varices with congestion of the overlying or surrounding mucosa, particularly those with characteristic red spots and red wale markings ("whip-like" discolorations from dilated venules), and gastric varices are also associated with increased risk of bleeding.[43]

In children, the risk of bleeding may change over time. In those with extrahepatic portal vein obstruction, the development of a decompressing collateral circulation may actually decrease the risk as children get older. However, in the Bicêtre study, almost half of the children studied serially showed a progression in the severity of varices over time, and more than one-third of these had a bleeding episode.[43] Finally, the severity of underlying cirrhosis increases not only the risk of bleeding[45] but also the mortality after variceal hemorrhage. In a study of 134 children with biliary atresia, children after a first esophageal variceal bleed, the relative risk of death or transplant was 12.0 if the total bilirubin was more than 10 mg/dL compared with 7.2 if the bilirubin was 4 to 10 mg/dL and 0.6 if the bilirubin was less than 4 mg/dL compared with a same-aged child without a variceal bleed.[47]

Management of Acute Variceal Bleeding

Hematemesis or melena as a result of variceal bleeding is often massive, and the child may present to an emergency

TABLE 59-3 FACTORS PREDICTING VARICEAL BLEEDING

Portal vein–hepatic vein gradient > 12 mm Hg
Large, tense varices
Red wale marks, red spots on varices
Severity of underlying liver disease

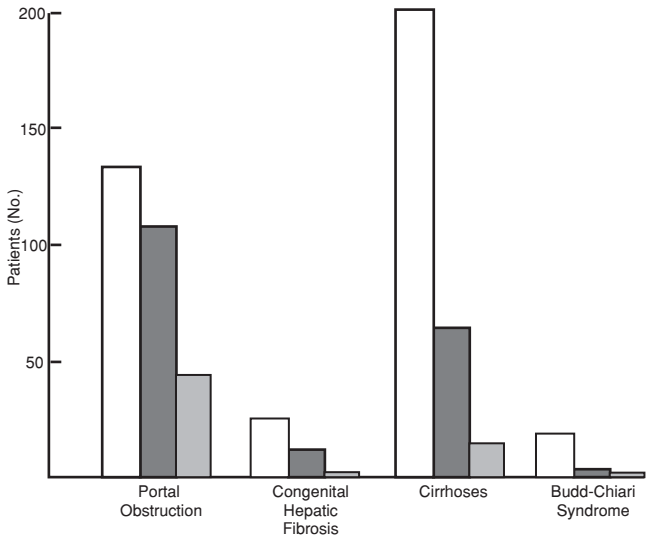

FIGURE 59-3 Relationship between the etiology of portal hypertension and risk of gastrointestinal bleeding in 380 children investigated for portal hypertension. For each etiologic group, the total number of children studied; number of children who experienced one episode of bleeding; number of children who bled before age 3 years. Reproduced with permission from Bernard O et al.[43]

room in cardiovascular shock. Immediate placement of a large-bore intravenous cannula or, if necessary, intraosseous needle in children < 2 to 3 years of age is essential so that large volumes of fluid and blood can be rapidly delivered. Children with known poor liver function should be assumed to be coagulopathic, and clotting factor supplementation should be instituted immediately. Many children will also have thrombocytopenia secondary to hypersplenism, and platelet transfusions are indicated. However, gastrointestinal bleeding in children with portal hypertension may not always be so dramatic. Small variceal bleeds or bleeding from portal hypertensive gastropathy can be much more subtle, with only small to moderate amounts of blood loss, a slow decline in hematocrit, and no overt cardiovascular decompensation. However, the propensity for these children to develop more severe bleeding must not be underestimated, and all should be admitted and carefully observed to better optimize therapy (see Figure 59-2).

Gastric lavage with saline via a nasogastric tube may be helpful in determining the extent and duration of bleeding. Perhaps the most important use of gastric lavage is to help clear the stomach of blood to allow better visualization of the mucosa at the time of endoscopy. Contraindications to gastric lavage include children in whom the procedure may increase bleeding (known large varices or intractable coagulapathy) or induce esophageal perforation (recent sclerotherapy with possible esophageal ulcerations). The choice of lavage solution is probably not particularly important. Room temperature saline is the most physiologic; iced saline lavage has not been shown to be more efficacious. Once the patient is fully resuscitated and stabilized, upper endoscopy should be performed, primarily to confirm the site and cause of bleeding and to determine if treatment is indicated. Other etiologies of upper gastrointestinal bleeding will alter management, such as portal hypertensive gastropathy, gastric or duodenal ulcers, or Mallory-Weiss tears. If variceal bleeding is confirmed, therapeutic sclerotherapy or variceal ligation may be attempted, although this is frequently technically very difficult if bleeding is still active.

In the child who continues to have uncontrollable bleeding, balloon tamponade may be the only method that can stabilize the patient until a more definitive procedure, such as liver transplant or a portosystemic shunt, can be undertaken. The Linton tube is used for small children or if bleeding gastric varices are present, and the Sengstaken-Blakemore tube is used for larger children. The length of the esophageal balloon limits the use of the Sengstaken-Blakemore tube to children weighing over 40 kg. Both are highly effective and can stop esophageal and or gastric variceal bleeding in up to 90% of patients.[48] However, experience is required to minimize the considerable risks associated with balloon tamponade, such as aspiration, esophageal rupture and ulcers, and airway obstruction. Correct positioning of the tube must be confirmed radiographically to avoid inflating the gastric balloon in the esophagus. The volume of air inflated into the gastric and esophageal balloons varies with the child's size and must be enough to create adequate pressure to compress the bleeding sites but without causing ischemic injury to the esophageal or gastric mucosa. Pressure in the esophageal balloon should be 15 to 40 mm Hg. The gastric balloon should be inflated to 30 mL and can be incrementally increased to about 200 to 300 mL depending on the size of the child. It is recommended that the appearance of the gastric balloon in relation to the size of the stomach is checked radiographically after each incremental change in volume to avoid the risk of overinflation.

Children should be intubated and sedated to minimize the risk of aspiration. The balloons can be safely left inflated only for 12 to 24 hours. As such, balloon tamponade can be viewed only as a temporizing measure.

Prevention of Rebleeding and Prophylaxis of First Variceal Bleeding

Several modalities, alone or in combination, have been investigated to control variceal bleeding. These include sclerotherapy, variceal ligation, vasoactive drugs, and portosystemic shunts. Most large controlled trials have been performed in adults, and the results have generated considerable controversy over the effectiveness of each modality.[49–53] Common principles, also relevant to pediatrics, are discussed below.

Sclerotherapy and Variceal Ligation. Obliteration of esophageal varices may be achieved by endoscopic injection of sclerosing substances or by ligation of varices, commonly using elastic bands. Prevention of rebleeding, which occurs in up to 50% of patients and incurs a mortality of 20 to 70% if untreated, is the goal of aggressive attempts to obliterate varices.[53,54]

Sclerotherapy is a well-established modality to control variceal bleeding in children and has decreased the need

for shunt surgery.[55,56] After a first variceal bleed, elective sclerotherapy, usually requiring repetition, can successfully eradicate esophageal varices in up to 90% of patients with a low incidence of rebleeding and recurrent varices. Because rebleeding often occurs within 2 to 6 weeks of the initial bleeding episode, the first sclerotherapy should be scheduled early. The short-term benefits of reducing rebleeding episodes are not to be underestimated and are particularly important while the child awaits liver transplant. Sclerotherapy or endoscopic variceal ligation should now be considered the first line of treatment for variceal bleeding. In a study comparing outcomes in children treated with a surgical shunt versus sclerotherapy, the low rate of rebleeding after sclerotherapy led the authors to conclude that the more invasive shunt surgery could usually be avoided.[57] Although some controlled trials in adults have shown that sclerotherapy reduces long-term mortality,[58] it must be remembered that sclerotherapy does nothing to decrease portal hypertension itself but only redirects blood away from the esophageal collateral circulation to other collaterals. Until the child undergoes a definitive procedure that actually decreases or eliminates portal hypertension (ie, shunt operation or liver transplant), the patient remains at risk of life-threatening variceal bleeding, often from newly formed gastric varices. Portal hypertensive gastropathy with increased bleeding risk may also be exacerbated by esophageal variceal obliteration.[59]

No consensus as to the value of prophylactic sclerotherapy has been reached. A randomized controlled trial of 100 children with esophageal varices showed that prophylactic sclerotherapy compared to observation resulted in a significant reduction in variceal bleeding in the treatment group but more congestive hypertensive gastropathy. Importantly, there was no difference in survival between the two groups.[60] In another pediatric series, 42% of children bled after prophylactic sclerotherapy.[57] In some adult studies, use of a scoring system that predicts a high risk of variceal hemorrhage has been used to justify prophylactic sclerotherapy. There is conflicting evidence as to whether the incidence of bleeding is reduced or the survival improved.[45,61]

Sclerotherapy still requires considerable operator skill, particularly in small children. Although techniques and choice of sclerosant vary among endoscopists, convincing evidence that one is better than another is lacking. Paravariceal injection of sclerosant is favored by some and intravariceal injection by others. Sclerosants used include ethanol, morrhuate, ethanolamine, and tetradecyl. We use ethanolamine 5% or diluted 1:1 with ethanol. To decrease complications, it is important to avoid a large volume of sclerosant on any single injection and to limit the number of injections, even if of relatively small volume, performed at any one time. We recommend 1 mL or less of sclerosant per site and no more than 5 to 6 mL per session in children < 10 years of age. Both practices decrease the risk of esophageal ulceration and the eventual development of esophageal strictures, perforation, and systemic absorption of sclerosant.

In recent years, the newer technique of endoscopic ligation of esophageal varices with elastic bands has supplanted sclerotherapy for variceal obliteration in adults and is now being used in children (Figure 59-4). Variceal ligation may be a more effective modality to prevent a first variceal bleed compared with sclerotherapy. In a randomized trial of 49 children comparing endoscopic ligation with sclerotherapy for bleeding esophageal varices secondary to extrahepatic portal venous obstruction, the rebleeding rate was significantly higher in the sclerotherapy group (25% versus 4%).[62] The advantages are increased efficacy with a reduced incidence of complications, such as esophageal ulceration, perforation, stricture, systemic sclerosant, and gastroesophageal reflux.[63] The disadvantage, now mostly eliminated in adults, is the need for a large-caliber endoscope that can accommodate, within its lumen, an outer cylinder that snares the varix and an inner cylinder that deploys the bands. Because many early models could deploy only one band at a time, an overtube was often used so that multiple intubations of the esophagus were avoided. Improved endoscopes have eliminated these problems for adults, and smaller-caliber endoscopes suitable for use in pediatric patients have been developed. As well, recent technical advances in pediatric endoscopes have overcome the previous limitation of only one band being placed at a time. Successful esophageal ligation in children is increasingly being described.[64–68] A high rate of eradication is reported (72–100%) and a low risk of rebleeding (< 25%). Note that in these studies, the mean age is between 7 and 8 years. Price and colleagues performed endoscopic variceal ligation in 22 children, ranging in age from 8 months to 19 years.[69] Of 18 children who did not undergo early liver transplant, 12 had complete eradication of the varices over an average of four sessions. Rebleeding between sessions occurred but not after obliteration of varices. None of the children developed esophageal stenosis or gastroesophageal reflux. However, perforation of the cervical esophagus occurred in one

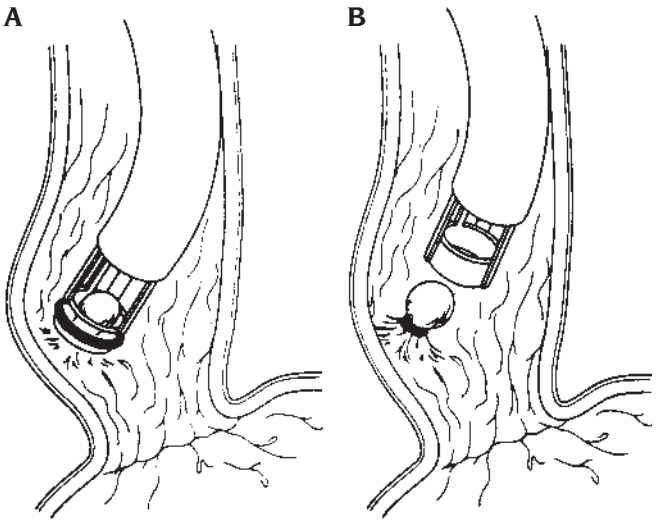

FIGURE 59-4 Endoscopic ligation of esophageal varices. The esophageal varix is drawn up into the ligation device with suction (*A*) and the base of the varixis ligated with an elastic band (*B*). From Greenfield LJ, Mulholland MW, Oldham KT, et al. Surgery, scientific principles and practice. Philadelphia: Lippincott-Raven; 1997.

child, underscoring the size limitations of the instruments needed in small children. These authors stress that the diameter of the child's esophagus should be 10 mm or more to allow for the safe passage of a 32-French instrument. They advocate limiting the technique to children over 1 year of age until endoscopic instruments can be further miniaturized. However, in a recent study using a small-diameter endoscope, 28 children, some as young as 3 months, were treated, with obliteration of varices in 26 and rebleeding in only 2.[70]

Surgical Management: Shunts, Transjugular Intrahepatic Portosystemic Shunts, and Nonshunt Procedures.

Shunts. The success of sclerotherapy and variceal ligation in controlling variceal bleeding and the availability of liver transplant have reduced the need to perform portosystemic shunts to manage uncontrollable bleeding.[57] However, portosystemic shunts are still an important modality to treat variceal bleeding in selected cases: children with extrahepatic portal vein obstruction; children with congenital hepatic fibrosis; children with well-compensated cirrhosis, in which liver transplant may not be required for several years; children with variceal bleeding, in whom liver transplant is contraindicated; and, rarely, children awaiting liver transplant to control life-threatening variceal hemorrhage. Prophylactic shunt surgery is not advocated because previous studies showed a decreased survival and an increased risk of encephalopathy compared with no treatment.[53]

Shunt procedures, including transjugular intrahepatic portosystemic shunts (TIPS), are the only modalities that effectively reduce portal pressure and thus definitively treat the underlying cause of variceal bleeding (Figure 59-5). The major disadvantages of portosystemic shunts are hepatic decompensation caused by reduced portal blood flow and precipitation of encephalopathy. Both complications occur much more commonly with nonselective (total) shunts, that is, portocaval, mesocaval, and central splenorenal shunts (see Figure 59-5). The development of selective shunts, notably the distal splenorenal shunt first described by Warren and colleagues in 1967,[71] significantly reduces both complications as forward flow of portal venous blood to the liver is preserved. The distal splenorenal shunt and its modifications are now the preferred shunt, whenever technically possible, particularly in elective situations.[72] In a pediatric series, there was no rebleeding and no encephalopathy in the 81% of children in whom the shunt was successful.[73] In the emergency setting, surgical options are more limited, and portocaval or mesocaval shunts may be the only feasible choice. Bleeding is effectively controlled, but the mortality rate may be as high as 20 to 50%.[74,75] This is most likely related to the severity of the underlying liver disease in patients undergoing these procedures. Both portocaval and mesocaval shunts are equally effective in stopping bleeding. The side-to-side portocaval shunt and the mesocaval and portocaval H-graft shunts have the theoretical advantage of preserving at least some forward portal flow, although all have a high incidence of encephalopathy and hepatic decompensation, particularly in patients with underlying cirrhosis.

The applicability of shunt procedures to pediatric patients is constrained by the small caliber of the veins to be shunted and the subsequent risk of shunt thrombosis. In two pediatric studies,[76,77] the median ages were 9 years and 8 years, respectively, although in the latter series, children as young as 2 years were shunted. These two studies reported patency rates of 9% and 80%, respectively. In children with underlying cirrhosis, complications included ascites, hepatorenal syndrome, and encephalopathy (occurring in one patient with a nonselective shunt).

Children with extrahepatic portal vein obstruction are particularly good candidates for shunts.[78] In one experience, shunt patency was 93% in a group of 92 children with a mean age of 6.5 years.[43] Innovative shunt procedures[79] designed to restore portal blood flow include bypassing the cavernoma by an autograft (using a portion of the patient's jugular vein) placed between the superior mesenteric vein and the left portal vein (the Rex shunt). In two reports, portal decompression was achieved, with concomitant decreases in spleen size, increased white cell and platelet counts, control of bleeding, and restoration of physiologic hepatopetal flow. All shunts were patent at a median of 6 months after the procedure.[80,81]

An important consideration in placing a surgical shunt is to be certain that the shunt procedure itself does not compromise a potential liver transplant procedure required in the future.[82] Mazzaferro and colleagues showed that properly performed portosystemic shunts do not preclude successful liver transplant or have an impact

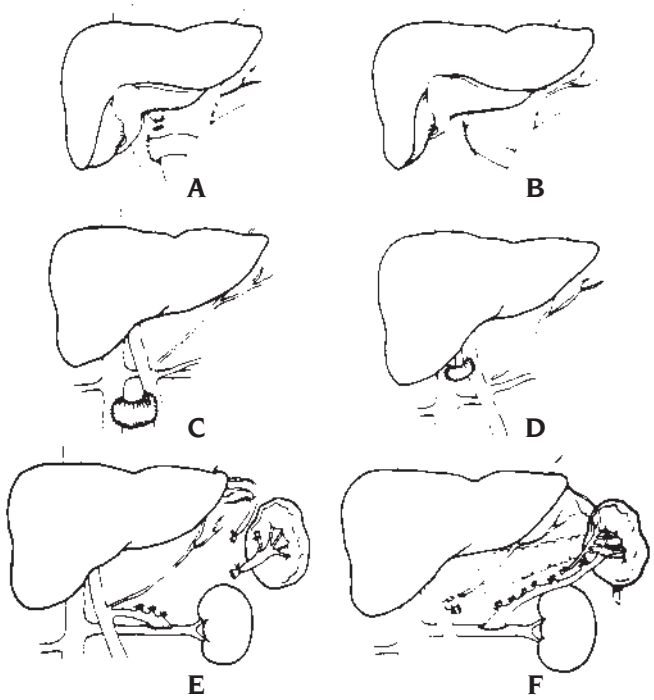

FIGURE 59-5 Portosystemic shunts used for emergency treatment of variceal bleeding: end-to-side portocaval shunt (*A*), side-to-side portocaval shunt (*B*), mesocaval interpositional H-graft (*C*), portocaval interpositional H-graft (*D*), central splenorenal shunt (*E*), and selective distal splenorenal shunt (Warren Shunt; *F*). Reproduced with permission from Terblanche J et al.[49]

on post-transplant survival.[83] A potential advantage of the mesocaval shunt, as opposed to the portocaval shunt, is that the dissection is distant from the porta hepatis and, thus, less likely to create complications for the transplant surgeon in the future.

Transjugular Intrahepatic Portosystemic Shunts. The creation of a shunt between the intrahepatic portions of the portal vein and hepatic vein (Figure 59-6) by a minimally invasive technique avoids the risks of the major surgical procedure required for a standard shunt operation. This is a particular advantage in patients who are already severely compromised by their underlying liver disease. In brief, the procedure is performed by cannulating the right jugular vein to access the right hepatic vein. The needle is then passed through the intrahepatic portion of the hepatic vein and into the liver parenchyma to enter a branch of the portal vein. An expandable metallic stent is deployed across the hepatic parenchyma to create a shunt between the hepatic and portal vein branches. The size of the stent is increased until the gradient between the portal vein and the hepatic vein is ideally < 18 mm Hg.[84] To ensure success, the procedure requires technical expertise and a very careful appraisal of possible variations in vascular anatomy.[85] In adults, there is a 10% complication rate from the procedure itself, most often intra-abdominal bleeding.[86] The major complications are shunt occlusion or stenosis (25–75%), encephalopathy (5–35%),[87] progressive liver failure, and portal vein thrombosis. The success of the TIPS procedure in controlling bleeding (and also ascites)[88] has been widely reported in adults.[89,90] In two randomized trials, one comparing TIPS versus drug therapy[91] and another TIPS versus variceal ligation plus propranol,[92] both found that TIPS-treated patients had more complications. Although in one study, the incidence of rebleeding was less, neither study showed any difference in survival between the groups.[91] It appears to be most useful as a bridge to liver transplant and for those failing sclerotherapy or variceal ligation. A TIPS procedure is preferable to an operative shunt in the transplant candidate because it is associated with less operative complications at the time of transplant. However, migration of the stent into the suprahepatic vena cava or right atrium has been associated with major technical complications during the transplant procedure.[93]

In children, the TIPS procedure is made more complicated by the small size of the liver and the diminutive caliber of the portal and hepatic veins.[84] As well, there is more likelihood of anatomic variance, particularly of the portal vein, in some pediatric liver diseases, such as biliary atresia. Despite these technical limitations, there are now several reports describing the successful use of TIPS children,[94,95] even as an emergency procedure,[96] and in an infant.[97] In experienced hands, the overall success rate of 75 to 90% is similar to reports in adults. Hackworth and colleagues used TIPS to control variceal bleeding in 12 children (age 2 to 16 years; median age 9 years) awaiting liver transplant.[98] Ten of the 12 shunts were patent at the time of transplant at a median of 53 days after placement. None of the children rebled, and one developed encephalopathy. Heymen and colleagues described nine children (5 to 15 years in age) in whom TIPS was attempted.[99] In two children, vascular anomalies precluded successful TIPS placement. Although shunt occlusion occurred in four children, TIPS revision restored patency in three. All but one patient had successful control of bleeding. These two studies emphasize the important principles of the use of TIPS in children: size (and therefore age) is still a limiting factor, anatomic variations can preclude success, and the small caliber of the stent may increase the risk of stent occlusion.

Once in place, the patency of the TIPS stent should be monitored by ultrasonography every 3 to 4 months. In adult series, shunt stenosis or obstruction occurs in 25 to

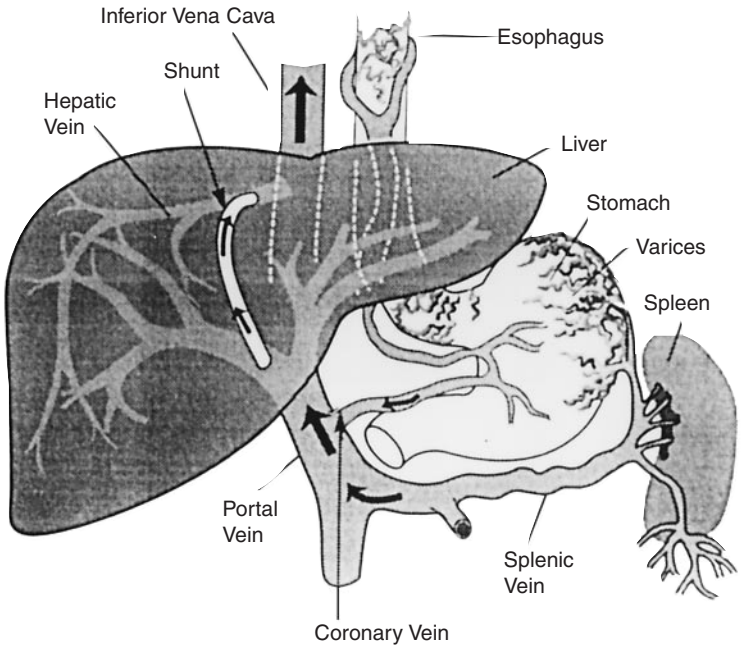

FIGURE 59-6 Anatomic location of the transjugular intrahepatic portosystemic shunt. Reproduced with permission from Vargas HE and colleagues.[33]

75% of patients.[89] Doppler ultrasonography has a reported sensitivity of 92% and a specificity of 72% in detecting shunt malfunction.[100]

At present, TIPS appears to be most useful in children who have failed sclerotherapy while waiting for transplant.[101] Shunt patency decreases markedly with time (48% patency at 1 year, 26% at 2 years in one study)[102]; therefore, the procedure should generally be reserved for children with refractory bleeding who will be transplanted within 6 to 12 months. Other more controversial indications include the use of TIPS to treat severe hypersplenism; however, a consistent improvement in white cell and platelet cell counts has not been demonstrated.[99]

In adult patients, TIPS placement has also been suggested for medically refractory ascites, Budd-Chiari syndrome, and veno-occlusive disease. These indications have not yet been explored adequately in pediatric patients. In addition, there is no proven role for placement of TIPS to prevent bleeding from portal hypertensive gastropathy.

The TIPS procedure is contraindicated whenever there is infection present in the liver, that is, hepatic abscess or cholangitis. Polycystic liver disease, hepatic neoplasm, right-sided heart failure, and severe hepatic failure with uncorrectable coagulopathy are also contraindications.[84]

Pharmacologic Therapy. The aim of drug therapy in the control of variceal bleeding is to reduce portal pressure either by decreasing flow into the splanchnic bed with vasoconstrictors or by decreasing the vascular resistance of the intrahepatic and portal circulation with vasodilators.[103]

Vasopressin, a potent vasoconstrictor, was the prototype drug used, and although it has been shown to increase the chance of stopping acute bleeding, no survival benefit has yet been demonstrated. The serious systemic vasoconstrictive side effects of vasopressin, including myocardial infraction, mesenteric ischemia, cerebrovascular accidents, and limb ischemia, are its major disadvantages.[104] To counteract these effects, some protocols combined vasopressin with nitroglycerin, a potent vasodilator, and the systemic vasoconstrictive properties of vasopressin were lessened.[33]

Somatostatin has proven to be a much safer alternative to vasopressin and can effectively decrease portal pressure by decreasing splanchnic blood flow and reducing the portal vein to hepatic vein pressure gradient with few systemic side effects.[105,106] However, its usefulness is limited by a very short half-life. More recently, a synthetic analog of somatostatin, octreotide, has been shown to have similar efficacy to somatostatin and vasopressin, with very few side effects and an acceptable half-life.[107–109] This agent is currently the preferred agent to treat children with acute variceal bleeding.[110] The advantage of beginning pharmacologic therapy early in the management of an acute variceal bleed is that the high technical expertise of sclerotherapy or variceal ligation is not required, and bleeding may be controlled enough to allow elective sclerotherapy. In one randomized study, octreotide alone was as effective as emergent sclerotherapy in stopping bleeding.[109] Octreotide dosing recommendations are to begin with a bolus of 1 μg/kg followed by continuous infusion of 1 μg/kg/h, with titration of both the bolus and constant infusion up to 5 μg/kg/h. This regimen was found to be effective in stopping bleeding in 86% of patients at a mean time of 40 hours.[110]

Nonselective β-blockers have long been used for the prevention of first variceal bleeds and rebleeding. Several randomized trials in adults have confirmed that both propranolol and nadolol have a significant benefit in both the prophylaxis of variceal bleeding and prevention of rebleeding.[53] In some trials, prevention of a first variceal bleed also increased survival.[111,112] Nadolol's advantage over propranolol is that it is not metabolized by the liver and can be given once a day.[113] Nadolol was combined with isosorbide mononitrate (nitrate vasodilators also decrease portal pressure) and compared in a randomized trial with sclerotherapy to prevent variceal rebleeding. Although the probability of rebleeding was significantly decreased in the nadolol and isosorbide group, there was no survival benefit.[114] Extrapolating from the adult doses used in the study, some pediatric patients have been treated with a starting dose of 1 mg/kg/d of nadolol, with titration of the dose until the 25% reduction of heart rate is achieved. Then isosorbide nitrate is added to reach a dose over the course of 1 week of 0.5 mg/kg twice a day.

Few studies are published in children regarding the use of β-blockers in preventing first variceal bleeds. In a nonrandomized study, 14 of 21 children had no episode of rebleeding when treated with propranolol. Success correlated with a reduction in heart rate of more than 25% of baseline and a dose of at least 1 mg/kg/d of propranolol.[115] In a study of 60 children with cirrhosis, propranolol (1–2 mg/kg/d) was most successful in preventing a first bleed (15.6% of children bled), whereas 53.3% of children bled if propranol was initiated after a first bleed.[116] However, the use of nonselective β-blockers can be limited by their side effects. This is particularly important in children with asthma or cystic fibrosis, in whom bronchospasm must be avoided.

More recently, several randomized trials of endoscopic treatment alone versus endoscopic treatment plus drug therapy for acute variceal bleeding, or to prevent rebleeding, have been published. Combined therapy was more effective for controlling bleeding[117] and for the prevention of rebleeding,[118] but there was no difference in survival between treatment groups. Similar studies have not yet been performed in children.

Transection and Devascularization Procedures. With the success of sclerotherapy, improved pharmacologic agents, and availability of liver transplant, esophageal transection and devascularization procedures are very infrequently necessary to control acute variceal bleeding. However, such major surgical procedures still have a place in treating exsanguinating hemorrhage uncontrollable by any other means. Three techniques are currently practiced[49]: staple gun transection of the esophagus, the extensive Sugiura procedure (devascularization of the abdominothoracic lower esophagus and upper gastric areas, followed by splenectomy, pyloromyotomy, vagotomy, and esophageal transection), and a more limited procedure combining esophagogastric devascularization with staple gun transec-

tion. None of these procedures have been well studied in children. However, the results in adults, particularly of the more extensive procedures, have shown a high mortality.[49] Unless contraindicated, liver transplant, even in this highly emergent situation, is most likely a better option.

ASCITES

In the child with chronic liver disease, the onset of ascites indicates that the two prerequisite conditions for ascites formation, portal hypertension and hepatic insuffiency, are worsening.[119] About 50% of patients will die within 2 years of developing ascites.[40]

The pathophysiology of ascites is discussed in detail in Chapter 5.2. In brief, intra-abdominal factors that result in a net flow of fluid (and protein) out of the mesenteric capillary bed into the peritoneal cavity are (1) decreased plasma colloid osmotic pressure, (2) increased capillary pressure, (3) increased ascitic colloid osmotic fluid pressure, and (4) decreased ascitic fluid hydrostatic pressure (Figure 59-7).[120,121] The dynamic relationship between these factors in the formation of ascites is complex. For example, hypoalbuminea (ie, decreased plasma colloid osmotic pressure) alone is not sufficient to cause ascites, and in the hepatic causes of ascites, capillary pressure increased by portal hypertension plays a key role, as supported by the observation that ascites may be ameliorated by creating portosystemic shunts.

Ascites in liver disease occurs in the context of sinusoidal and/or postsinusoidal portal hypertension and is, in part, related to obstruction of hepatic lymph flow from the sinusoids into the hepatic vein.[122] When the rate of hepatic lymph formation exceeds its drainage into the hepatic venous system, lymph accumulates in the space of Disse and then escapes into the peritoneal cavity as ascitic fluid.

Apart from the local factors leading to ascites, three theories invoke the role of systemic factors in ascites formation: (1) the underfill theory, in which decreased plasma volume increases the activity of the renin-angiotensin-aldosterone pathway, causing sodium retention[123]; (2) the overfill theory, in which renal sodium retention is the initiating event, leading to an increase in plasma volume[124]; and (3) the peripheral arterial vasodilation theory, in which the primary event is splanchnic arteriolar vasodilation secondary to portal hypertension, which causes sequestration of blood in the splanchnic bed, a decrease in circulating blood volume, and subsequent sodium and water retention.[125]

Understanding the central role of sodium retention in the pathogenesis of all three proposed mechanisms is essential for the successful management of ascites. The ability to excrete free water, independent of sodium retention, is also impaired in cirrhotic patients and may be secondary to increased plasma levels of antidiuretic hormone.[121,126]

Diagnosis

Significant volumes of ascites are easily detected on physical examination. The abdominal flanks bulge with fluid, a fluid level can be percussed, the umbilicus protrudes, and a fluid wave may be detected. In addition, the liver and spleen may become ballotable, and, particularly in young children, inguinal hernias and hydroceles may develop. Common findings on a plain film of the abdomen are diffuse abdominal haziness, separation of bowel loops by fluid, and medial displacement of the bowel.

More subtle ascites is best assessed by ultrasonography, which can detect small volumes of fluid. Confirming ascites becomes important if paracentesis is being considered to diagnose spontaneous bacterial peritonitis. The ultrasound examination is also useful to differentiate free from loculated ascitic fluid.[127]

Paracentesis is usually not indicated in the initial diagnostic evaluation of ascites in the child with known liver disease. The other causes of ascites that might occur in adults with liver disease, such as malignant or tuberculous ascites, are very rare in children. It is, however, important to know the usual composition of ascitic fluid in patients with liver disease without secondary complications. The ascitic fluid is generally clear, straw colored, or bile tinged and has a protein content of < 2.5 g/dL. The cell count is < 250 cells/mm^3 and is mostly composed of lymphocytes. The glucose and lactic dehydrogenase content mirror that of plasma.[120]

Management

Sodium restriction and the promotion of sodium excretion are the cornerstones of ascites management (Table 59-4).[128] As the excretion of fluid passively follows that of sodium, fluid restriction is generally not necessary in the initial management plan. Dietary sodium intake should be limited to 1 to 2 mEq/kg. However, only 10 to 20% of patients, generally those with a relatively normal serum sodium and a urinary sodium of > 15 mEq/24 h, will

respond to sodium restriction alone.[108] Once the urine sodium excretion falls below about 15 mEq/24 h, diuretic therapy is required.

The most logical first choice of diuretic is spironolactone because secondary hyperaldosteronism is almost always present in chronic liver disease.[129] Spironolactone is rapidly and almost completely absorbed from the gastrointestinal tract and is metabolized to a number of active compounds that competitively inhibit the binding of aldosterone to its specific receptor in the distal renal tubule and collecting system.[130]

Spironolactone therapy has proved to be safe and efficacious over many years of use. The dose should be initiated at 2 to 3 mg/kg/d per os in divided doses. At least a 3- to 4-day delay should be expected before a diuretic effect is seen.[131] If no increase in urine output occurs, the dose can be safely doubled.[120] Failure to respond to high-dose spironolactone prompts the use of a more potent second diuretic, most often furosemide. Furosemide induces not only sodium but also potassium loss in the urine so that careful monitoring of serum potassium is required. A balance between the potassium-sparing effects of spironolactone and the potassium loss induced by furosemide may obviate the need for potassium replacement when the two drugs are combined.

Hyponatremia is the electrolyte disturbance most often associated with diuretic therapy, indicating that sodium losses are exceeding water losses. Serum sodium is seldom less than 120 mEq/mL and at this level is not associated with significant complications and rarely needs to be treated. When the sodium falls below 120 mEq/mL, diuretic therapy should be suspended and fluid intake restricted.[120,128]

Monitoring 24-hour urine sodium excretion can be an important guide to therapy, particularly if ascites is failing to respond to interventions. With appropriate sodium restriction and diuretic therapy, urine sodium should certainly exceed 15 mEq/d. It has been estimated that a negative sodium balance of 120 mEq/d results in 1 L of fluid loss.[120] If the child on diuretic therapy, restricted to 1 to 2 mEq/d of sodium, still fails to diurese, water restriction of 50 to 75% of the normal daily requirement may be necessary. In patients with hypoalbuminemia, intravenous albumin infusions, which rapidly increase the intravascular colloid osmotic pressure, can be used to quickly mobilize extravascular fluid into the intravascular space. When combined with a diuretic, a brisk diuresis results. Concentrated 25% albumin can be given at a dose of 1 mg/kg intravenously followed by 0.5 to 1 mg/kg of intravenous furosemide.[120]

The most important and serious complication of aggressive diuretic therapy is hypovolemia, which occurs when water loss outstrips ascitic fluid resorption. Renal blood flow is decreased, creatinine and blood urea nitrogen are increased, and renal failure can be precipitated. Once peripheral edema has been mobilized by diuretic therapy (this occurs early in treatment), care must be taken to monitor weight, fluid balance, electrolytes, blood urea nitrogen, and creatinine. A net water loss of 200 to 300 mL/d is a useful goal,[120] but in very small children, it may be excessive. When ascites requires intensive management, such as outlined above, children should be hospitalized so that electrolyte balance, volume status, and renal function can be assessed on a daily basis. Vigorous diuretic treatment may also precipitate encephalopathy.

In children, refractory ascites is rare. Medical therapy alone is generally sufficient to reduce abdominal distention, allowing improved enteral feedings and diminished respiratory distress. However, in a recent series, if large-volume paracentesis is required, using a paracentesis needle rather than an intravascular catheter improved the efficiency of fluid removal without an increase in complications.[132] The complications of paracenteses include cardiovascular decompensation caused by rapid fluid shifts, intraperitoneal infection, and hemorrhage.

Surgical Options

Nowadays, the availability of liver transplant has made the surgical treatment of refractory ascites in children almost obsolete. The LeVeen shunt creates a drainage path from the intraperitoneal cavity to a jugular vein. Maintaining long-term patency is a problem, and in randomized trials, peritonovenous shunts, compared with medical therapy, did not improve survival.[133–135]

Controlling refactory ascites by decreasing portal hypertension through the creation of portosystemic shunts is a sound physiologic approach to the problem.[136] TIPS has become the most popular method. In adult studies, this procedure has been successful in controlling ascites in the majority of patients. However, mortality rates of 40 to 67% at 1 year and an incidence of encephalopathy of about 50% after TIPS have tempered enthusiasm for this approach. In one randomized trial in adults, mortality after the TIPS procedure was significantly higher compared with medical therapy alone.[137]

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) is defined as bacterial infection of the ascitic fluid in the absence of secondary causes, such as bowel perforation or intra-abdominal abscess. The clinical presentation of SBP can be subtle and even asymptomatic. Fever is generally present, but signs of abdominal pain and rebound tenderness are frequently absent. The child may present only with fever and irritability, the latter suggesting increasing encephalopathy. A high index of suspicion for SBP must always be maintained

in any child with ascites who presents with nonspecific deterioration.[138]

Paracentesis and ascitic fluid culture are essential to the diagnosis and appropriate antibiotic therapy of SBP. Studies in adult patients have emphasized that the presence of coagulopathy is not a contraindication to paracentesis.[139] The incidence of intra-abdominal wall hematoma is surprisingly low (< 1%), and clinically evident bowel perforation is very rare when small-sized cannulas are used.

The preferred site of paracentesis is in the avascular linear alba, 2 cm directly below the umbilicus. Care must be taken that a very large spleen is not impinging on the site. The alternative location is midway along the line drawn between the umbilicus and the anterior right iliac crest. Under aseptic conditions, a 16- to 18-gauge catheter-over-the-needle is introduced, and 10 to 20 cc of fluid is withdrawn. The ascitic fluid should be directly injected into blood culture bottles at the bedside. This technique not only increases the yield of positive cultures but also decreases the time for cultures to become positive.[140,141] Examination of the cell count of the ascitic fluid is important (Table 59-5). A polymorphonuclear (PMN) count of > 500/mm^3 has a sensitivity of 80% and a specificity of 98% for a positive culture. Cell counts of > 250 PMN/mm^3 have a slightly increased sensitivity to 85% but a small reduction of specificity to 93%. The PMN cell count is particularly important in differentiating SBP from the more sinister causes of secondary bacterial peritonitis. With bowel perforation or intra-abdominal abscesses, the PMN count will exceed 10,000/mm^3. As well, multiple organisms are cultured, the ascitic glucose concentration is decreased, and the lactate dehydrogenase concentration is increased. Differentiating primary from secondary bacterial peritonitis is crucial because secondary peritonitis is best managed by surgical intervention.[142,143]

Antibiotic therapy should be started, pending culture results, when the PMN count exceeds 500/mm^3, irrespective of signs or symptoms. When the PMN count is > 250/mm^3 or < 500/mm^3 and there is an index of clinical suspicion, antibiotics should still be started. If withheld, retapping within 48 hours is recommended.[138]

The culture results usually yield a single gram-negative organism, with *Escherichia coli* accounting for about half of the organisms.[144] Other gram-negative enteric rods, such as *Klebsiella*, are also found. Gram-positive organisms, particularly *Streptococcus* species, are seen in about 25% of cases. Anaerobic infections are very rare. Initial antibiotic therapy should cover both the likely gram-negative and -positive organisms. Cefotaxime alone has an 85% reported success rate. Avoiding aminoglycosides is important because many of these patients may already have some renal compromise. However, it should be remembered that cefotaxime alone will not cover *Enterococcus*, which is sometimes the offending organism. In this instance, ampicillin is the best choice Once the culture results are known, the antibiotic regimen can be tailored accordingly. An intravenous course of 10 to 14 days is recommended, although some studies have indicated that the ascitic fluid may become sterile within a few days.[145]

TABLE 59-5 PMN COUNTS ON ASCITIC FLUID

PMN COUNT	TREATMENT
< 250 mm^3	No treatment
> 250 < 500 mm^3	Intravenous antibiotics if clinical suspicion high or wait and retap
> 500 mm^3	Intravenous antibiotics (eg, cefotaxime + ampicillin)
> 500 mm^3	Rule out secondary peritonitis

PMN = polymorphonuclear.

Spontaneous infection of ascitic fluid is most likely a result of portal hypertension leading to an increased chance of translocation of the patient's own enteric organisms into the mesenteric lymph nodes, which drain via the thoracic duct into the systemic circulation.[146] Transient bacteremia occurs, with subsequent seeding of the ascitic fluid. Also adding to the risk are the decreased complement levels in both serum and ascitic fluid, poor reticuloendothelial system function, and defective neutrophil and phagocyte function observed in patients with severe liver disease.[142,147,148]

The first occurrence of SBP portends an accelerating risk of death from liver disease and underscores the urgency for liver transplant. In adult series, mortality during the first year after SBP is as high as 79%, usually related to complications of progressive liver failure rather than the SBP itself.[149,150] Recurrence is common—70% after the first episode in some studies.[150] Although oral antibiotic prophylaxis for SBP has been advocated by some authors for adult patients with high-risk factors for SBP (eg, elevated bilirubin, prolonged prothombin time, variceal bleeding),[151] there is no good evidence to support this concept in children. Because almost all of these children are liver transplant candidates, the risk of inducing resistant bacterial strains and fungal superinfection, both of which may have serious consequences in the post-transplant period, would seem to far outweigh any benefits.

HEPATORENAL SYNDROME

The hepatorenal syndrome is defined as functional renal failure in patients with severe liver disease. Histologically, the kidneys are normal, as evidenced by recovery of function after successful liver transplant and the successful transplant of cadaveric kidneys from patients with hepatorenal syndrome.[152] Hepatorenal syndrome most often occurs in decompensated chronic liver disease but also has been described in acute liver failure.[153] Hepatorenal syndrome is sometimes precipitated by other supervening complications of end-stage liver disease, particularly spontaneous bacterial peritonitis.[154]

About 10% of adult patients with chronic liver disease develop hepatorenal syndrome, with an associated mortality of more than 70% without liver transplant. There are few published studies of the prevalence of hepatorenal syndrome in children; however, it appears to be much less common compared with adult patients,[155] although still associated with significant mortality in the pretransplant period.[156]

Inherent in the diagnosis of hepatorenal syndrome is the careful exclusion of all other potential contributors to renal impairment. Most importantly, there must be no evidence of hypovolemia. This is particularly important in small children who may have unexpectedly large fluid losses from the intravascular compartment as a result of aggressive diuretic therapy for ascites, increased enteric losses from vomiting or diarrhea, or fluid shifts secondary to hypoalbuminemia. Measurement of central venous pressure can be very useful to determine intravascular fluid volume status. Importantly, intravenous fluid challenges will improve urine output in the hypovolemic child but will have no effect on the child with hepatorenal syndrome. Ongoing or recent hypovolemic shock, causing renal failure secondary to acute tubular necrosis, must be excluded.

Other important contributing factors to poor renal function that must be excluded are the effects of nephrotoxic drugs (particularly aminoglycosides and nonsteroidal anti-inflammatory drugs) and other intrinsic kidney diseases. Of the childhood diseases that cause chronic liver disease and have associated renal pathology, the most common are hereditary tyrosinemia, Alagille syndrome, and polycystic liver-kidney disease.

Diagnosis and Definition

The diagnosis of hepatorenal syndrome is supported by a characteristic pattern of urine electrolyte abnormalities: urine sodium of < 10 mEq/L, a fractional excretion of sodium of < 1%, and a urine-to-plasma creatinine ratio of < 10 (Table 59-6).[157,158] Although these findings are not pathognomonic for hepatorenal syndrome and, in particular, do not differentiate hypovolemia from hepatorenal syndrome, they help to exclude unsuspected acute tubular necrosis, characterized by an increased urine sodium and increased fractional excretion of sodium, as well as other causes of intrinsic renal disease. Generally, the glomerular filtration rate (GFR) is profoundly decreased, and the child is oliguric (< 1 mL/kg/h of urine output). Significant amounts of protein or blood in the urine usually exclude the diagnosis. Type 1 hepatorenal syndrome is a rapidly progressive renal failure, often associated with a precipitating event, and has a poor prognosis, whereas type 2 is a more moderate and less precipitous loss of renal function.

It is important not to rely solely on serum creatinine as an estimate of the degree of renal impairment.[159,160] For example, a creatinine level of 0.5 mg/dL in a small child may not appear worrisome, but if such a child has reduced muscle mass, this creatinine may represent a tripling of normal creatinine for age. Moreover, the rise in serum creatinine is not linearly associated with falling GFR. By the time creatinine rises above normal, GFR is already reduced by about 50%. True GFR is easily measured by plasma clearance of an isotope (eg, indium = 111 diethylenetriamine pentaacetic acid) because creatinine clearance and calculated GFR both overestimate true GFR.[161] These fundamental principles are essential to diagnose impending renal failure in children and initiate appropriate corrective action.

TABLE 59-6 HEPATORENAL SYNDROME: DIAGNOSTIC CRITERIA

Oliguria: < 1 mL/kg/d
Fractorial excretion sodium < 1%
Urine-to-plasma creatinine ratio < 10
↓ Glomerular filtration rate, ↑ creatinine
Absence of hypovolemia
Other kidney pathology excluded

Pathogenesis

The hallmark of hepatorenal syndrome is intense renal vasoconstriction with coexistent systemic vasodilation.[162] Renal blood flow, particularly to the renal cortex, is markedly reduced, despite the characteristic systemic hemodynamic changes seen in end-stage liver disease: decreased systemic vascular resistance, increased cardiac output, and decreased systemic blood pressure.[158,163] Ascites is often present, and hepatorenal syndrome is more likely to develop when ascites is resistant to diuretic therapy.[164] The mechanism of renal vasoconstriction is not yet fully understood, although several theories have been advanced. Gines and Arroyo suggest that the arterial vasodilation concept (also relevant in the mechanism of ascites generation) best explains the relationship between the opposing hemodynamic changes at the renal and systemic levels.[158] This theory proposes that portal hypertension as a result of cirrhosis causes splanchnic vascular vasodilation, with a subsequent reduction in effective systemic blood volume. The baroreceptor response is triggered, causing the activation of several systems that cause renal vasoconstriction. The splanchnic vascular system appears to be protected from the generalized vasoconstriction by the production of locally active vasodilator substances.

A variety of different mediators of renal vasoconstriction and splanchnic vasodilation have been proposed,[121] with the hope, not yet realized, that treatment could be aimed at inhibiting the causative agent.[165] The role of the renin-angiotensin axis has long been implicated in the vasoconstrictive response because cirrhotic patients are known to have high renin levels.[129] Also important is the activation of the sympathetic nervous system by the baroreceptor response to arterial hypotension. Increased sympathomimetic tone increases renal vasoconstriction and decreases GFR.[166,167] In some studies, the administration of clonidine, which decreases norepinephrine levels, has been shown to decrease renal vascular resistance.[168] Levels of antidiuretic hormone, which also cause renal vasoconstriction, are known to be elevated in cirrhotic patients.[121]

New attention is being focused on the endothelins, which are known potent vasoconstrictors that are released from many endothelial cells under conditions of stress.[169] Plasma endothelin 1 and 3 levels are two to three times higher in patients with cirrhosis and ascites, including children with biliary atresia[170] and cirrhosis,[171] compared with normal controls and are markedly increased in patients with hepatorenal syndrome.[172,173] Increased production of endothelin in the liver or splanchnic bed has been proposed. Interestingly, Nozue and colleagues reported that in eight children with cirrhosis, endothelin 1

levels were significantly higher than in normal controls, and they correlated this with increased levels of urinary sodium acetyl-β-D glucose aminidase, a sensitive indicator of renal injury.[174] After successful liver transplant in patients with hepatorenal syndrome, endothelin 1 levels fall preceding the improvement in renal function.[175] Because endothelin levels can be elevated in a variety of stress situations that may coexist in patients with hepatorenal syndrome, their causative role in mediating renal vasoconstriction in hepatorenal syndrome remains to be determined. However, preliminary reports suggest that hepatorenal syndrome may be ameliorated by infusion of endothelin antagonists.[176]

Decreased production of renal prostaglandins, which mediate renal vasodilation, may contribute to hepatorenal syndrome. This is supported by evidence that inhibitors of prostaglandin synthetase, particularly nonsteroidal anti-inflammatory drugs, decrease GFR and renal blood flow in patients with ascites. However, treatment of hepatorenal syndrome with systemic prostaglandins has not been successful.[177]

As a mediator of the excessive vasodilation evident in systemic circulation, nitric oxide has been the best studied.[178] Nitric oxide overproduction might explain both the hyperdynamic circulation so characteristic of end-stage liver disease and the splanchnic vascular vasodilation, which results in diversion of blood away from the kidney. It has also been proposed that a local increase in the production of nitric oxide within the kidney may help protect renal perfusion by counterbalancing the renal vasoconstriction that typifies hepatorenal syndrome.[179]

A direct relationship between the liver and kidney has also been invoked to explain the changes in renal circulation seen in liver failure. The proposed mechanisms are a decrease in synthesis of a liver-associated renal vasodilator factor[180] or a hepatorenal reflex that triggers baroreceptors in the liver to increase renal sympathetic nerve activity.[181]

The hepatorenal syndrome is best treated by timely liver transplant because complete recovery can be expected.[182,183] While awaiting transplant, dialysis is the mainstay of treatment. Low-dose dopamine may increase renal blood flow but does not appear to increase GFR.[184] Peritoneovenous shunts[185] or TIPS, by reducing portal hypertension, may transiently improve renal function, but neither have shown sustained benefit.[186,187]

More recently, success has been reported in the treatment of hepatorenal syndrome in adults using terlipressin, a nonselective vasopressin analog. The mechanism of the beneficial effect on renal function is thought to be secondary to the intense splanchnic bed vasoconstriction induced, which allows improvement in systemic arterial circulation and renal blood flow. Patients who receive combined therapy with albumin infusion and terlipressin, which further improves circulatory function, have the best response. In one recent study, 77% of patients receiving albumin and terlipressin alone achieved a serum creatinine level < 1.5 mg/dL.[188] This modality may be a useful bridge until transplant. Unfortunately, at this time, terlipressin is not approved for use in the United States.

Although hepatorenal syndrome is associated with increased mortality before transplant in both adult[189] and pediatric series,[156,190] once transplanted, preexisiting hepatorenal syndrome has little effect on overall survivals.[191,192]

PULMONARY INVOLVEMENT IN LIVER DISEASE

Hepatopulmonary Syndrome

The triad of hypoxemia, intrapulmonary vascular dilations, and liver disease constitutes the hepatopulmonary syndrome.[193,194] It is defined by an arterial oxygen pressure of < 70 mm Hg in room air with an alveolar/arterial gradient of > 20 mm Hg. In adults, the prevalence is between 5 and 29%,[195] with a 41% overall mortality described in hospitalized patients.[196] In children, estimates of the prevalence range from 0.5% in those with portal vein obstruction to as high as 20% in children with biliary atresia and polysplenia syndrome.[197] In other causes of childhood cirrhosis, the prevalence is between 2 and 4%.[198] Hepatopulmonary syndrome has been described in children as young as 6 months. Generally, hepatopulmonary syndrome is seen in chronic liver disease, but it has also been described in acute liver failure[199] and extrahepatic portal venous obstruction.[200] Portal hypertension is not a prerequisite for developing hepatopulmonary syndrome, although there is some evidence that the risk increases as the severity of liver disease progresses. Intrapulmonary vascular dilations may occur in patients with well-compensated chronic liver disease without demonstrating hypoxemia.[201]

There are two forms of hepatopulmonary syndrome; both are characterized by a right to left shunt within the lungs but with differing underlying mechanisms.[202] In type 1, which is more common, there is extensive dilation of the pulmonary precapillary circulation. Blood flowing through the dilated capillaries—particularly the red blood cells flowing in the central core of the stream—is less exposed to oxygen contained in the alveoli, resulting in a ventilation-perfusion mismatch. The patients with this functional shunt will be able to increase their PaO_2 to some degree when breathing 100% oxygen.

About 10% of patients with hepatopulmonary syndrome will have the much more sinister type 2 form, in which anatomic arteriovenous shunts within the pulmonary circulation, and occasionally between the portopulmonary systems, can be demonstrated on pulmonary angiography.[196,203,204] These shunts may not be in close proximity to the alveoli for oxygen exchange. Patients with these fixed anatomic shunts will not be able to increase PaO_2 when breathing 100% oxygen. The prognosis for type 2 hepatopulmonary syndrome is very poor.

Hepatopulmonary syndrome should be suspected if cyanosis, particularly of the lips and fingers, and digital clubbing are found on examination. Many patients with hepatopulmonary syndrome will have a plethora of spider nevi.[205] Because the pulmonary vascular dilations are more prominent at the lung bases, many patients will have increased dyspnea with standing (platypnea). Brain

abscesses have been described as a complication of the intrapulmonary shunts.[206]

Arterial blood gas analysis, both in room air and in 100% oxygen, is essential and should be obtained with the patient standing. The fall in PaO_2 in moving from the recumbent to the standing position (orthodeoxia) is characteristic of hepatopulmonary syndrome. The normal response to breathing 100% oxygen is a PaO_2 > 500 mm Hg. Patients with hepatopulmonary syndrome breathing 100% have a moderate shunt if the PaO_2 is > 300 mm Hg but < 500 mm Hg and a severe shunt if the PaO_2 is > 100 mm Hg but < 300 mm Hg.[207]

The site and extent of the right to left shunt can be assessed by either a technetium 99m–labeled macroaggregated albumin (Tc 99m MAA) study or by a contrast echocardiogram.

The Tc 99m MAA study uses peripherally injected labeled albumin particles with a diameter of > 20 μm.[208] Because the usual pulmonary capillary diameter is 8 to 15 μm, normally all of the labeled albumin will be trapped in the lungs. In the presence of pulmonary vasodilation, the labeled albumin particles can be detected in the kidneys and brain and the degree of shunt correlated to the isotope concentration in these extrapulmonary sites. Note that this scan does not differentiate intracardiac from intrapulmonary shunting.

The best method to evaluate the shunt in hepatopulmonary syndrome is the contrast-enhanced echocardiogram,[209] making the diagnosis in 9.1% of 88 children with biliary atresia, although only 50% had symptoms.[210] In this procedure, an agitated solution of contrast is injected peripherally. When cardiopulmonary circulation is normal, microbubbles with a diameter of > 15 μm are trapped in the lungs. If an intracardiac shunt is present, the microbubbles immediately opacify the left ventricle, whereas if there is an intrapulmonary shunt, it requires three to six ventricular contractions before the microbubbles appear in the left heart. Particularly in children who may have congenital heart disease complicating chronic liver disease (eg, Alagille syndrome or biliary atresia), distinguishing the site of the shunt is essential.

The mediator of the pulmonary vascular dilation that characterizes hepatopulmonary syndrome remains speculative. In animal models, elevated levels of endothelium-derived nitric oxide were detected in the lung homogenates of animals with the clinical features of hepatopulmonary syndrome.[211,212] This finding would appear to be supported by reports documenting increased exhaled nitric oxide concentration in adults and children with hepatopulmonary syndrome.[213,214] However, without better understanding of the underlying mechanism, pharmacologic attempts to manage hepatopulmonary syndrome have not been generally successful to date.

Presently, the only definitive treatment for hepatopulmonary syndrome is liver transplant. In the past, hepatopulmonary syndrome was thought to be a contraindication to liver transplant. However, accumulated evidence documenting successful resolution of hepatopulmonary syndrome after liver transplant has reinforced the concept that in selected patients, hepatopulmonary syndrome is, in fact, best managed by liver transplant.[195,207,215,216] Patients with large anatomic shunts who are unable to increase PaO_2 over 100 mm Hg on 100% oxygen are still not suitable candidates for liver transplant.

In selecting patients for transplant, it must be determined if the patient is safe for anesthesia and if the oxygen content of the blood supplying the graft will be adequate to support early graft function. In an analysis of several studies, Krowka and colleagues noted that 30% of patients with PaO_2 < 50% in room air died after liver transplant compared with 4% of patients with PaO_2 > 50 mm Hg.[195] In successfully transplanted patients, complete normalization of hypoxemia occurred in 82% of transplant recipients. However, the duration of use of the mechanical ventilator and intensive care unit stay tend to be prolonged in patients with hepatopulmonary syndrome.

Encouraging evidence that hepatopulmonary syndrome is reversed by liver transplant is emerging in the pediatric experience. In seven children with hepatopulmonary syndrome undergoing liver transplant, complete reversal of the syndrome occurred in all at an average of 24 ± 10 weeks. Time to extubation in this group was 58 ± 21 hours. In one pediatric study, a PaO_2 in room air lower than 60% uniformly resulted in death after transplant,[217] and in another study, there were no survivors after liver transplant if the PaO_2 was < 200 mm Hg in 100% oxygen.[197] Egawa and colleagues categorized 21 children with hepatopulmonary syndrome into three groups, depending on their shunt ratio: mild, less than 20%; moderate, 20 to 40%; and severe, > 40%.[218] An adverse significant effect on patient and graft survival was found with an increasing shunt ratio. One-year actuarial patient survivals were 80%, 66.7%, and 40% in the mild, moderate, and severe groups, respectively. Prolonged ventilator dependence, hypoxic injury to the graft, portal vein thrombosis, and intracranial thrombosis are some of the sequelae in transplanted children with severe hepatopulmonary syndrome.

PORTOPULMONARY HYPERTENSION

This phenomenon is the antithesis of hepatopulmonary syndrome and is characterized by pulmonary artery vasoconstriction (Table 59-7).[219] Why the chronically diseased liver causes two such diverse effects on pulmonary function is an unresolved conundrum. Portopulmonary hypertension has only rarely been described in children. A summary of the basic principles of the pathogenesis, diagnosis, and management is included here.[220,221]

Portopulmonary hypertension is defined as a mean pulmonary artery pressure > 25 mm Hg with a pulmonary capillary wedge pressure of < 15 mm Hg in the absence of any secondary causes of pulmonary hypertension, such as cardiac valvular disease.

On pathologic examination of the pulmonary arteries, concentric medial hypertrophy and intimal fibrosis are found.[222] The coexistence of portal hypertension appears to be a prerequisite for the development of portopulmonary hypertension.[223] In adults, the prevalence of portopulmonary hypertension in patients with portal hypertension

TABLE 59-7 COMPARISON AND CONTRAST: HEPATOPULMONARY SYNDROME AND PORTOPULMONARY HYPERTENSION

HEPATOPULMONARY SYNDROME	PORTOPULMONARY HYPERTENSION
Intrapulmonary vasodilation	Intrapulmonary vasoconstriction
Alveolar arterial gradient > 20 mm Hg	Alveolar arterial gradient usually normal
Normal mean pulmonary artery (PA) pressure	Mean PA pressure > 25 mm Hg
Perform shunt fraction study	Perform right heart catheterization
Trial of 100% O_2	Vasodilator therapy trial
Often reversible with liver treatment	May not reverse with liver transplant
Poor prognosis: PaO_2 < 300 mm Hg on 100% O_2	Poor prognosis: PA pressure > 45 mm Hg
Histology: PA normal	Histology: PA abnormal; concentric medial hypertrophy

and cirrhosis is 1 to 2%, although an 8.5% incidence was found in a recent large series of patients evaluated for liver transplant.[224] The prevalence in children is unknown.

The diagnosis may be suspected by finding abnormalities on the electrocardiogram, which are present in up to 95% of patients.[225] Right ventricular hypertrophy, right axis deviation, and right bundle branch block are common. A right heart catheterization is essential to document right heart and pulmonary pressures accurately and also allows for a trial of vasodilator therapy. Vasodilator treatment with nitric oxide, calcium channel blockers, and eprostonol has been used with varying success in adult studies.[220,226,227]

There are very few published guidelines regarding treatment of portopulmonary hypertension in children. The management of choice advocated in one article is early diagnosis followed by liver transplant as soon as possible.[228] However, experience from the adult literature recommends that patients must be carefully selected for liver transplant and that mean pulmonary artery pressure should not exceed 50 mm Hg. In one study, a mean pulmonary artery pressure of > 50 mm Hg was associated with a 100% cardiopulmonary mortality and a 50% mortality if > 35 mm Hg but < 50 mm Hg.[229] Selection of patients implies the pretransplant diagnosis of portopulmonary hypertension. However, often the diagnosis is made when anesthesia is induced at the time of transplant, thereby limiting appropriate decision making. Maintaining a high index of clinical suspicion before transplant is therefore imperative. This applies particularly to older children with cirrhosis who may wait for long periods for transplant.[230] Patients with mild to moderate pulmonary hypertension (< 40 mm Hg) will usually show resolution after liver transplant, whereas those with severe portopulmonary hypertension frequently develop progressive fatal right heart failure.

CENTRAL NERVOUS SYSTEM INVOLVEMENT

Clinically evident encephalopathy in children with chronic liver disease appears to be less common compared with adults. However, it is also possible that encephalopathy is underdiagnosed in children because its more subtle manifestations are difficult to appreciate, and there is no specific laboratory test that correlates well with encephalopathy. Irritability and lethargy are the two most common signs but may be evident in any chronically ill child. Acute changes in mental status should prompt an investigation for occult gastrointestinal bleeding (which increases ammonia production from blood in the intestinal lumen) or an intracranial hemorrage secondary to coagulopathy. Aggressive diuretic therapy, spontaneous bacterial peritonitis, and placement of a portosystemic shunt may all precipitate the development of encephalopathy.

The pathophysiology and treatment of hepatic encephalopathy are discussed in detail in Chapter 5.3, "Normal Hepatocyte Function and Mechanisms of Dysfunction." In brief, the main principle of management is to decrease gut-derived nitrogen production by restricting dietary protein, evacuating blood from the gastrointestinal tract, and administering oral lactulose or neomycin to reduce bacterial flora in the bowel. Oral lactulose is preferred, although care must be taken not to induce hypovolemia and electrolyte disturbances from increased stool losses. Oral neomycin has some systemic absorption, which has been associated with ototoxicity; therefore, extended use should be avoided.

CHOLESTATIC LIVER DISEASES: SPECIAL ISSUES

CHOLANGITIS

Ascending infection of the biliary system is most often seen in pediatric liver disease in the context of biliary atresia with a poorly functioning Kasai portoenterostomy. The major risk factors for infection are stasis in the biliary system secondary to poor bile flow and the creation of a Roux-en-Y limb, which approximates the small intestine directly to the porta hepatis. Children with biliary atresia and recurrent episodes of cholangitis may have intrahepatic bilomas, which can be diagnosed on ultrasonography.

Although cholangitis in children with biliary atresia most often occurs when there is evidence of impaired bile flow, generally within the first year after the Kasai procedure,[231] it has also been described late after surgical repair in children with no evidence of biliary obstruction.[232] Under these circumstances, direct ascending infection through the Roux-en-Y limb occurs. However, although these children have a normal serum bilirubin, biliary stasis in the small intrahepatic bile ducts may still be a contributing factor.

Primary and secondary sclerosing cholangitis and the variants of congenital hepatic fibrosis and choledochal cysts with multiple intrahepatic biliary cysts are other intrahepatic cholestatic liver diseases of children in whom cholangitis can occur. In sclerosing cholangitis, the development of jaundice and recurrent cholangitis should prompt the radi-

ographic examination of the biliary system, either by endoscopic retrograde cholangiopancreatography or percutaneous cholangiography, to rule out a dominant stricture that could be stented. In general, obstructive lesions to the external biliary system, such as stones in the common bile duct, cause cholangitis but do not cause chronic liver disease if treated appropriately. These disorders are discussed in Chapter 50.3, "Disorders of the Biliary Tract: Other Disorders."

Cholangitis is diagnosed in the child with cholestatic liver disease who presents with fever and elevated bilirubin and/or serum transaminases from baseline. The alkaline phosphatase or γ-glutamyltransferase will also be elevated. Abdominal pain is only variably present. The most common organisms are gram-negative enteric organisms, such as *E. coli*, *Klebsiella*, *Pseudomonas*, and *Enterococcus*. Blood cultures are frequently negative; therefore, it is important to initiate appropriate antibiotic treatment without waiting for culture results when the clinical index of suspicion is high. If the child fails to defervesce after 72 hours or has frequent recurrences, percutaneous liver biopsy with culture of the liver tissue may be indicated. A common initial antibiotic regimen is ampicillin and cefotaxime given for 10 to 14 days intravenously.

Prophylaxis of recurrent cholangitis is of variable efficacy. In one survey, 73% of physicians used antibiotic prophylaxis after the Kasai procedure.[233] Oral administration of trimethoprim-sulfamethoxazole is most conveniently used.[233] Long-term intravenous antibiotic prophylaxis in children via central venous catheters is occasionally indicated, although the risk of inducing multiply resistant bacterial organisms or fungal colonization must be considered.

There is no definitive effective treatment for recurrent cholangitis in the child with biliary atresia except liver transplant. As such, recurrent cholangitis is an indication for listing children with biliary atresia for transplant.[234] There is some evidence that children with biliary atresia who suffer recurrent episodes of cholangitis develop cirrhosis more quickly than those without cholangitis.[235]

Pruritus

Intense pruritus can be a complication of cholestatic liver disease, causing misery to children and their caregivers alike. The well-being of the child is overwhelmed by the intense need to itch. Severely afflicted children cannot sleep, do not eat, and are constantly irritable. Although the etiology may be multifactorial, accumulation of bile acids appears to be important because pruritus is most often associated with cholestasis and is particularly problematic in progressive familial intrahepatic cholestasis syndromes. Another contributing factor appears to be increased opiate tone because opiate antagonists have some therapeutic benefit.[236,237]

Treatment is often poorly effective.[238,239] Cholestyramine is generally not helpful because there are already unusually low concentrations of bile acids in the intestinal lumen. Choleretics, such as phenobarbital, can be tried. Antihistamines are the first line of treatment but are seldom adequate alone. Ursodeoxycholic acid, by altering bile composition, will often help reduce pruritus and should be used in doses of 25 to 30 mg/kg/d in divided doses.[240] Rifampin has also been successfully used in doses of 10 mg/kg/d.[241] Rifampin may alter bile acid composition via 6-hydroxylation of bile salts. Rifampin interacts with the nuclear receptor pregnane X and induces cyp3A, which can hydroxylate bile salts (see Chapter 5.1, "Bile Formation and Cholestasis").

Other modalities that are less well studied in children are intravenous naloxone,[242] plasmapheresis, charcoal absorption,[243] and phototherapy. The opiate antagonist approach appears to be very promising. Naloxone has been shown to be efficacious but is limited in its application by poor oral bioavailability and short half-life. Oral preparations of opiate antagonists, such as naltrexone and nalmefene, may help some patients.[244,245] A recent report suggests that dronabinol (a cannabinoid) may also be beneficial.[246]

Partial biliary diversion procedures have been successful in treating some children with progressive familial intrahepatic cholestasis syndromes and intractable pruritus.[247–249]

ACKNOWLEDGMENT

I am indebted to the expertise of Dinora Duarte in the preparation of this chapter.

CHAPTER 60

LIVER TRANSPLANT

Deirdre Kelly, MD, FRCP, FRCPI, FRCPCH

Successful pediatric liver transplant evolved in the 1980s and became established in the 1990s. The success of this complex procedure has led to a significant increase in the number of children undergoing liver transplant worldwide and has radically changed the prognosis of many babies and children dying of end-stage liver failure.

Liver transplant was first performed in the United States and Europe in 1963, but the first successful pediatric liver transplant was not performed until 1967, in a young girl with a malignant hepatic tumor. There were rapid advances in adult transplant throughout the 1970s, particularly after the introduction of cyclosporin A in 1978,[1] but technical difficulties and donor shortages meant that pediatric liver transplant remained hazardous. By 1986, when most adult units claimed a 1-year survival rate of 80%, average 1-year survival rates in children were only 60%.[2] Since then, there have been considerable advances in both medical and surgical management, with international 1-year survival rates from pediatric liver transplant in excess of 90% and 5- to 10-year survival rates of 80%.[3]

The improved survival rates are related to improving pre- and postoperative management in association with the development of innovative surgical techniques to expand the donor pool. These techniques have not only reduced deaths on the waiting list and improved survival overall but also have extended the range of indications for liver transplant to include semielective liver replacement, transplant for inborn errors of metabolism, and unresectable hepatic tumors. As short-term survival has improved, interest in research has focused on evaluating quality of life in long-term survivors.

By 2002, 4,252 children had undergone liver transplant in Europe,[4] with more than twice that number of children transplanted in the United States.[5] In Europe, 40% of transplants were performed in children under 2 years of age, 50% in children aged 2 to 12 years, and 10% in children aged 12 to 15 years (Figure 60-1).[4]

Despite its recorded success, liver transplant remains a complex procedure with large resource implications and a 10% mortality rate; thus, careful consideration should be given to the selection of potential recipients and the exclusion of other therapies.

INDICATIONS

Liver transplant is now accepted therapy for acute or chronic liver failure (Table 60-1; see Figure 60-1).

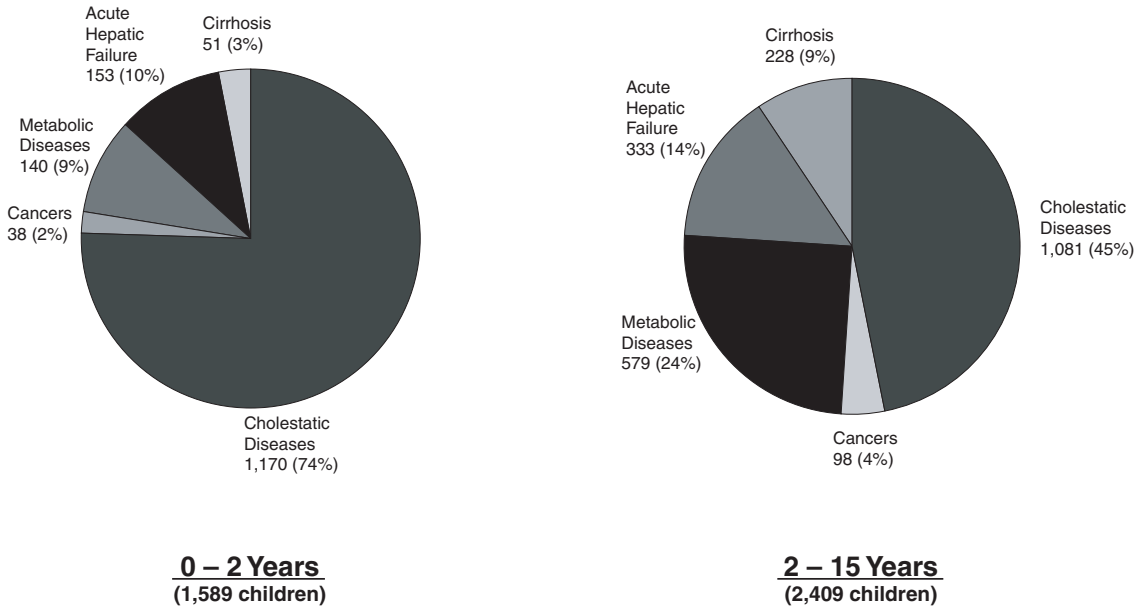

FIGURE 60-1 Primary indications of liver transplant in 3,998 pediatric patients, 1988 to 2001. Adapted from the European Liver Transplant Registry, 2002.

TABLE 60-1 INDICATIONS FOR LIVER TRANSPLANT IN CHILDREN

CHRONIC LIVER FAILURE
Cholestatic liver disease
Biliary atresia
Idiopathic neonatal hepatitis
Alagille syndrome
Progressive familial intrahepatic cholestasis
Nonsyndromic biliary hypoplasia
Metabolic liver disease
α_1-Antitrypsin deficiency
Tyrosinemia type I
Wilson disease
Cystic fibrosis
Glycogen storage type IV
Chronic hepatitis
Autoimmune
Idiopathic
Postviral (hepatitis B, C, other)
Cryptogenic cirrhosis
Fibropolycystic liver disease ± Caroli disease
Primary immunodeficiency
ACUTE LIVER FAILURE
Fulminant hepatitis
Autoimmune hepatitis
Halothane anesthesia
Acetaminophen poisoning
Viral hepatitis (A, B, C, or NA-G)
Metabolic liver disease
Fatty acid oxidation defects
Neonatal hemochromatosis
Tyrosinemia type I
Wilson disease
INBORN ERRORS OF METABOLISM
Crigler-Najjar syndrome type I
Familial hypercholesterolemia
Organicacidemia
Urea cycle defects
Primary oxalosis
HEPATIC TUMORS
Benign tumors
Unresectable malignant tumors

CHRONIC LIVER FAILURE

Cholestatic Liver Disease

Chronic liver failure secondary to cholestatic liver disease is the most common indication for liver transplant in children (see Figure 60-1). Of diseases of this type, biliary atresia remains the main indication for liver transplant in children worldwide. Despite professional education on the importance of early diagnosis and management of this condition, many children continue to be referred for treatment too late to benefit from a palliative Kasai portoenterostomy. Children who have an immediately unsuccessful Kasai portoenterostomy or who develop intractable nutritional or hepatic complications[6] should be referred for urgent transplant. Approximately 60% of children with biliary atresia will have a successful Kasai portoenterostomy; in these children, cirrhosis and portal hypertension will develop at a much slower rate, and their need for liver transplant will depend on the rate of development of hepatic complications.[7]

The outcome of cholestatic liver diseases such as Alagille syndrome and progressive familial intrahepatic cholestasis is more variable. Many children will have compensated liver disease for some time or will be well maintained on supportive management. Liver transplant is indicated if decompensated cirrhosis and/or intractable portal hypertension develop, if malnutrition and growth failure are unresponsive to nutritional support, or if there is intractable pruritus that is resistant to maximum medical therapy or biliary diversion.[8]

Some infants who present with giant cell hepatitis or neonatal hepatitis of unknown etiology develop persistent cholestasis and rapid progression to cirrhosis and portal hypertension and become candidates for liver transplant in the first 2 or 3 years of life.

Metabolic Liver Disease

α_1-Antitrypsin deficiency is the most common form of inherited metabolic liver disease presenting in childhood in Europe and the United States. Although 20 to 40% of children in any population develop persistent liver disease progressing to cirrhosis, only a minority (approximately 20 to 30%) require liver transplant in childhood.[9]

Tyrosinemia type I is an autosomal recessive disorder of tyrosine metabolism, with a clinical presentation that includes both acute and chronic liver disease and multiorgan failure with cardiac, renal, and neurologic involvement. The management of this disorder has changed dramatically since the introduction of 2(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexenedione (NTBC), which prevents the formation of toxic metabolites and produces rapid clinical and biochemical improvement. The widespread use of this drug in tyrosinemia has altered both the natural history of the disease and the indications for transplant.[10,11] Prior to the introduction of NTBC, liver transplant was indicated for acute or chronic liver failure but, more importantly, for hepatic dysplasia or hepatocellular carcinoma. Liver transplant is now indicated only for those children who have a poor quality of life (ie, those who do not tolerate the restrictive low-protein diet and the frequent bloodletting and amino acid monitoring) or do not respond to NTBC or in whom hepatic malignancy is thought to have developed.[11] Routine monitoring of children with tyrosinemia type I being treated with NTBC includes ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) to detect the development of nodules and/or early hepatocellular carcinoma in association with regular α-fetoprotein levels. A persistent or sustained rise of α-fetoprotein may indicate the early development of hepatocellular carcinoma, which should be confirmed by the detection of hepatic dysplasia on liver biopsy.[12,13]

Wilson disease is a rare indication for liver transplant in childhood. Early diagnosis and therapy with penicillamine should be curative, but many children will present with established cirrhosis or fulminant liver failure. Liver transplant is indicated for those children who present with advanced liver disease (Wilson score > 6) or fulminant liver failure or who have progressive hepatic disease despite penicillamine therapy or other therapy, such as trientene and zinc.[14,15]

The short-term survival for children with cystic fibrosis has improved with increased attention to nutrition and

appropriate management of pulmonary disease. Liver disease develops in approximately 20% of children, mainly in boys,[16] and is becoming an increasingly common indication for liver transplant.[17] Referral for liver transplant and the timing of transplant are particularly difficult for children with cystic fibrosis. Many children present with compensated liver disease but with bleeding esophageal varices from portal hypertension.[18] In these children, management of portal hypertension by conservative means (sclerotherapy or band ligation of esophageal varices or insertion of a transhepatic portal systemic shunt) may be sufficient to control symptoms and improve quality of life for some years.[18]

Liver transplant in cystic fibrosis is indicated if there is evidence of hepatic decompensation (falling serum albumin or prolonged coagulation unresponsive to vitamin K), severe malnutrition unresponsive to nutritional therapy, or severe complications of portal hypertension that are unresponsive to medical management, such as ascites or uncontrolled variceal bleeding.[17,19] Careful assessment of pulmonary function is essential because severe lung disease (< 70% predicted lung function) may indicate the necessity for heart, lung, and liver transplant.[17,19] In some children, the choice of timing of the liver transplant may be advanced by the recognition of rapidly deteriorating pulmonary function. The management of pulmonary disease is particularly important before transplant and should include vigorous physiotherapy, intravenous antibiotics, and deoxyribonuclease.

Most children with glycogen storage disease type I should not require liver transplant and can be managed appropriately with medical and nutritional treatment. Transplant is indicated only for children who develop multiple hepatic adenomas or in whom metabolic control has affected the quality of life. Children with glycogen storage disease types III and IV are more likely to progress to cirrhosis with portal hypertension and require transplant because of hepatic dysfunction.[20]

The rare disorders of bile acid metabolism that present with persistent cholestasis may now respond to oral bile acids, reducing the need for transplant.[21,22]

Chronic Hepatitis

Autoimmune Liver Disease Types I and II. Liver transplant is a rare indication for children with autoimmune liver disease type I or II, who usually respond to immunosuppression with prednisolone or azathioprine. Liver transplant is indicated for those children who have not responded to immunosuppression despite alternative therapy such as cyclosporin A, mycophenolate mofetil, or tacrolimus and for those children who present with fulminant hepatic failure.[23] Fulminant hepatic failure is more likely in children with type II autoimmune hepatitis, who have a worse prognosis and an increased requirement for liver transplant.

Chronic Hepatitis B or C. Although chronic hepatitis B or C is a major indication for transplant in adults, it is less common in children, many of whom will not develop symptomatic liver disease in childhood. Recurrence of hepatitis B or C is likely in 90% of patients transplanted for chronic disease but not for fulminant hepatitis. Prevention or recurrence of hepatitis B is less likely with prophylactic treatment of hepatitis B immunoglobulin and/or lamivudine.

Fibropolycystic Liver Disease. Fibropolycystic liver disease is an unusual indication for liver transplant in childhood because liver function remains normal despite the development of severe portal hypertension. Liver transplant is indicated for those children in whom hepatic decompensation occurs secondary to recurrent cholangitis or portal hypertension or if hepatic enlargement affects the quality of life. Because the disease may be associated with infantile polycystic kidney disease in some children, both liver and kidney replacement may be required.[24]

Primary Immunodeficiency. As bone marrow transplant for primary immunodeficiency becomes increasingly successful, it has been recognized that many children with these diseases have associated liver disease. The most common immunodeficiency is CD40 ligand deficiency (hyper-immunoglobulin M syndrome), in which recurrent cryptosporidial infection of the gut and biliary tree lead to sclerosing cholangitis. In this group of children, it is important to consider bone marrow transplant before the development of significant liver disease or to consider combined liver and bone marrow transplant if necessary.[25]

Timing of Transplant for Chronic Liver Failure. The timing of liver transplant for children with chronic liver failure may be difficult because many children will have compensated liver disease for some years. Although it may be possible to predict biochemical decompensation by studying serial estimates of lidocaine metabolite formation and excretion,[26] this has not proved universally to be of value. The most useful guide to the timing of liver transplant is provided by a variety of parameters that include (1) a persistent rise in total bilirubin > 150 μmol/L (> 9 mg/dL), (2) prolongation of the prothrombin ratio (international normalized ratio [INR] > 1.4), and (3) a persistent fall in serum albumin to < 35 g/L.[27] Serial evaluation of nutritional parameters is a useful guide to early hepatic decompensation. Progressive reduction of fat stores (measured by triceps skinfold or subscapular skinfold) or protein stores (measured by midarm circumference or midarm muscle area) despite intensive nutritional support is a good guide to hepatic decompensation.[28] Recently, the development of the PELD Score (PELD = pediatric end-stage liver disease) has confirmed these observations.[29]

An important consideration in timing liver transplant is psychosocial development. Children with chronic liver disease may have both social and motor developmental delays that increase with time unless reversed following early liver transplant.[6,30,31]

Children with severe hepatic complications such as chronic hepatic encephalopathy, refractory ascites, intractable pruritus, or recurrent variceal bleeding despite appropriate medical management should be referred immediately for transplant. In some children, hepatopul-

monary syndrome secondary to pulmonary shunting develops and is an important indication for liver transplant.[32] It is essential that transplant is performed prior to the development of severe pulmonary hypertension because this will preclude successful liver transplant.[33]

For children with chronic liver disease to benefit from transplant, it is essential that this procedure be considered before the complications of liver disease adversely impair the quality of the children's lives and before their growth and development are irreversibly retarded.

ACUTE LIVER FAILURE

Liver transplant is indicated for acute liver failure secondary to a wide range of primary etiologies (see Table 60-1). It is good practice to refer children with acute liver failure early to a specialist unit with facilities for transplant so that the child may be stabilized and sufficient time can be given to find an appropriate donor organ.

Fulminant Hepatitis

The management of children with fulminant hepatitis is first to assess prognosis and the necessity for liver transplant and then to prevent or treat hepatic complications while awaiting a suitable donor organ or regeneration of the native liver. The factors known to imply a poor prognosis for children with fulminant hepatitis are as follows:

1. Non–A–G hepatitis
2. Development of grade III or IV hepatic coma
3. Reduction in hepatic size in association with falling transaminases and increasing bilirubin (> 300 µmol/L or > 16 mg/dL).
4. Persistent severe coagulopathy (> 50 seconds over control; INR > 4)[34]

In infants with fulminant hepatitis, coagulopathy may be more severe than encephalopathy, and both are not required prior to listing for liver transplant.[35]

It is essential that all children who have reached grade III hepatic coma or who have a persisting coagulopathy without evidence of irreversible brain damage from cerebral edema or hypoglycemia be listed for liver transplant. It may be difficult to exclude underlying brain disease. Cerebral CT or MRI may demonstrate cerebral infarction, ischemia, or hemorrhage, whereas electroencephalography (EEG) may indicate reduced voltage of brain waves, but none of these techniques are infallible. Although intracranial pressure monitoring has been demonstrated to improve selection for liver transplant by excluding children with persistently raised intracranial pressure, it has not influenced survival.[36] The technique may be impossible in children with prolonged coagulopathy and is associated with significant morbidity unless coagulopathy can be adequately corrected without inducing cerebral edema. Measurement of cerebral blood flow is not useful because it may be reduced in hepatic failure; measurement of cerebral perfusion pressure may be a more sensitive indicator for selection. EEG may demonstrate a reduction in voltage of electrical activity and ultimately brain death, but these results should be interpreted cautiously in ventilated patients or those treated with thiopental or other phenobarbitals because the EEG tracing may be affected by these drugs.

Acetaminophen overdose is a common indication for liver transplant in adults in the United States but is less common in pediatric practice. Of 73 children in one study who developed overdose, only 8% required liver transplant.[37] Children are more likely to require liver transplant if the overdose was taken with another drug (eg, LSD [lysergic acid diethylamide] or Ecstasy [3,4-methylenedioxymethamphetamine]) or alcohol and if they present with a persistent coagulopathy (INR > 4), metabolic acidosis (pH < 7.3), and rapid progression to hepatic coma grade III.[38]

Metabolic Liver Disease

Metabolic liver disease such as Wilson disease and tyrosinemia type I may present with acute liver failure, whereas fatty acid oxidation defects and/or mitochondrial disease occur in the neonatal period. In contrast to fulminant hepatitis, the clinical presentation is subacute, and liver failure develops in the presence of an underlying cirrhosis. Selection for liver transplant is based on response to medication and the presence of advanced liver disease or severe coagulopathy. Jaundice or encephalopathy may not be obvious.[14]

Neonatal hemochromatosis is a rare disorder of iron handling. The presentation is within days or weeks of birth, with severe coagulopathy, encephalopathy, and hypoglycemia. The diagnosis is based on the clinical features and presence of extrahepatic iron deposition. Recent experience has shown that medical management using an antioxidant "cocktail" may be beneficial for those children with a milder phenotype, particularly if the cocktail is started shortly after birth.[39,40]

Inborn Errors of Hepatic Metabolism

A number of inborn errors of metabolism are secondary to hepatic enzyme deficiencies that do not lead to liver disease. Liver function is normal, but the enzyme deficiency leads to severe extrahepatic disease. The purpose of liver transplant in this group of diseases is to replace the missing hepatic enzyme to prevent or reverse extrahepatic disease. Selection is based on the child's quality of life, on medical management, and on the potential mortality and morbidity of the primary disease related to the risks and outcome following liver transplant.

The timing of transplant depends on the rate of progression of the disease, the quality of life of the affected child, and the development of severe irreversible extrahepatic disease.[41]

Crigler-Najjar Syndrome Type I. Crigler-Najjar syndrome type I is an autosomal recessive disease in which there is an absolute deficiency of glucuronyl transferase, which leads to high levels of unconjugated bilirubin and the eventual development of structural brain damage secondary to kernicterus. Current management includes many hours of phototherapy daily to reduce the level of unconjugated bilirubin.

Liver transplant is curative, and children should be selected for transplant prior to the development of irreversible brain damage and at a time when continuous pho-

totherapy is affecting the quality of their life. The recent development of auxiliary liver transplant (see below), in which only part of the liver is transplanted, may be the most appropriate transplant operation for these children because it allows the possibility of gene therapy in the future.[42]

Familial Hypercholesterolemia. Children with homozygous or heterozygous familial hypercholesterolemia are prone to premature development of coronary artery disease owing to a deficiency in the number of receptors needed for the metabolism of cholesterol on hepatocytes. Liver transplant should be performed before there is irreversible coronary artery disease, but recent progress with gene therapy for this condition suggests that auxiliary liver transplant or gene therapy may be more appropriate treatment strategies at present.[42,43]

Organicacidemias. These rare disorders include propionicacidemia or methylmalonicacidemia, in which there are abnormalities in the metabolism of propionate and methylmalonate, respectively. Children with these diseases are at risk of recurrent metabolic acidosis, developmental delay, and irreversible brain damage. Liver transplant is palliative treatment for these conditions because the enzyme deficiency affects all parts of the body. Isolated case reports have indicated that orthotopic liver replacement was necessary to provide adequate enzyme supplementation, but it is possible that auxiliary liver transplant may be sufficient for mildly affected patients.[42]

Four main disorders of the urea cycle lead to neurotoxicity with accumulation of ammonia and glutamine. The defective enzymes are (1) carbamyl phosphate synthetase, (2) ornithine transcarbamylase, (3) argininosuccinic acid synthetase (deficiency causes citrullinemia), and (4) argininosuccinate lyase. Medical management of these conditions is reduction of ammonia by withdrawing dietary protein and treatment with oral sodium benzoate (0.1–0.25 g/kg/d) and/or phenylbutyrate (0.25–0.6 g/kg/d).

Liver transplant in these urea cycle defects is considered for patients in whom dietary and medical management is ineffective. Although liver transplant corrects hyperammonemia, it does not completely correct the amino acid abnormality or reverse any preexisting neurotoxicity,[44] thus indicating that transplant should be considered prior to irreversible neurotoxicity.

Primary Oxalosis. In this rare autosomal recessive disorder, there is a deficiency of the hepatic enzyme alanine–glycoxylate aminotransferase, which leads to overproduction of oxalate with deposition in the cornea, brain, cardiac muscles, bones, and kidneys, leading to renal failure and systemic oxalosis. There is considerable controversy over the best management of this condition, but it is agreed that liver transplant is required before the development of renal failure or severe systemic oxalosis. In those infants who present with renal failure, combined liver and kidney transplant is required.[45–47] Because the enzyme deficiency results in overproduction of oxalate, auxiliary liver transplant is not suitable.

Hepatic Tumors

With the increasing success of liver transplant, children with either benign or malignant tumors are considered for liver transplant. Benign tumors include hemangiomas or hemoangioendotheliomas, adenomas, and focal nodular hyperplasia. These tumors are selected for liver transplant only if they cause hepatic dysfunction or are associated with an unacceptable increase in liver size and hepatic resection is impractical. Persistent heart failure in hemangioendotheliomas is best treated by selective hepatic embolism.

Malignant hepatic tumors such as hepatoblastoma or hepatocellular carcinoma that are either unresectable or refractory to chemotherapy are considered for liver transplant as long as there are no extrahepatic metastases.[48] It is important to carry out a search for extrahepatic metastases that includes CT of the chest and abdomen and regular monitoring of serum α-fetoprotein. A careful assessment of cardiac function is essential to exclude the cardiotoxic effects of chemotherapeutic drugs such as daunorubicin. It is best to time the transplant between chemotherapy treatments to prevent relapse or recurrence, and elective living-related transplant is particularly helpful in this situation. Children with rhabdomyosarcomas may not be considered for transplant because of the extent of the tumor and the early presence of extrahepatic metastases.

PRETRANSPLANT EVALUATION

The pretransplant evaluation of the patient (Table 60-2) is particularly important and should include the following:

1. Assessment of the severity of the liver disease and the possibility for medical management

TABLE 60-2 PRETRANSPLANT ASSESSMENT

Nutritional status
Height, weight, triceps skinfold, midarm muscle area, midarm circumference
Identification of hepatic complications
Ascites, varices
Cardiac assessment
Electrocardiography, echocardiography, chest radiography, cardiac catheterization
Respiratory function
Oxygen saturation,* ventilation-perfusion scan,* lung function tests†
Neurologic and developmental assessment
Electroencephalography, Bailey developmental scales, Stanford-Binet intelligence scales
Renal function
Urea, creatinine, electrolytes, urinary protein-to-creatinine ratio, chromium EDTA
Serology
Cytomegalovirus; Epstein-Barr virus; varicella-zoster virus; herpes simplex virus; hepatitis A, B, and C; HIV; measles
Hematology
Full blood count, platelets, blood group
Radiology
Ultrasonography of liver and spleen for vascular anatomy, wrist radiography for bone age and rickets
Dental assessment

EDTA = ethylenediaminetetraacetic acid; HIV = human immunodeficiency virus.
*If cyanosis present.
†In cystic fibrosis.

2. Assessment of the technical feasibility of the operation
3. Consideration of any contraindications
4. Psychological preparation of the family and child

The severity of liver disease should be assessed by evaluating the following:

1. Hepatic function. Listing for liver transplant is based on evidence of deterioration in hepatic function as indicated by albumin (> 35 g/L), coagulation time (INR > 1.4), and cholestasis, as evidenced by a rise in bilirubin (150 µmol/L, 8 mg/dL). Portal hypertension should be established by estimating the size of the spleen and portal vein by ultrasonography and by diagnosing esophageal and gastric varices by gastrointestinal endoscopy.
2. Renal function. Many children with acute or chronic liver failure will have abnormalities of renal function, including renal tubular acidosis, glomerulonephritis, acute tubular necrosis, and/or hepatorenal syndrome. Assessment of renal function is important to provide a baseline for the nephrotoxic effects of immunosuppressive drugs post-transplant and to consider the necessity for perioperative renal support.
3. Hematology. Baseline information on full blood count, platelets, and coagulopathy is obtained. Determination of blood group is essential for organ donor matching.
4. Serology. Previous evidence of varicella, measles, or infection with hepatitis A, B, or C viruses; cytomegalovirus (CMV); or Epstein-Barr virus (EBV) is important information for postoperative management. Donor grafts are matched by CMV status if possible.
5. Radiology. The rapid development of Doppler ultrasonography techniques has greatly improved the pretransplant assessment of vascular anatomy and the patency of hepatic vessels. It is unusual now to require MRI or angiography for these assessments. Evidence of retrograde flow and/or a reduction in the size of the portal vein (< 4 mm at the porta hepatis) suggest advancing portal hypertension and are indications for early transplant.[49] Children with biliary atresia have an increased incidence of abnormal vasculature, the hypovascular syndrome, which consists of an absent inferior vena cava, preduodenal or absent portal vein, azygous drainage from the liver, and polysplenia syndrome.[50] It may be associated with situs inversus, dextrocardia, or left atrial isomerism. Because these abnormalities may increase the technical risk of a liver transplant, it is important to diagnose these before transplant.[51]
6. Cardiac and respiratory assessment. Liver transplant is associated with significant hemodynamic changes during the operative and anhepatic phases. It is important, therefore, to have baseline information on both cardiac and respiratory function. Electrocardiography, echocardiography, and oxygen saturation will provide most of the necessary information. It is also important to determine the presence of congenital cardiac disease. Children with biliary atresia have an increased incidence of congenital cardiac disease, particularly atrial and ventricular septal defects, whereas peripheral pulmonary stenosis is a known feature of Alagille syndrome. Cardiomyopathy may develop secondary to tyrosinemia type I and the organicacidemias, although children with malignant tumors who have received chemotherapy need particular cardiac assessment. Cardiac catheterization is required in some cases to determine whether cardiac function is adequate to sustain the hemodynamic effect of liver transplant or if cardiac surgery is required preoperatively. If the cardiac defect is inoperable, liver transplant occasionally may be contraindicated. A small percentage of children with end-stage liver disease develop intrapulmonary shunts (hepatopulmonary syndrome). Clinical signs include cyanosis, digital clubbing, and reduced oxygen saturation. The diagnosis can be confirmed by bubble echocardiography, ventilation-perfusion scans, and/or cardiac catheterization.[32]
7. Neurodevelopmental assessment. Because the aim of liver transplant is to improve quality of life, it is important to identify any preexisting neurologic or psychological defects not only to consider whether they would be reversible post-transplant but also to evaluate the necessity for corrective management.[30,31]
8. Dental assessment. Advanced liver disease has an adverse affect on all aspects of growth and development, including dentition. Pretransplant dental problems include hypoplasia with staining of the teeth and gingival hyperplasia. Because gingival hyperplasia is a significant side effect of cyclosporine immunosuppression, it is important to establish good dental hygiene in the patient prior to transplant.[52]

CONTRAINDICATIONS FOR LIVER TRANSPLANT

With increasing experience, there are fewer contraindications to transplant. Although historically considered difficult, age < 1 year and size < 10 kg are no longer contraindications for transplant. Portal vein thrombosis increases the technical risk of the surgery, but it can now be managed with venous or prosthetic grafts. Vascular abnormalities such as the hypovascular syndrome are no longer considered contraindications. Although infection with human immunodeficiency virus (HIV) was a contraindication, the improvement in long-term prognosis with antiviral drugs means that this disease can be controlled before transplant. The following contraindications remain:

1. Severe systemic sepsis (in particular, fungal sepsis) at the time of operation. It is important that the operation be deferred until the infection has been appropriately treated.
2. Malignant hepatic tumors with confirmed extrahepatic metastases.[53]
3. Severe extrahepatic disease that is not considered reversible following liver transplant. This includes severe cardiopulmonary disease for which there is no possibility of corrective surgery or severe structural brain damage with a poor prognosis.
4. Multiorgan failure, especially owing to mitochondrial cytopathy,[54] because it has been shown that unless the

mitochondrial defect is confined to the liver, liver transplant is not curative.

5. Alpers disease and sodium valproate toxicity, related disorders in which defects in the respiratory chain have been identified in some patients. Liver transplant is contraindicated in the presence of these diseases in the same way as in the case of mitochondrial cytopathies because of the progression of neurodegeneration despite transplant.[55]
6. Recurrent disease. Hepatitis B and C have a recurrence rate of 90 to 100% post-transplant but can now be treated with antiviral agents before and after transplant.[56,57] Autoimmune liver disease recurs in 24% of cases, as does primary sclerosing cholangitis. Although liver transplant is not contraindicated for these conditions, the rate of recurrence must form part of the counseling of families. Autoimmune hemolytic anemia in association with giant cell hepatitis is a rare and fatal disease in which there is a 100% recurrence rate post-transplant, and transplant is not recommended.[58]

PREPARATION FOR LIVER TRANSPLANT

Immunization

Most units consider live vaccines to be contraindicated after liver transplant because of the risk of dissemination secondary to immunosuppression. It is therefore better to complete normal immunizations before transplant. This includes diphtheria, tetanus, polio, Pneumovax for protection from streptococcal pneumonia, and *Haemophilus influenzae* type b vaccine for protection against *H. influenzae*. In children older than 6 months, measles, mumps, rubella, and varicella vaccinations should be offered in addition to hepatitis A and B vaccination.

Management of Hepatic Complications

It is important to ensure that specific hepatic complications are appropriately managed while the patient waits for transplant.

Recurrent variceal bleeding should be managed as described (see Chapter 59, "Treatment of End-Stage Liver Disease"), with sclerotherapy or esophageal varix ligation. Difficult or intractable variceal bleeding may require the insertion of a transjugular intrahepatic portal systemic shunt.[59]

Sepsis that includes ascending cholangitis and spontaneous bacterial peritonitis should be treated with broad-spectrum antibiotics, whereas in children awaiting transplant for acute liver failure, prophylactic antifungal therapy is essential.

Ascites should be managed with diuretics and restriction of salt. Intervention with hemodialysis and hemofiltration should be considered if acute renal failure or hepatorenal failure develops.[60]

Nutritional Support

The importance of nutritional support has been demonstrated with studies indicating that nutritional status at liver transplant is an important prognostic factor in survival.[61,62]

The main purpose of nutritional therapy is to prevent or reverse the malnutrition associated with liver disease and to minimize fat malabsorption and ongoing catabolism. A high-calorie protein feed (150 to 200% estimated average requirement) may be effective (Table 60-3). It is possible to provide this high-energy intake with standard feeds using calorie supplements, but a moderate liver feed that can be adapted more easily may be better for infants. Because many of the modular or supplemented feeds are unpalatable, they are best given by nocturnal nasogastric enteral feeding or continuous enteral feeding. Occasionally, enteral feeding is not tolerated owing to severe hepatic complications such as ascites and intractable variceal bleeding; in these circumstances, parenteral nutrition is necessary.[63]

Psychological Preparation

Liver transplant is a major undertaking for the child and family; thus, psychological counseling, information giving, and preparation of the child and family are paramount using a skilled multidisciplinary team with play therapists, psychologists, and schoolteachers. Particular care is required when counseling parents and children with inborn errors of metabolism who are not dying of liver failure. These families must be aware of the risks and complications of liver transplant and must make informed decisions with regard to potential mortality and to the necessity for long-term immunosuppression compared with medical treatment available for their children's conditions.

Parents of children who develop acute liver failure may be too stressed to fully appreciate the implications and consequences of liver transplant. In these families, counseling—in particular, counseling of the child—should continue postoperatively.

TABLE 60-3 NUTRITIONAL SUPPORT IN INFANTS AND CHILDREN UNDERGOING LIVER TRANSPLANT*

	PREOPERATIVE	POSTOPERATIVE
Carbohydrate (g/kg/d)	Glucose polymer 15–20	Glucose 6–8
Protein (g/kg/d)	Low-salt protein 3–4	Whole protein 2.5–3
Fat (g/kg/d)	40–60% MCT 8	80–90% LCT 5–6
Energy intake (EAR)	120–150%	120%

Adapted from Kelly DA and Mayer ADM.[64]

EAR = estimated average requirement; LCT = long-chain triglyceride; MCT = medium-chain triglyceride.

*Best provided as a modular feed in infants and as calorie supplements in older children.

LIVER TRANSPLANT SURGERY

The organization of liver transplant is complex and involves a large multidisciplinary team. The process involves four stages: organ procurement, the donor operation, the "back-table" operation, and the recipient operation.

Organ Procurement

Organ donation and procurement are handled regionally or nationally, depending on geographic variation, but all countries have a national network (United Networks for Organ Sharing [UNOS] in the United States, United Kingdom Transplant Support Service Authority [UKTSSA] in the United Kingdom, and Eurotransplant in Europe). Once patients are accepted by the transplant team, they are listed and prioritized according to the severity of liver disease. All countries recognize a priority system, which allows patients with acute fulminant hepatic failure the greatest prioritization. Many countries use a system that subsequently and sequentially prioritizes patients in intensive care, in hospitals, or at home. In the United States, a scoring system (PELD) is used to prioritize patients who do not have acute fulminant hepatic failure. The majority of liver grafts are retrieved from heart-beating donors, although there are increasing donations from living-related donors. The procurement coordinator is responsible for establishing the suitability of potential cadaveric organs, for coordinating the procurement team, and for the donor operation. Liver grafts are matched by size, blood group, and (for CMV-negative children) CMV status. There are no absolute age limits, but, in general, malignancy (except localized brain tumors), uncontrolled bacterial sepsis, and HIV positivity remain absolute contraindications for acceptance as donors.[64]

The development of reduction hepatectomy has extended the size range applicable to young children, but the donor shortage has led to replacement of reduction hepatectomies with split-liver grafts.

Donor Operation

It is usual to retrieve the liver from a cadaver donor as part of a multiorgan operation in which liver, kidneys, heart, lungs, small bowel, corneas, skin, and bone may also be removed. It is important to maintain appropriate hemodynamic stability and ventilation while paralyzing agents are given to prevent spinal reflexes and broad-spectrum antibiotics are used to prevent infection. The liver is evaluated to identify abnormal arterial anatomy, which is particularly important for split-liver grafting. The porta hepatis is dissected, and the common bile duct is divided. The common hepatic artery, the superior mesenteric vein, and the hepatic veins are identified. Once the cardiothoracic organs are mobilized, heparin is administered to achieve full anticoagulation, and the abdominal organs are perfused with ice-cold preservation solution and packed with ice slush to achieve rapid cooling. Liver dissection is completed once the cardiothoracic organs have been removed. The hepatic artery is resected with a patch of aorta at the origin of the celiac trunk. The portal vein is divided at the confluence with the superior mesenteric and splenic veins. The infrahepatic vena cava is divided above the origins of the renal veins, whereas the suprahepatic vena cava is divided at the junction of the right atrium. Once the liver is removed, the hepatic artery and portal vein are flushed with preservation solution, and the bile duct is rinsed. The liver is hermetically sealed in a plastic bag, immersed in preservation solution, and transported, packed in ice.

Back-Table Operation

The back-table operation is particularly important for reduction hepatectomies and split-liver grafting. It is usually performed at the recipient hospital at the same time as the hepatectomy of the recipient. If a whole-liver graft is being used, the back-table operation is straightforward, but in the majority of pediatric liver transplants, either a liver reduction or a split-liver graft is performed.

Some units recommend that liver reduction or splitting be performed in situ as part of the donor operation, which has the advantage that the surgery is performed in a well-perfused functioning liver, without the risk of warm ischemia. However, this increases the operating time at the donor hospital, which may compromise other donor organs. The principles of the liver reduction are based on the segmental anatomy of the liver.[65] The liver has eight segments, and although it is possible to use a single-segment liver graft for neonates, in practice, the liver is divided along the plane of the falciform ligament to produce a left lateral segmental graft (segments 2 and 3) drained by the left hepatic bile duct (Figure 60-2). The common bile duct, portal vein, and hepatic artery are all preserved with the left lateral segment. For a split-liver graft, the portal vein is preserved with the left graft, and the hepatic artery, common bile duct, and inferior vena cava are preserved with the right graft. At implant, an arterial anastomosis is required for the left split graft.[66–69] Cur-

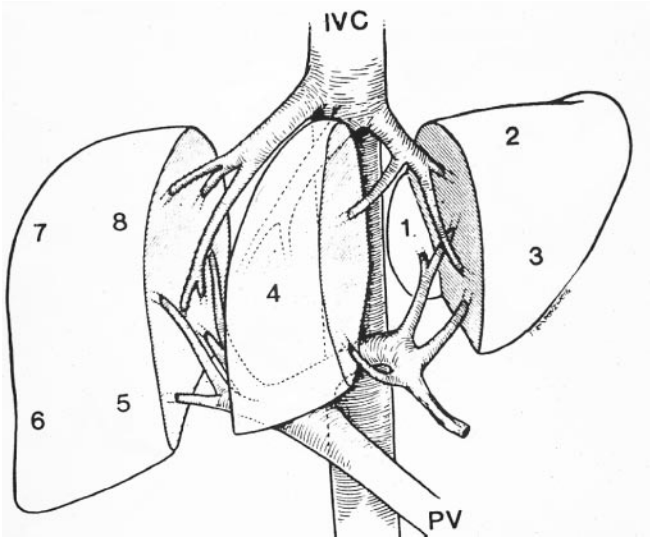

FIGURE 60-2 Schematic diagram of liver demonstrating eight segments. The left lateral segments 2 and 3 are most commonly used for reduction hepatectomy, split livers, living-related transplant, or auxiliary transplant.

rently, split-liver grafting is performed only using high-quality donor livers because of concerns related to primary graft dysfunction.

Recipient Operation

Management of the recipient operation has been much improved by an understanding of coagulation disorders, improved monitoring, and sophisticated hemostatic techniques that have reduced transfusion requirements and allowed better hemodynamic stability. Constant monitoring of electrolytes and blood gases and coagulation is essential. Thromboelastography, if available, is helpful to assess coagulation. Adequate supplementation of bicarbonate, electrolyte solutions, coagulation products, and platelets is essential.

In adults and older children, venovenous bypass is used, in which blood is diverted from the portal and intrahepatic cable circulation to the superior vena cava, reducing portal hypertension and intestinal congestion when the portal vein is clamped. This technique also improves venous return and renal perfusion when the vena cava is clamped during the hepatectomy phase.

In patients who have had no previous abdominal operations, the hepatectomy is straightforward. The liver is mobilized, with division of adhesions and ligamentus attachments. The porta hepatis is dissected, and the bile duct, hepatic artery, and portal vein are divided. In children with biliary atresia following a Kasai portoenterostomy, the hepatic dissection is more difficult, and there is a higher risk of gastrointestinal perforation.

It is important to carry out graft implant quickly to minimize warm ischemic injury that occurs as soon as the liver graft is removed from the cold preservation fluid. If a whole graft is being implanted, the suprahepatic vena cava, infrahepatic vena cava, and portal vein are anastomosed to the equivalent recipient vessels. If a left lateral segment graft is being performed, a triangular incision is made on the anterior aspect of the recipient vena cava to anastomose the graft left hepatic vein. A similar procedure is carried out for a split-liver graft. Once the venous anastomoses are complete, the liver is flushed with a warm rinsing solution, and the venous clamps are removed. The arterial anastomosis is carried out once the liver has been perfused from the portal vein. The donor celiac artery is anastomosed to the bifurcation of the recipient hepatic and gastroduodenal or splenic arteries. A donor arterial graft may be required to act as a conduit in children with small or aberrant vessels. The biliary anastomosis is the last to be performed. In adults and larger children without biliary pathology, the donor recipient ducts may be joined together to form a duct-to-duct anastomosis. Children with biliary atresia and those weighing less than 40 kg require a choledochojejunostomy using a Roux-en-Y loop of recipient jejunum.

Once the anastomosis is completed, the operative field is examined for hemostasis, and perfusion of the liver is established. If the liver graft is too large to permit abdominal closure without compromising hepatic venous outflow, then either a Silastic patch may be inserted or the abdomen may be left open temporarily until the liver has reduced in size.

Living-Related Liver Transplant

The shortage of suitable organ donors for young infants led to the development of living-related liver transplant.[70] This technique not only improves the supply of liver grafts for small children, it also allows optimal timing and reduces the stress of waiting for a suitable organ. In addition, the graft is obtained from a healthy individual with minimal preservation time.

The operation has received wide acceptance in Japan, where cadaveric transplant has not been possible until recently. The graft obtained from a live donor is usually a left lateral segmental graft. The liver parenchyma is divided along the line of the falciform ligament, keeping the blood supply intact. The bile duct, hepatic artery, portal vein, and hepatic vein are divided, and the graft is flushed with cold preservation fluid. Microvascular techniques are required during implant to reduce the risk of thrombosis.[71]

Although excellent results have been obtained,[72] particularly in Japan, the case for living-related transplant remains controversial because there are potential risks to the donor. Even in healthy individuals, partial hepatectomy has an appreciable morbidity, with an estimated risk of mortality of 1 in 250. It is important that donors are not only carefully evaluated for anesthetic risk, blood group compatibility, liver size, and anatomy but also that they are fully informed about the dangers of the procedure and, more importantly, the prospect of finding a cadaver graft for their child. Current organ donor shortages mean that most units will continue to offer living-related transplant.

Auxiliary Liver Transplant

In auxiliary liver transplant, part of the donor liver (usually segments 2 and 3) is implanted beside or in continuity with the native liver. The main purpose of this form of liver transplant is to ensure that the native liver is retained in the event of graft failure or for the future development of gene therapy. This operation is advisable for patients with metabolic liver disease secondary to hepatic enzyme deficiency in whom the liver is functioning normally but for whom liver transplant is considered because of the development of severe extrahepatic disease. Auxiliary transplant is now accepted therapy for Crigler-Najjar syndrome type I[42] and also for propionicacidemia and ornithine transcarbamalase deficiency.[73]

The role of auxiliary liver transplant in the management of fulminant hepatic failure is more controversial. The rationale for using this technique in this condition is that, with time, the native liver may regenerate. Two recent studies in adults demonstrated that the native liver regenerates in approximately half of the patients.[74,75]

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Postoperative Management

Immediate postoperative management is based on ensuring hemodynamic stability, respiratory function, and fluid balance. Most patients remain in the intensive care unit for 24 or 48 hours until liver function is satisfactory, with good

hepatic artery and portal vein flow on Doppler ultrasonography. Infants with severe malnutrition owing to chronic liver disease or patients with hepatic coma secondary to fulminant hepatic failure may require a more prolonged period of intensive care.[6]

The aim of fluid management is to maintain circulating volume with crystalloid while replacing wound losses with colloid. It is important to ensure that the urine output is > 1 mL/kg/h and that central venous pressure is satisfactory (> 5–6 mm Hg). To prevent postoperative hepatic artery thrombosis, hemoglobin should be maintained between 8 and 10 g/L.[76] Immunosuppression is started immediately postoperatively, and the protocol will vary with center and experience. Standard protocols now include (1) cyclosporine microemulsion (Neoral), prednisolone, and azathioprine or (2) tacrolimus combined with low-dose steroids. Mycophenolate mofetil is a new immunosuppressive agent that may replace azathioprine in time (Table 60-4).[77,78] Recent studies that induce immunosuppression using the recently developed interleukin-2 antibodies, which selectively block the interleukin-2 receptors on T cells, reduce nephrotoxicity but are not yet in established practice.[79] Sirolimus, which is a macrolide antibiotic that prevents T-cell proliferation, is also sparing to the kidneys because it does not inhibit calcineurim. Its use in children is anecdotal.[80]

Broad-spectrum antibiotics should be prescribed for 48 hours unless there is persistent infection. Fluconazole or liposomal amphotericin is advisable in children with acute liver failure or in those who have a second laparotomy. Low-dose cotrimoxazole or trimethoprim is used for prophylaxis against *Pneumocystis carinii*, and oral nystatin and amphotericin are used to prevent oral and esophageal candidiasis for 6 to 12 months.

Most units use prophylaxis for CMV infection for CMV-negative recipients of a CMV-positive donor organ. Acyclovir (1,500 mg/m^2 IV) or ganciclovir (10 mg/kg IV/d) usually prevents CMV infection in the short term.[81] Although there is no proven prophylaxis for EBV, many units use either acyclovir or ganciclovir for this purpose.

Other medications include ranitidine (3 mg/kg), sucralfate (2–3 g qds), or omeprazole (10–20 mg IV bid) as prophylaxis against stress ulceration.

TABLE 60-4 POSTOPERATIVE IMMUNOSUPPRESSION

	TROUGH LEVELS*	
TIME OF INTRODUCTION (MO)	CYCLOSPORIN A (MICROEMULSION) (5 MG/KG BD)	TACROLIMUS (0.15 MG/KG)
0–1	180–230 ng/L	10–15 ng/mL
1–3	100–160 ng/L	8–12 ng/mL
3–12	70–110 ng/L	5–8 ng/mL
>12	60–90 ng/L	3–5 ng/mL

TIME OF INTRODUCTION	IMMUNOSUPPRESSANT
3–12	Prednisolone 2 mg/kg
12	Azathioprine 2 mg/kg
—	Mycophenolate mofetil 1–3 g/d

*Whole-blood monoclonal assay.

Because vascular thrombosis is higher in children than in adults, prophylaxis with antiplatelet drugs such as aspirin (3 mg/kg/d) and dipyridamole (25–50 mg tds) may be useful. Antihypertensive medication is usually necessary secondary to immunosuppressive treatment with steroids, tacrolimus, or cyclosporin A. Nifedipine (5–10 mg, 4 to 6 hourly) or atenolol (25–50 mg/d) may be required.[64]

Some children will require parenteral nutrition perioperatively, but the majority will begin enteral feeds between days 3 and 5. It is important to maintain adequate calories (see Table 60-3) and to encourage normal feeding.

Postoperative Complications

Early postoperative complications include primary graft nonfunction, surgical complications (eg, intra-abdominal hemorrhage), vascular thrombosis, and venous outflow obstruction.

The most common cause of primary graft failure is primary nonfunctioning of the graft or thrombosis of the hepatic artery or portal vein.[82] Primary nonfunctioning of the transplanted liver occurs within 48 hours. The cause is unknown and may be related to donor factors. The presentation is with prolonged coagulation (INR > 3), raised aminotransferases (> 5,000–10,000 IU/L), a rising bilirubin, and, ultimately, a rise in serum potassium (> 6 IU/L). Primary graft function may occasionally be secondary to hyperacute rejection, the diagnosis of which can be made only by liver biopsy. The only appropriate management is retransplant.

Hepatic artery thrombosis occurs in approximately 10% of pediatric liver grafts, and its frequency has decreased considerably following the introduction of reduction hepatectomy or living-related transplant because of the increased size of the donor vessel.[83] The development of microsurgical techniques for hepatic arterial reconstruction has been additionally beneficial (Figure 60-3).[84]

Portal vein thrombosis is a less common complication, but its incidence has not been altered with reduction or split-

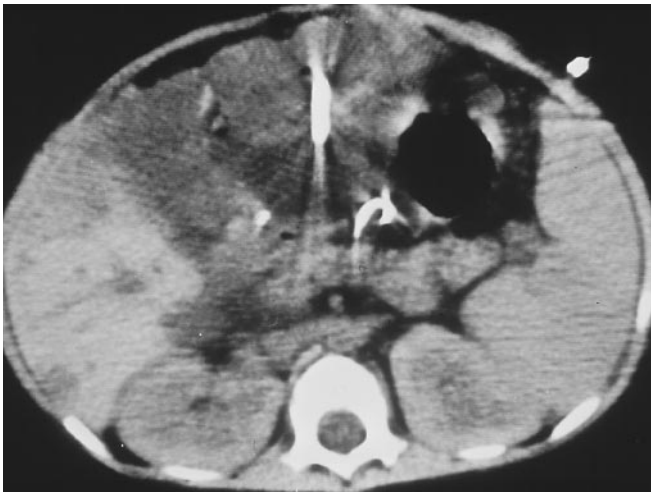

FIGURE 60-3 Hepatic artery thrombosis is a potentially life-threatening complication following liver transplant. This computed tomographic scan demonstrates a large area of infarction with abscess formation following thrombosis of the hepatic artery 7 days post-transplant. The child was successfully retransplanted.

liver techniques, although there are some advances in the management of this complication with innovative surgery.[85]

The diagnosis of hepatic artery or portal vein thrombosis is made by Doppler ultrasonography and is confirmed by angiography. Both complications may be treated by emergency thrombectomy and the use of anticoagulants or infusion of thrombolytic agents such as streptokinase. If hepatic perfusion is not adequately re-established, retransplant is required. Hepatic artery ischemia ultimately results in biliary complications, such as leaks and strictures, or hepatic abscesses.[86]

Hemorrhage from the cut surface of the liver is an occasional complication. It should be managed conservatively unless there is persistent bleeding or hemodynamic instability. Abdominal tamponade from hemorrhage may decrease blood flow and lead to renal failure.

Many factors may predispose the patient to postoperative renal failure within the first week. Patients with impaired renal function preoperatively may be further compromised by intraoperative cardiovascular instability or inotropic support. In addition, the administration of nephrotoxic immunosuppression such as cyclosporine or tacrolimus may precipitate renal failure.[64]

Oliguria (< 1 mL/kg) is common and may be managed conservatively with fluid replacement or a furosemide challenge (1–2 mg/kg IV). The development of anuria with an increase in urea, creatinine, and potassium necessitates renal dialysis or hemofiltration.

Rejection

Acute cellular rejection may occur between 7 and 10 days postoperatively. The incidence of acute rejection varies. It is less common in infants (20%) but increases to 50 to 60% in older children and adults.[87,88] Clinical features include fever, irritability, abdominal discomfort, and, occasionally, ascites. The diagnosis is confirmed by detecting a rise in bilirubin, alkaline phosphate, γ-glutamyl transpeptidase, and aspartate and alanine transaminases. Histologic confirmation is essential. Acute rejection is indicated by demonstration of a mixed inflammatory infiltrate, including eosinophils in portal tracts. There is usually a subendothelial lymphoid infiltration of blood vessels (endotheliitis) and inflammation and infiltration of the bile ducts.[89] Most units will treat acute rejection initially by using intravenous methylprednisolone in doses varying from 20 mg/kg/d for 3 days to 45 mg/kg in total, in association with an increase in baseline immunosuppression. If there is insufficient histologic or biochemical response, treatment with methylprednisolone may be repeated, but if the rejection is unresponsive to steroids, then it is usual to convert to a more potent immunosuppressive drug such as tacrolimus or to add other agents, such as muromonab-CD3, mycophenolate mofetil, or sirolimus.[90]

Cyclosporin A (Sandimmune) has been replaced by the partially water-soluble cyclosporine microemulsion Neoral. Several studies in both adult and pediatric patients post-transplant have indicated that Neoral is very well absorbed, with a peak absorption at 2 hours and a half-life of approximately 8 to 12 hours[77,91–93] in patients immediately post-transplant and in stable patients in the long term. The incidence of side effects with Neoral is similar to the range of side effects with Sandimmune, namely, gingival hyperplasia and hirsutism, whereas the incidence of hypertension and nephrotoxicity is less. It is possible that monitoring C2 levels (2 hours after dosing) may be more effective than trough level monitoring for preventing rejection and reducing side effects.[94]

Experience with tacrolimus (FK506) is increasing, and long-term prospective therapeutic studies comparing tacrolimus and Neoral are in progress. Preliminary results with tacrolimus indicate that it is an extremely effective immunosuppressive drug in the prevention of acute rejection.[78,90] It does not cause hirsutism or gingival hyperplasia, but there has been an increase in serious neurologic side effects, lymphoproliferative disease, and hypertrophic cardiomyopathy in children taking high doses of tacrolimus.[95]

Many units consider prednisolone withdrawal at postoperative intervals ranging from 3 to 12 months, which has proved easier to accomplish using tacrolimus therapy.[96]

Chronic rejection occurs in less than 10% of children after transplant.[88] Clinical features include gradual onset of jaundice, pruritus, and pale stools, indicating biliary obstruction. The diagnosis may be confirmed by detecting biochemical changes that include a relative increase in bilirubin, alkaline phosphatase, and γ-glutamyl transpeptidase compared with aminotransferases. Liver histology demonstrates extensive damage and loss to bile ducts (vanishing bile duct syndrome with arterial obliteration and fibrosis). There may be a response to an increase in immunosuppression (eg, a change to tacrolimus[97] or the addition of mycophenolate mofetil). Nonresponse to medical management requires retransplant.[98]

Biliary Complications

The range of biliary complications after transplant includes biliary leaks and strictures, which have increased with the use of reduction hepatectomies.[86] Biliary strictures may develop secondary to an anastomotic stricture related to edema of the bile ducts or hepatic artery ischemia. Biliary leaks may be secondary to leakage from the cut surface of the reduction hepatectomy or from hepatic artery ischemia. The majority of biliary leaks settle with conservative management, but large leaks that cause biliary peritonitis, biliary abscesses, or sepsis should have surgical drainage and reconstruction. The management of biliary strictures should initially be conservative, with ursodeoxycholic acid (20 mg/kg) used to allow edema to settle. Persistent strictures leading to biliary dilatation should initially be managed radiologically, using percutaneous transhepatic cholangiography. The dilated biliary tree is cannulated, and external biliary drainage is established. Once sepsis and edema of the biliary tree have reduced, biliary dilatation may be performed using balloons and biliary stents. Surgical reconstruction is required for anastomotic or recurrent biliary strictures if interventional radiology is unsuccessful.

Other Complications and Sepsis

Persistent drain losses may be due to preoperative ascites or secondary to rejection, sepsis, hepatic obstruction, or bacterial peritonitis. This troublesome complication leads to acidosis and coagulopathy owing to loss of bicarbonate and coagulation factors in the ascitic fluid. It is best to treat the primary cause if possible and to manage the condition conservatively with fluid restriction and diuretics.

Infection is still the most common complication following liver transplant.[6,99] Bacterial infections are most common immediately after transplant and are related to the high doses of immunosuppressive drugs and central line infections. The main bacteria identified are *Streptococcus faecalis* and *Streptococcus viridans*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus*. Postoperative fungal infections are more likely in patients undergoing transplant for acute liver failure or in children undergoing laparotomies for technical complications post-transplant.[100] The most common fungal infection is with *Candida albicans*, but aspergillosis may occur in 20% of patients with fungal infections.

More recently, vancomycin-resistant enterococcus has become a significant pathogen following both liver and small bowel/liver transplant.[101] Risk factors for developing vancomycin-resistant enterococcus are recurrent central line infections treated with vancomycin therapy, but it is important to differentiate between patients who are colonized and those who have systemic infection. The mortality of patients with systemic infection is high but improved with new agents such as quinupristin and linezolide.

Late Complications Post-transplant

Late complications may occur at any time after transplant. They include CMV or EBV infection, side effects of immunosuppression, post-transplant lymphoproliferative disease (PTLD), late biliary strictures, and hepatic artery or portal vein thrombosis. Chronic rejection may occur at any time, particularly as a result of nonadherence.

Infection with CMV occurs between 5 and 6 weeks following liver transplant. The risk of CMV disease is highest in CMV-negative recipients who receive an organ from a CMV-positive donor.[81,102,103] Although prophylaxis with intravenous ganciclovir (5 mg/kg/d) and intravenous immunoglobulins is more effective than prophylaxis with ganciclovir alone, approximately 20% of patients will develop primary infection. Treatment with intravenous ganciclovir and intravenous immunoglobulin is usually effective.[104]

The development of primary infection with EBV is a significant problem in pediatric transplant. Because two-thirds of children undergoing liver transplant are likely to be EBV negative before transplant and 75% of this group will develop primary infection after transplant,[79] it is essential to diagnose primary EBV infection to reduce immunosuppression and thus prevent the development of lymphoproliferative disease.[105]

There is a well-known association between the development of primary EBV infection and the subsequent development of post-transplant lymphoproliferative disease.[105] EBV stimulates lymphocyte proliferation, which ranges from benign hyperplasia to malignant lymphoma. The clinical features are varied and include symptoms of infections, mononucleosis (tonsillitis and lymphadenopathy), isolated lymph node involvement, and EBV infiltration in the liver, gut, and iris, ranging from isolated organ involvement to malignant lymphoma.[106]

Considerable efforts have been devoted to the early diagnosis of EBV infection and PTLD. It is now possible to measure EBV polymerase chain reaction (PCR) prospectively and to reduce immunosuppression when high levels are achieved.[106–108] Serologic confirmation of EBV infection (EBV IgM antibodies) is usually a late feature, and it may be more appropriate to measure EBV PCR sequentially. Patients who develop gut PTLD may present with diarrhea, weight loss, and gastrointestinal bleeding. The diagnosis should be confirmed histologically by biopsy of the appropriate tissue (liver, gut).[107] Characteristic histology includes polymorphic B-cell proliferation or lymphomatous features of nuclear atypia necrosis. Immunofluorescent staining of heavy- and light-chain immunoglobulins may differentiate monoclonal from polyclonal infiltrates, which has significant prognostic implications. Confirmation of EBV involvement may be obtained by using in situ hybridization techniques to demonstrate EBV-encoded small nuclear ribonucleic acid.[108] It was initially felt that the incidence of PTLD was higher with tacrolimus than with cyclosporine, but this may be due to use of inappropriately high levels of tacrolimus when the drug was initially released.[109] First-line treatment for PTLD is reduction of immunosuppression. Acyclovir (1,500 mg/m^2/d) or ganciclovir (5 mg/kg/d) may also be prescribed, but there is no clear evidence that either is effective. Use of rituximab, a monoclonal antibody, and human leukocyte antigen–matched T-cell therapy directed against EBV are under investigation and may prove effective.[110,111] As reduction of immunosuppression leads inevitably to graft rejection, balancing treatment for PTLD and rejection may be difficult. Under these circumstances (or if lymphoproliferative disease becomes overtly malignant), chemotherapy is required.[112]

Late biliary strictures may be due to hepatic artery ischemia or thrombosis and may lead to recurrent cholangitis, hepatic abscess, and the development of secondary biliary cirrhosis. Although they may be treated radiologically, as described above, retransplant may be required for the development of biliary cirrhosis.[113]

Portal vein stenosis owing to anastomotic stricture may lead to portal hypertension with varices and splenomegaly. Initial treatment is radiologic by venoplasty, but surgical reconstruction with an intrahepatic mesoportal shunt may be required.[85,114]

Gastrointestinal perforation is an infrequent complication after liver transplant. It is related to previous abdominal surgery and to malnutrition.[114,115] Some units take this potential complication so seriously that an elective laparotomy is planned at 7 and 14 days post-transplant.[116]

SURVIVAL

Current results from international centers indicate that 1-year survival following liver transplant may be in excess

of 90%.[3–6] Long-term survival (5–10 years) ranges from 60 to 80%.[3,117] Preliminary results suggest that patients who undergo elective living-related transplant have a higher 1-year survival rate (94%) than those of equivalent hepatic status receiving cadaveric grafts (78%).[118]

Many different factors influence survival. Initially, age at transplant was considered a significant risk factor, and transplant was contraindicated in infants aged under 1 year and weighing less than 10 kg.[119] Reduction hepatectomy and living-related transplant have not only reduced the waiting-list mortality in this group of children[120] and extended liver transplant to this young age group,[6] they also have demonstrated that equivalent survival may be achieved in infants transplanted under the age of 1 year compared with that of older children (Figure 60-4).[121]

It has previously been demonstrated that protein malnutrition at the time of liver transplant has a significant influence on both morbidity and mortality.[61,62] The degree of malnutrition, in addition to the severity of liver disease, has been demonstrated to have a significant effect on short-term survival,[29,122,123] and a number of studies have demonstrated improved survival for children with transplants and metabolic liver disease compared with those with chronic liver disease or fulminant hepatitis (see Figure 60-4).

In general, outcome is not related to diagnosis, although children with fulminant hepatic failure are less likely to survive the initial transplant.[113] An important aspect contributing to improved survival has been the increase in surgical and medical experience,[124] particularly with the development of innovative surgery.

There has also been an improvement in the rate of retransplant for technical problems or graft failure secondary to chronic rejection.[113,125] It is clear that although the rate of retransplant has fallen with increased surgical experience, survival following retransplant is considerably less. Children receiving more than one graft have a 50% 1-year survival compared with 90% in children receiving only one graft. This may be related to the factors contributing to the necessity for retransplant, such as primary graft nonfunction, technical problems, and the development of multiorgan failure.

In some instances, survival may be affected by the recurrence of the original disease. Recurrence of hepatitis B virus (HBV) infection is 100% in patients who were positive for HBV deoxyribonucleic acid (DNA) or hepatitis B e antigen at the time of their initial operation.[126] Recurrent HBV disease is associated with chronic hepatitis or cirrhosis (79%), submassive necrosis (9%), or fibrosing cholestatic hepatitis (25%).[56,127] The recurrence rate of chronic hepatitis B post-transplant has been much reduced by therapy with the nucleoside analog lamivudine.[128]

Chronic hepatitis C is a rare indication for transplant in children, but recurrence is inevitable in those children who were infected preoperatively before screening for hepatitis C virus became available[129,130] and in those who were infected perioperatively.[131–133] The outcome for these children is varied, with the majority developing nonspecific hepatitis. However, a minority develop rapidly progressive liver failure. Treatment for hepatitis C infection has improved with the combination of interferon and ribavirin, which achieves a 45% sustained remission rate overall.[134]

It is now clear that there is recurrence of autoimmune hepatitis both immunologically and histologically post-transplant in 25% of cases. It may be more severe than the original disease,[135] and it is important to ensure that immunosuppression with steroids is continued in this group of patients. A variant of autoimmune liver disease, giant cell hepatitis with autoimmune hemolytic anemia, has also been demonstrated to recur post-transplant.[58] Recurrence of malignant hepatic tumors in children transplanted for hepatoblastoma or hepatocellular carcinoma is directly related to the presence of extrahepatic metastases at the time of surgery.[48,53]

DE NOVO AUTOIMMUNE HEPATITIS

Several studies have documented the development of autoantibodies (antinuclear antibodies, smooth muscle antibodies, and, rarely, liver-kidney antibodies) post-transplant in both children and adults in recipients without autoimmune disease pretransplant,[136,137] which is associated with a graft hepatitis and progressive fibrosis. The hepatitis resolves with steroid therapy or azathioprine.[138,139]

LONG-TERM RENAL FUNCTION

The calcineurin inhibitors cyclosporine and tacrolimus both cause nephrotoxicity, and 4 to 5% of patients develop severe

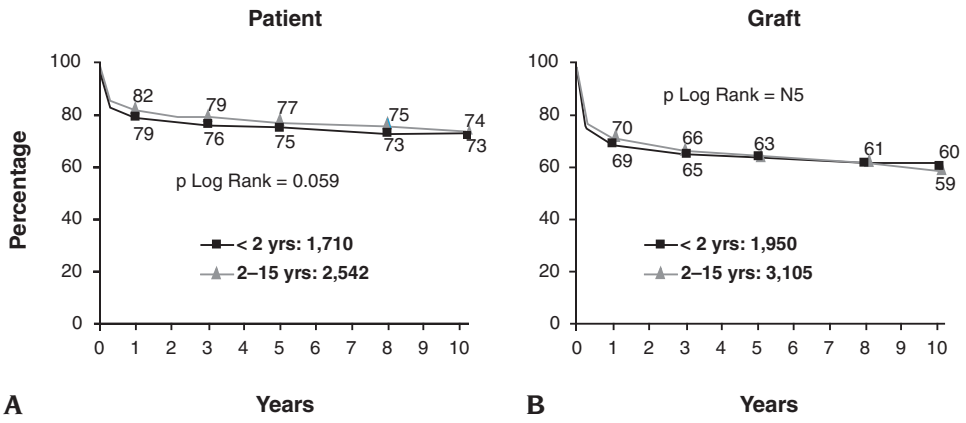

FIGURE 60-4 Patient (*A*) and graft (*B*). Survival of children following liver transplant less than and greater than 2 years at transplant, 1988 to 2001. Mean follow-up was 10 years. The survival of children older than 2 years (n = 2,542) for all indications was similar to those children under 2 years (n = 1,710) (*A*). There was no difference in graft survival (*B*). Adapted from the European Liver Transplant Registry, 2002.

chronic renal failure long term, requiring renal transplant. The use of low-dose calcineurin inhibitors or renal-sparing drugs such as mycophenolate mofetil or sirolimus for maintenance immunosuppression prevents significant renal dysfunction.[139,140] Acute postoperative hypertension is seen in 65% of children but persists long term only in 28%.[141]

HYPERLIPIDEMIA

As children survive longer, it is important to remember that both cyclosporine and sirolimus increase serum lipids, particularly cholesterol, and high levels may require transfer to tacrolimus or mycophenolate mofetil.[90]

TRANSPLANT TOLERANCE

It is now thought that 20% of adults will develop tolerance to the graft and can be withdrawn from immunosuppression.[142] Complete withdrawal of immunosuppression in children has not been documented.

QUALITY OF LIFE AFTER TRANSPLANT

It is now anticipated that children who survive liver transplant will achieve a normal lifestyle despite the necessity for continuous monitoring of immunosuppressive treatment. Children transplanted for certain metabolic liver diseases such as α_1-antitrypsin deficiency, Wilson disease, and tyrosinemia type I may have both phenotypic and functional recovery. Children with Crigler-Najjar syndrome type I have functional recovery of enzyme activity following either orthotopic or auxiliary liver transplant, whereas children with organicacidemias will have only palliation of their defect because the enzyme defect is not restricted to the liver (propionicacidemia or methylmalonicacidemia).[143] Children transplanted owing to urea cycle defects and organicacidemias may require protein restriction particularly during acute illness, reflecting the partial cure of their disease.

An important aspect in achieving normal quality of life is nutritional rehabilitation after transplant. Although early studies evaluating growth in children after liver transplant indicated that almost two-thirds did not achieve their growth potential,[144] recent studies have demonstrated that with appropriate nutritional support, 80% of survivors will achieve normal growth patterns and body habitus.[6,145] Nutritional rehabilitation begins in the first year, with a return to normal muscle and fat stores within 6 to 12 months after transplant.[6,145] Initially, weight gain may be excessive owing to the effects of steroids, increased appetite, and salt and water retention, but most children regain normal weight within 12 months, and the weight is maintained for the long term.

Linear growth may be delayed between 6 and 24 months, which is directly related to steroid dosage and preoperative stunting.[146] Children who were particularly growth retarded or stunted before transplant (height standard deviation score < –1) initially have rapid catch-up growth but may not achieve their genetic potential,[147,148] whereas children who were less stunted (height standard deviation score > –1) have slower catch-up growth but may eventually achieve normal height.

The growth-suppressive effects of corticosteroid therapy after liver transplant have been clearly demonstrated. Centers that discontinue steroids post-transplant or institute alternate-day steroids early have reported increased catch-up growth at an earlier stage.[149]

Future growth may depend on the etiology of the pretransplant disease. For instance, 50% of children who were transplanted for the hepatic complications of Alagille syndrome and who were growth retarded before transplant did not achieve normal height.[150]

Additional factors in the etiology of post-transplant growth failure may be behavioral feeding problems and the difficulties in establishing normal feeding. Before transplant, many children will have been fed unpalatable feeds, often by nasogastric tube, and may have missed their normal developmental milestones for chewing, swallowing, and feeding. A significant proportion of these patients will have difficulty establishing normal feeding regimens post-transplant and will require nocturnal enteral feeding for 1 to 2 years.[146]

An important aspect of long-term survival is the development of puberty. A long-term study from France has demonstrated that there are no differences between the genders in attaining puberty and developing secondary sexual characteristics.[148] Girls develop menarche, and successful pregnancies have been reported for females receiving both cyclosporine and tacrolimus immunosuppression.[151]

Side Effects of Immunosuppression

The side effects of immunosuppression are well known (Table 60-5). Hypertension is common with steroids, cyclosporine, and tacrolimus but tends to be short term and related to the intensity of immunosuppression. Growth failure and stunting related to steroids may have a significant effect on the ability to regain normal height. Hirsutism and gingival hyperplasia are recognized side effects of cyclosporine that are dose related and, although

cosmetic, have an important effect on quality of life, particularly in adolescence (Figure 60-5). There remains a long-term risk of PTLD, skin cancer, and other tumors.

Psychosocial Development

It is of particular concern that neurodevelopmental outcomes following liver transplant should be normal. Previous studies have demonstrated that there is an initial deterioration in psychosocial development in the first year after transplant, as noted by a deterioration in social skills, language development, and eye/hand coordination,[152] presumably related to the stress of the operation, the high doses of immunosuppression, and prolonged hospitalization. It is now known that most children will achieve normal psychosocial development within 1 to 2 years but that the rate of improvement is related to the age at the onset of liver disease and the age at the time of transplant.[153] Risk factors for persistent developmental delay include malnutrition at the time of transplant, length of hospital stay, and age at transplant, with younger children at particular risk of developmental delay.[31] In a longer-term study of a small group of children, 80% achieved normal height and weight measurements over a 5-year period, and all of the children attended school, but 30% had special educational needs. Psychological testing indicated that 75% of this group were functioning normally.[153–155]

The stress of liver transplant on family structure and dynamics is well known, although most parents indicate improved psychological symptoms following successful liver transplant. A longer-term study indicated that 20% of marriages dissolved and that 30% of families were considered to be functioning outside the normal range.[156]

FIGURE 60-5 Quality of life of children following liver transplant is an important aspect and may be affected by cosmetic side effects such as hirsutism (*A*) or gingival hyperplasia (*B*) secondary to cyclosporine.

NONCOMPLIANCE WITH THERAPY

Noncompliance with immunosuppressive therapy is less common in liver transplant recipients than in renal transplant recipients,[157,158] which may be related to the median age at renal transplant (14.3 years) compared with 2.5 years for liver transplant. It is possible that children who were grafted at a young age are more likely to accept medication through their adolescence, or there may be insufficient long-term data as yet.

SUMMARY

Liver transplant for acute or chronic liver failure or for metabolic liver disease is an effective therapy that restores good quality of life to over 80% of recipients. Considerable advances in medical and surgical expertise and immunosuppression have improved not only survival but also the quality of life for the majority of liver transplant recipients. It is essential to encourage both child and family to return to a normal life as far as possible, although continued counseling and support by a multidisciplinary team are essential. The long-term outlook for children receiving liver transplant in the twenty-first century is likely to be limited by organ donor shortages, the side effects of immunosuppressive drugs, and the potential development of post-transplant lymphoproliferative disease or other tumors. It is hoped that advances in molecular genetics will lead to effective gene therapy or hepatocyte transplant and reduce the need for solid organ transplant.[159,160]

CHAPTER 61

GALLBLADDER DISEASE

Annemarie Broderick, MB, BCh, MRCPI, MMedSc
Brian T. Sweeney, MB, BCh, Bao, MD

The role and importance of the gallbladder are summarized wittily in the following short poem:

> Chemo Memo
>
> Man's liver is a brownish blob
> That does a most prodigious job.
> It manufactures gall, or bile
> And normally keeps some on file
> Stored neatly in a pear shaped sac.
> From there the liver's yields attack
> The food man eats, to change its state
> By methods man can't duplicate,
> Or even halfway understand.
> He ought to treat this outsize gland,
> With due respect and loving care
> To keep it in top-notch repair,
> Because to get along at all
> Man needs an awful lot of gall[1]

The essential functions of bile or "gall" manufactured by the liver and stored in the gallbladder are to facilitate absorption of fats and fat-soluble vitamins from the diet and to secrete heavy metals such as copper from the body. Gallstones were recognized in ancient Egypt, but it was many centuries before the functions of the gallbladder and the relationship of gallstones to disease were understood. Up until the nineteenth century, it was (mistakenly) believed that the removal of the gallbladder was incompatible with life. The first cholecystectomy was not performed until 1882 in Berlin, and it was a great success.[2]

The gallbladder is a vesicular structure, usually found under the right lobe of the liver between the porta hepatis and inferior tip of the liver lying in the gallbladder fossa. It is covered by the same peritoneal covering as the liver.[3] The liver, bile ducts, and gallbladder arise from the primitive foregut. The cranial portion develops into the hepatic parenchyma and the intrahepatic ducts, and the more caudal section evolves into the gallbladder and extrahepatic bile ducts.[4] This chapter reviews the epidemiology, genetics, pathogenesis, diagnosis, and treatment of common gallbladder diseases with particular reference to children. Gallstone disease is the most expensive gastrointestinal disease in adults in the United States today[5]; therefore, most research has concentrated on adults. The literature and clinical practice pertinent to children, extrapolating from adult studies where necessary, are reviewed.

PHYSICAL CHEMISTRY COMPOSITION OF BILE

Bile is an aqueous solution composed of bile salts, cholesterol, phospholipid, water, electrolytes, and heavy metals, as well as proteins, immunoglobulin A, vitamins, and toxins.[6] The functions of bile are myriad and in part are dependent on the function of individual components. Bile salts in the intestine act as detergents, which solubilize and aid the absorption of dietary lipids and lipid-soluble vitamins. Bile is the major route of elimination of a large number of compounds, including cholesterol, bilirubin conjugates, drugs, and heavy metals, especially copper. Cholesterol elimination from the body occurs mainly in bile either as cholesterol or as bile salts, which are products of cholesterol metabolism. Bile also contains secretory immunoglobulin A, which may play a role in prevention of infection. Bile flow resulting from the active transport of bile acids into the canalicular lumen is termed bile acid dependent, and bile flow due to the transport of glutathione and bicarbonate is bile acid independent.[7] The bicarbonate and electrolyte concentrations of human bile differ little from serum.[6,8]

A constellation of transporters, which are found on hepatocytes and cholangiocytes, modulates bile composition. Transporters allow the uptake into hepatocytes of molecules such as cholesterol and bile salts and their subsequent export into the lumen of canaliculi. These transporters are discussed in the section dealing with gallstone formation.

EPIDEMIOLOGY

In adults living in the United States, gallbladder disease is one of the most expensive digestive diseases, and annual costs of treatment were estimated to total more than $6 billion dollars in 2001.[5] Treatment of children accounts for only a fraction of this budget because gallbladder disease is uncommon in childhood. Ascertaining the true prevalence of gallbladder disease in either adults or children is difficult because most patients with gallstones are asymptomatic. Studies of hospitalizations, surgical records, and autopsy series underestimate the prevalence of gallstone disease. The introduction of ultrasonography allowed non-

invasive screening for gallstone disease and therefore a more accurate estimate of prevalence. A study of gallstone prevalence in 1,570 children between the ages of 6 and 19 years in Bari, Italy, found ultrasonographic evidence of gallstones in just two asymptomatic girls, aged 13 and 18 years—a prevalence rate of 0.13%.[9] One of the two girls had a family history of gallstone disease, but the other had no recognized risk factors. In contrast, approximately 20.5 million adults in the United States are estimated to have gallstones based on extrapolation of the findings of 14,238 ultrasound examinations performed between 1988 and 1994 as part of the Third National Health and Nutrition Examination Survey (NHANES III) study.[10]

Within the United States, there are striking differences in cholesterol gallstone prevalence between ethnic groups. Native Americans have the highest rate of all groups in the United States. For example, the Pima Indians, a tribe in Arizona, were found to have a gallstone prevalence rate of 48.6%.[11] This rate was established in Pima Indians using an age- and sex-stratified random sample of 600 members of the tribe, by review of medical records, and by performing oral cholecystography in those without a history of cholecystectomy or a previous abnormal cholecystogram. In those aged 15 to 24 years, the prevalence was 5.9% in females and 0% in males. However, there was a dramatic increase in prevalence in females aged 25 to 34 years to 73.2%. In males aged 25 to 34 years, the increase was only to 4.4%. Prevalence rates in men did not approximate those of women until they were older than 55 years.[11] To investigate the reasons for this dramatic increase in gallstone prevalence in Pima Indians with age, bile composition and bile acid pool size of a group of 66 children and adolescents aged 9 to 21 years were studied. Bile cholesterol saturation increased during puberty in both genders but was 15% higher in females than in males. In males but not females, the bile acid pool increased. Hence, the metastable bile found in prepubertal children is altered by the increasing cholesterol concentration during puberty, and cholesterol precipitation and gallstone formation can occur.[12]

There are other medical conditions in children that are associated with a recognized increase in the prevalence of gallstone disease. These diseases include cystic fibrosis and hemolytic diseases, which increase the risk of pigment gallstones and are discussed in more detail later in this chapter.

As noted, the proportions of bile constituents change at puberty in both children and adolescent Pima Indians and also in white children.[13,14] Before puberty in the Pima Indians, bile cholesterol saturation (expressed as a percentage) is saturated but metastable in both girls, 116 ± 7%, and boys, 99 ± 7%. After puberty, there is a significant increase in this index, an increase that is higher in females, 156 ± 16%, than in males, 124 ± 2%. Lithogenic bile was present in 71% of females older than 19 years but only 13% of females younger than 13 years.[13] Two series have shown lower cholesterol-to-bile salt excretion ratios in white children than in adults.[15,16] Mean biliary cholesterol saturation index in 10 healthy American children with an average age of 2.3 ± 0.6 years was 0.72 ± 0.04 compared with 1.08 ± 0.09 in healthy adults[15] and 0.57 ± 0.12 in 11 Swiss children.[16] It is important to note that in these studies of bile composition in children, bile-rich duodenal aspirates were used.

In another study, gallbladder bile composition was investigated in 18 children from whom gallbladder bile was aspirated at the time of laparotomy for nonhepatobiliary disease. Significant differences were noted between infants and children in this study. Infants displayed more dilute bile than children, but bile was more saturated with cholesterol. The cholesterol saturation index in all infants was greater than 1, whereas in almost all children, it was less than 1. Infants also had a significantly shorter nucleation time, 11.6 days, compared with children, who had a nucleation time of 28.6 days, which is similar to that of healthy adults. Total biliary lipid of infants, 3.3 ± 3.8 g/dL (mean ± SD), is significantly lower than in children, in whom the total content is 9.1 ± 3.0 g/dL. Interestingly, in all bile samples, even those supersaturated with cholesterol, cholesterol was not present in the vesicular phase.[17] It is not clear why infant gallbladder bile is so different, but potential factors are a milk-only diet and the poor concentrating ability of the gallbladder.

FORMATION AND CONTENT OF GALLSTONES

For gallstones of any type to develop, some or all of the following need to occur: alterations in the proportion of bile constituents, nucleation, changes in gallbladder motility, or infection. Infection appears to be important only for brown pigment gallstone formation. The development of each of the three major gallstone types, namely cholesterol, black pigment, and brown pigment stones, is reviewed. The location of gallstone types differs with type; cholesterol and black pigment gallstones are almost always found in the gallbladder, but brown pigment gallstones are more commonly found in the extrahepatic ducts and even in the intrahepatic ducts.[18,19] In brief, the development of cholesterol gallstones requires hypersecretion of cholesterol into bile.[20] Black pigment stones are associated with a large number of diseases, all of which elevate bilirubin concentration in bile. Brown pigment stones, which are rare in both children and in the Western world, occur in the presence of obstruction and subsequent infection.

Cholesterol Gallstones

Cholesterol gallstones are a frequent problem in adults and, hence, extensively studied. For cholesterol gallstones to form, there must be (1) hypersecretion of cholesterol into bile, (2) decreased motility of the gallbladder, (3) increased mucin production by the gallbladder, (4) increased conversion of primary bile salts to more hydrophobic bile secondary bile salts, and (5) increased rate of formation of cholesterol crystals.[18,20] Once this pathway starts, it often leads to a self-perpetuating cycle as hypersecretion of cholesterol itself decreases gallbladder motility. This leads to a repeat of the cholesterol gallstone formation pathway, with the net result of more cholesterol gallstones.

How does cholesterol get into bile? Cholesterol is secreted into bile directly or in the altered form of bile salts, and these pathways are the routes of elimination of cholesterol from the body.[20] There are four potential fates

for cholesterol in hepatocytes. Cholesterol can be (1) stored in the hepatocyte as either or both the free and the ester form, (2) returned to serum as low-density lipoproteins, (3) secreted into bile, or (4) converted into bile salts. The latter two account for cholesterol elimination and are most relevant to bile formation and composition. Cholesterol is secreted into bile via adenosine triphosphate (ATP) binding cassette (ABC) twinned sterol half-transporters ABCG5 and ABCG8.[21–23] Cholesterol conversion to bile salts starts with 7α-hydroxylase, an enzyme found only in hepatocytes, the activity of which is regulated by bile salt concentration. As illustrated in Figure 61-1, bile salts are transported into bile by the bile salt export pump known as both BSEP and ABCB11[24] and phospholipid by ABCB4, previously known as multidrug-resistance protein (MDR)[35] at the canalicular membrane.

In Figure 61-2, the physical chemical pathways of vesicle and micelle formation are illustrated. In the canalicular lumen, cholesterol and phosphatidylchloline vesicles are formed and then dissolved by bile salts to form mixed micelles. As bile ducts get bigger, bile becomes more concentrated, and more phosphatidylcholine is solubilized by bile salts.[26] The cholesterol concentration of micelles increases, and, eventually, in the gallbladder these cholesterol-rich vesicles fuse and may lead to cholesterol crystal formation. Patients with cholesterol gallstones have higher cholesterol-to-phosphatidylcholine ratios than patients without gallstones.[27] Such people are secreting cholesterol in excess of the ability of bile salts and phosphatidylcholine to form micelles; thus, the cholesterol saturation index will be greater than 1, and bile will be metastable.[18] The importance of phosphatidylcholine secretion in prevention of cholesterol gallstone formation is illustrated by the discovery that defects in the *ABCB4* (*MDR3*) gene are associated with symptomatic intrahepatic and gallbladder cholesterol cholithiasis. A study of six adults with recurrent cholesterol gallstones postcholecystectomy revealed mutations in *ABCB4* in all six; three had homozygous missense mutations, and two were heterozygotes and one had homozygous nonsense mutations. Two of the six also displayed hepatic bile supersaturated with cholesterol and a low phospholipid concentration.[28] *ABCB4* (*MDR3*) defects are also associated with progressive familial intrahepatic cholestasis type 3 (see Chapter 55.6, "Biliary Transport")[29] and with intrahepatic brown pigment gallstones.[19]

For the actual formation of cholesterol gallstones, nucleation or aggregation of submicroscopic cholesterol crystals must occur.[30] Both pro- and antinucleating factors are described; immunoglobulins,[31] *N*-aminopeptidase,[32] and fibronectin[33] have been identified as pronucleating factors and apolipoprotein A-I[34] as an antinucleating factor. Once a nucleus has formed, further cholesterol monohydrate crystals attach, as can mucin, calcium, and even unconjugated bilirubin.[18] Cholesterol stones can vary in size from a few millimeters to a few centimeters and can be solitary or multiple.

Black Pigment Gallstones

Black pigment stone formation requires excess bilirubin in bile.[35] Excess secretion of conjugated bilirubin into bile occurs in (1) hemolytic diseases, (2) disorders of dysfunctional erythropoiesis, and (3) diseases that cause bilirubin

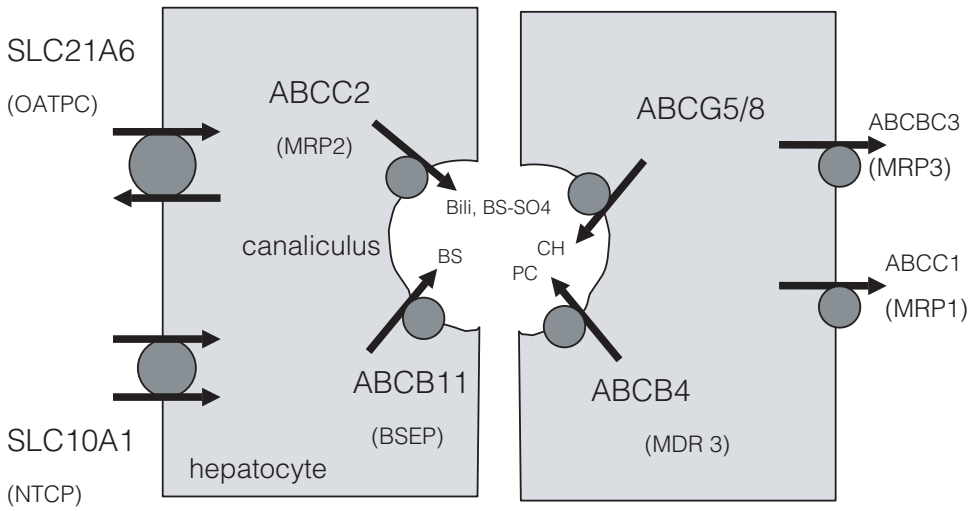

FIGURE 61-1 Transporters on the hepatocytes that have a role in modulating the composition of bile. A hepatocyte couplet is shown in this figure, and the canaliculus is in the center. The major canalicular transporters of biliary lipids are shown; the bile salt export pump (BSEP) (ABCB11) exports bile salts (BS). The half-transporters ABCG5/8 together transport cholesterol (CH). Multidrug resistance–associated protein (MRP) 2 (ABCC2) exports bilirubin conjugates (bili) and sulfated bile salts (BS-SO4). Multidrug-resistance protein (MDR) 3 P-glycoprotein (ABCB4) transports phosphatidylcholine (PC). On the basolateral surface of the hepatocytes, organic anion transporting polypeptide C (OATPC) (SLC21A6) and Na+-dependent taurocholate cotransporting polypeptide (NTCP) (SLC10A1) transport bile salts into the hepatocytes, MRP3 (ABCC3) allows monovalent bile salt efflux, and MRP1 (ABCC1) allows organic anion efflux, probably including unconjugated bilirubin. Courtesy of Dr. Richard S. Kwon, Brigham and Women's Hospital, Boston.

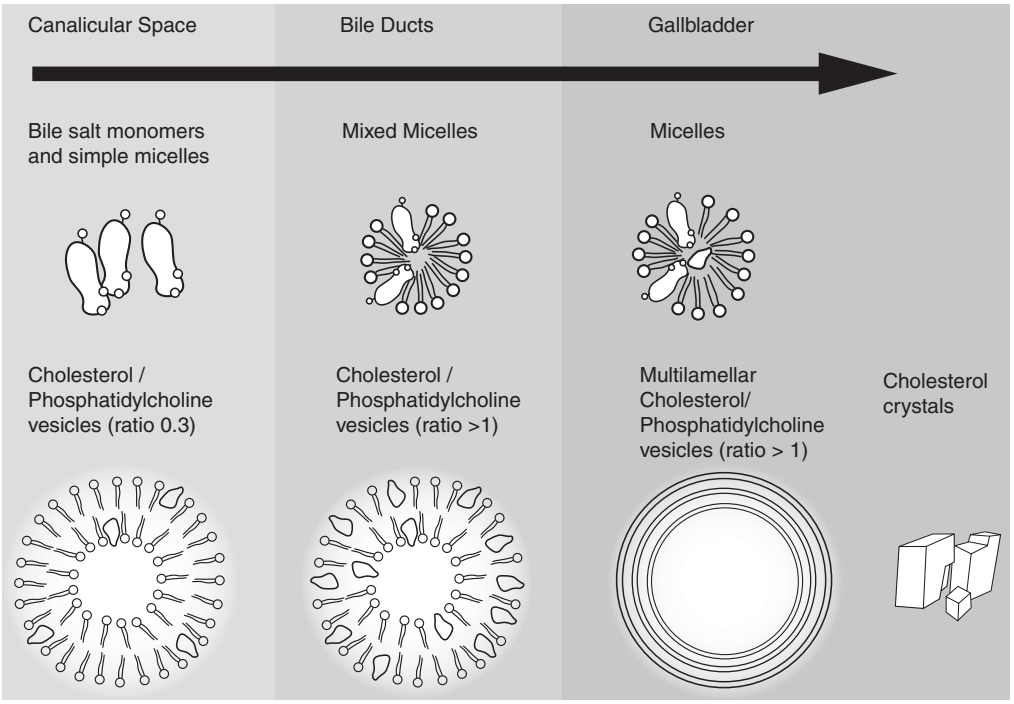

FIGURE 61-2 Pathway of cholesterol crystallization in bile. Cholesterol is hypersecreted into bile in the form of vesicles of cholesterol and phosphatidylcholine, as shown on the left of the diagram. As bile becomes more concentrated in bile ducts, the concentration of simple bile salt micelles also increases and the micelles preferentially extract phosphatidylcholine from vesicles, as shown in the middle column, creating thermodynamically unstable cholesterol-rich vesicles. In the gallbladder, as shown on the right, these vesicles fuse and aggregate to form a cholesterol-rich template for formation of cholesterol crystals. Reproduced with permission from Donovan JM.[20]

to undergo enterohepatic circulation.[36,37] When excess conjugated bilirubin is present in bile (ie, bilirubin supersaturation),[18] it can be deconjugated by β-glucuronidase or by other nonenzymatic means. This unconjugated bilirubin precipitates as an insoluble calcium salt known as calcium bilirubinate. Black pigment stones also contain calcium hydrogen bilirubinate, calcium carbonate, and calcium phosphate; small amounts of cholesterol (less than 20% by weight); and mucin in a glycoprotein matrix.[20] Free radical polymerization of calcium bilirubinate and possible oxidation in the presence of gallbladder mucin leads to the formation of black pigment gallstones.[20]

Brown Pigment Gallstones

Brown pigment stones are laminated and contain bacterial cytoskeletons,[38] calcium bilirubinate salts, cholesterol, and fatty acids.[20] These stones can occur in the presence of cholesterol or black pigment stones, which are causing obstruction and hence infection. Intrahepatic brown pigment stones are associated with decreased expression of MDR3 and phosphatidylcholine transfer protein as well as increased 3-hydroxy-3-methylglutaryl coenzyme A reductase activity.[19]

Genetics

Formation of cholesterol gallstones in humans is likely due to the interaction of environmental factors with genes, although none have been definitively identified in humans. Investigations in mice have led to the identification of *Lith* genes, which are candidate genes for cholesterol gallstone disease. The genetics of cholesterol gallstone disease is an example of a complex genetic trait, and a special investigative technique called quantitative trait locus (QTL) analysis is required.[39] Mice, which share similar hepatocyte and cholangiocyte transporter proteins to humans, are used as models for human gallstone disease. Environmental factors, especially diet, can be readily controlled in mice. To identify cholesterol gallstone genes by QTL analysis, mice strains that are gallstone resistant and others that are gallstone susceptible were identified. These mice were crossed and selectively back-crossed, and the progeny were phenotyped and genotyped. By this means, gallstone candidate genes are linked to polymorphic genetic markers, which differ between inbred mouse strains. The next step is to identify a chromosomal region that contains potential *Lith* genes by QTL analysis and to use the murine genome map to analyze these regions for genes, which could play a potential pathophysiologic role in cholesterol gallstone formation. Candidate genes, which colocalize with the QTLs, are studied in a specially bred mouse strain that expresses them, and the effects on cholesterol homeostasis and gallstones are investigated. Using this process, there are now nine potential *Lith* genes identified.[40]

The initial QTL experiments identified two potential *Lith* genes in mice. *Abcb11* is a strong candidate gene for *Lith 1*[41] and *Abcc2* for *Lith 2*.[39] *Abcb11* is also known as *Bsep* and is a member of the ABC family. It is found on the canalicular surface of hepatocytes and actively exports monovalent bile salts. There appears to be a gain of function so that bile salt secretion rates, along with those of cholesterol, are elevated in *Lith 1* congenic mice. ABCC2, also known as multidrug resistance–associated protein (MRP) 2, is an organic anion transporter also found on the canalicular membrane, which exports bilirubin and glutathione conjugates.[42] Other candidate *Lith* genes are involved in mucin regulation and cholesterol crystallization.[43] Human correlation of these candidate genes is actively being investigated.

For black pigment gallstones, the underlying disease (eg, sickle cell disease) leading to gallstone formation often has a genetic basis. It is interesting to note that pop-

ulations with a very high rate of cholesterol gallstone disease, such as the Pima Indians, develop pigment gallstones very rarely. Brown pigment stones are formed in the setting of infection, so genetic causes are less likely to be a major factor. However, as mentioned, gene expression differs in liver tissue from those with intrahepatic brown pigment stones.[19]

DISEASES ASSOCIATED WITH GALLSTONES IN CHILDREN

Cholesterol Gallstones

Cholesterol gallstones in children and adolescents have been associated with female gender, a positive family history, and parity. In a series of 96 patients under 25 years of age, the ratio of females to male with cholelithiasis was 4:1.[44] Unusually for a series of younger patients, only 2% of patients in this study had hemolytic disease. In another series of 50 children and adolescents with gallstones, 7 were young women who had adolescent pregnancies.[45] Three of the 50 patients in the latter study only had obesity as a risk factor for gallstones.[45] Finally, family history is significant in adults with cholesterol gallstones and in postpubertal Pima Indians.[13]

Pigment Gallstones

Black pigment gallstones are generally secondary to an identifiable risk factor. The many diseases associated with pigment gallstones in children are outlined in Table 61-1. These diseases can be categorized into three broad groupings.

Hemolytic Processes. Diseases resulting in hemolysis commonly lead to the formation of black pigment stones. An example is sickle cell disease, in which the prevalence of cholelithiasis increases with age. In an ultrasonographic study of children with major sickle hemoglobinopathies, gallstone prevalence was negligible in children younger that 6 years, but prevalence increased in the midteen years.[46] Interestingly, the severity of hemolytic disease as measured by hemoglobin levels, reticulocyte counts, and blood transfusions is not associated directly with gallstones.[46] Overall, gallstones are such a prominent feature of sickle cell disease that cholecystectomy is the most common surgical procedure performed for these patients.[47] Complication rates are equally high for both open and laparoscopic cholecystectomy in patients with sickle cell disease. Hospital stays are shorter in those who have a laparoscopic cholecystectomy, and preoperative transfusions decrease complications further.[47] Children with hereditary spherocytosis are also at increased risk of black pigment gallstone, and laparoscopic cholecystectomy for those with gallstones can be safely combined with laparoscopic splenectomy.[48] Although more common in adult populations, the presence of artificial cardiac valves can lead to red cell destruction and subsequent pigment gallstone formation in children.[49]

Enterohepatic Circulation of Bilirubin. Crohn disease, distal small intestinal resection, and cystic fibrosis

TABLE 61-1 DISEASES ASSOCIATED WITH GALLSTONES IN CHILDREN

DISEASE	GALLSTONE TYPE	PREVALENCE	AGE RANGE (YR)	REFERENCE
HEMOLYTIC PROCESSES				
Sickle cell hemoglobinopathies				
Homozygous HbSS	Pigment	26% (11/42)	2–18	46
Heterozygous HbSC	Pigment	20% (3/15)	2–18	46
β-Thalassemia anemia	Pigment	11.8% (2/17)	2–18	98
	Sludge	29.4% (5/17)	2–18	98
Hereditary spherocytosis	Pigment	3/50 children with gallstones	0–20	45
Cardiac valve replacement	Pigment	Case reports	Children and adults	52
PROBABLE ENTEROHEPATIC CIRCULATION OF BILIRUBIN				
History of abdominal surgery in infancy (especially ileal resection)	Pigment	29% < 1 yr 21% of 1–5 yr 5% of 6–21 yr	0–21	54
Cystic fibrosis	Pigment	13.2% (25/189)	3–22.5	52
Crohn disease	Pigment	Case reports	Children and adults	50
MISCELLANEOUS				
Prolonged parenteral nutrition > 4 wk	Pigment	13% (11/84)	Infants and children	53
	Sludge	3.6% (3/84)	Infants and children	53
Treatment of childhood cancer	Not reported	0.42% (16/6050)	10 yr after diagnosis of primary cancer	58
Post–heart transplant (cyclosporine immunosuppression)	Pigment and mixed type	3.2% (10/311); 8/10 transplanted < 3 mo of age	5 d to 3 yr at time of transplant	56
Down syndrome	Radiolucent gallstones (chemical analysis not reported)	4.7% (6/126)	1 mo–19 yr	57
Pregnancy	Cholesterol	7 of 50 children with gallstones	0–20	46
	Cholesterol	8/12 female patients younger than 18–26 yr with gallstones	18–26	99

HbSC = sickle cell trait (heterozygous); HbSS = sickle cell anemia (homozygous).

are examples of diseases that may result in enterohepatic circulation of excess unconjugated bilirubin from the intestine to the liver.[36,50,51] A proposed mechanism for enterohepatic circulation of unconjugated bilirubin in these disease processes is that malabsorption of bile salts from the terminal ileum leads to spillage of excess bile salts into the large intestine. These bile salts are accompanied by bilirubin conjugates, which are hydrolyzed in the large intestine by bacterial glucuronidases. The unconjugated bilirubin is further converted into either calcium salts or into urobilinoids. In the presence of large amounts of bile salts, passive nonionic diffusion of unconjugated bilirubin from the colon and return to the liver are promoted. Unconjugated bilirubin is taken up into hepatocytes, reconjugated mainly with glucuronic acid, and secreted again into canalicular bile.[36,37]

Children and adults with cystic fibrosis exhibit increased prevalence of gallstones. In a study of 189 patients (children and adults) with cystic fibrosis performed in Italy, 25 or 13.2% were found to have gallstones.[52] Gallstones have also been noted in children requiring parenteral nutrition. Those especially vulnerable are infants who have also undergone ileal resection and had multiple abdominal procedures.[53] Children with hepatobiliary disease are also at increased risk of gallstones.[54] Bile salt malabsorption leading to the interruption of the enterohepatic cycling of bile salts is the likely mechanism in the latter two diseases.

Miscellaneous. Other risk factors for black pigment gallstones are medications, especially furosemide in infants[55] and cyclosporine in cardiac transplant patients.[56] Bronchopulmonary dysplasia, independent of furosemide use, and gram-negative sepsis are also risk factors in infancy.[54] Children with Down syndrome are at increased risk of cholelithiasis, although the etiology is not understood.[57] Survivors of childhood cancers are at increased risk, although, again, the cause of this increased risk is not known.[58]

CLINICAL FEATURES OF GALLBLADDER DISEASE

The presentation of gallbladder disease is dependent on the underlying disease process. It can be difficult to gauge the contribution of chronic acalculous cholecystitis to chronic abdominal pain. Pain in patients with acute cholecystitis or acute biliary colic is usually clearly related to the presence of gallstones. It is also not clear why most individuals with gallstones are asymptomatic for long periods, whereas others have recurrent episodes of biliary colic. It is also unclear why others can present with disease outside the gallbladder as manifestations of gallbladder disease, for example, pancreatitis or cholangitis, although stone size appears to play a role. The clinical features of gallbladder disease are reviewed systematically.

Congenital Anomalies

These are generally asymptomatic, although they may predispose the patient to stasis and subsequent cholelithiasis.[59]

Acute Gallbladder Diseases

Biliary Colic. Gallstones can lead to pain, which patients describe as a steady, intense pain in the right upper quadrant or epigastrium. Some report that the pain radiates to the shoulder. Patients often vomit and classically are restless as they try to achieve a comfortable position. These episodes are usually referred to as biliary colic. Most patients have bouts of biliary colic that last for hours and can recur at random times.[60] Acute episodes of biliary colic present in a similar fashion in children, although a high index of suspicion is needed in young children. Adults can also complain of "dyspeptic" symptoms such as gas and heartburn during these episodes.

Acute Cholecystitis. If the gallbladder is inflamed and gallstones are present during these painful episodes, this is termed acute cholecystitis. Patients with acute cholecystitis can present with fever and right upper quadrant pain and may be Murphy sign positive. They often display a leukocytosis. If there are no gallstones present but the gallbladder is inflamed, this is termed acute acalculous cholecystitis, and this generally occurs in children with other major medical problems or infections. The clinical features are reviewed further in the section discussing acute acalculous cholecystitis.

Chronic Gallbladder Diseases

Chronic Gallstone Disease. Biliary colic often recurs; however, the acute episodes are short in duration rather than ongoing. A myriad of gastrointestinal complaints have been attributed to the presence of gallstones, such as indigestion, abdominal discomfort, and heartburn. It is important for patients to be aware that cholecystectomy will resolve the abdominal pain associated with episodes of biliary colic but may not resolve all gastrointestinal complaints.

Chronic Acalculous Cholecystitis. Patients with chronic acalculous cholecystitis, sometimes referred to as gallbladder dyskinesia, can present diagnostic and therapeutic challenges. These otherwise healthy children, often female, can complain of abdominal pain for months to years. The pain is often worse after eating and is localized to the right upper quadrant. Examination and routine workup are generally normal, and it is not until a hepatobiliary scintigraph scan is performed that the diagnosis is made. Excellent symptomatic relief has been reported in children with chronic alcalculous cholecystitis postcholecystectomy.[61]

Sphincter of Oddi Dysfunction. Those with sphincter of Oddi dysfunction (SOD) have complaints similar to those of patients with gallbladder dyskinesia, but cholecystectomy will not provide relief. When SOD is present, there is effectively an obstruction at the level of the sphincter, which may be caused by fibrosis or inflammation or by elevated sphincter tone. Endoscopic retrograde cholangiopancreatography (ERCP) with manometry provides the diagnosis, and sphincterotomy is the treatment of choice. In 50 healthy adult volunteers, normal basal pressure of

the sphincter of Oddi was 14.8 ± 6.3 mm Hg, and no pressure was greater than 40 mm Hg.[62] There are no comparable studies in normal children. SOD can lead to bile duct dilatation without evidence of choledocholithiasis pre- or postcholecystectomy. SOD has also been associated with acute recurrent pancreatitis and biliary colic–type pain in the absence of gallstones.

Gallstones can also lead to pancreatitis, the clinical features of which are reviewed in Chapter 64.1, "Pancreatitis: Acute and Chronic." Gallstones can also lead to obstruction of the common bile duct, causing pain, jaundice, and, if there is infection, fever.

ASSESSMENT OF FUNCTION AND IMAGING OF THE GALLBLADDER

Plain Abdominal Films

Plain films are not the investigation of choice for suspected gallstones. However, radiopaque stones, which account for 10 to 15% of all stones, can be seen in the gallbladder, common bile duct, and, occasionally, even the intrahepatic ducts and may be noted when the film is taken for other purposes.[63] A rare condition called "milk of calcium cholelithiasis" is associated with dramatic findings on abdominal radiographs. In this condition, bile is primarily composed of calcium carbonate, which is normally found in bones and teeth and is radiopaque. The gallbladder is often clearly seen, filled with multiple calculi. Surgery is curative, and the etiology is unknown.[59]

Ultrasonography

Ultrasonography of the gallbladder and bile ducts has permitted noninvasive and safe imaging of the gallbladder, gallstones, and biliary tree to be performed. Although now firmly established as the investigation of choice, ultrasonography was regarded with some suspicion in the 1970s. Indeed, the authors of one textbook stated that: "Neither we nor others have been convinced that this modality [ultrasonography] equals, let alone surpasses, currently available techniques."[3] Ultrasonography of the gallbladder is best performed on a patient who has fasted for 4 or more hours. Using a transducer placed on the anterior abdominal wall, the gallbladder is generally found on the undersurface of the liver between the right and left lobes. Rarely, the gallbladder can be found within the liver or underneath the left lobe.[64] Normal gallbladder size varies with fasting status and age. In infants less than 1 year of age, gallbladder length is usually between 1.5 and 3 cm. As shown in Figure 61-3, in older children, gallbladder length is usually 3 to 7 cm.[64,65] The diameter of the common bile duct varies with age. The following are the normal ranges of the common bile duct diameter: less than 1 mm in neonates, less than 2 mm in infants, less than 4 mm in children, and less than 7 mm in adolescents.[64,65] Gallbladder wall thickness increases when inflamed and is found to be greater than 3 mm in 50 to 75% of patients with acute cholecystitis.[64]

In the course of an ultrasonographic examination, the gallbladder is examined for evidence of stones, sludge, masses, distention, and pericholecystic fluid. Sludge, which is actually viscous bile, layers in the dependent part of the lumen and does not form acoustic shadows (Figure 61-4). Sludge moves slowly when the patient changes position.[64] Gallstones are usually mobile within the gallbladder lumen, unless impacted in the cystic or common bile ducts, and are brightly echogenic with posterior acoustic shadows (Figure 61-5).[65] Stones as small as 1 mm can be identified.[63] If gallstones are within the common bile duct, there is usually accompanying ductular dilatation. False-positive and -negative identification of gallstones can occur if the gallbladder is packed full of stones or nearby air-filled bowel loops create acoustic shadows.[64] Gallbladder polyps can be mistaken for gallstones, although they are not as mobile. Overall, ultrasonography

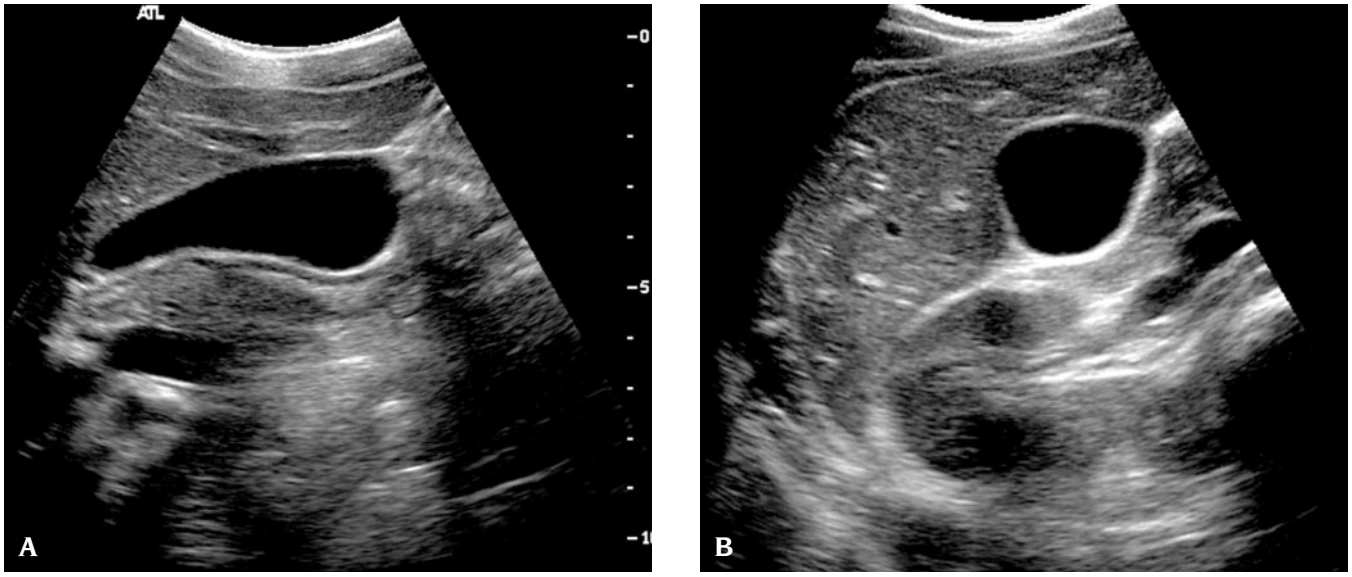

FIGURE 61-3 Ultrasonographic image of a normal gallbladder. A normal gallbladder of a healthy child is shown in two views. *A* shows the longitudinal view of the gallbladder, and *B* shows a cross-sectional view. Courtesy of Dr. Harriet J. Paltiel, Children's Hospital, Boston.

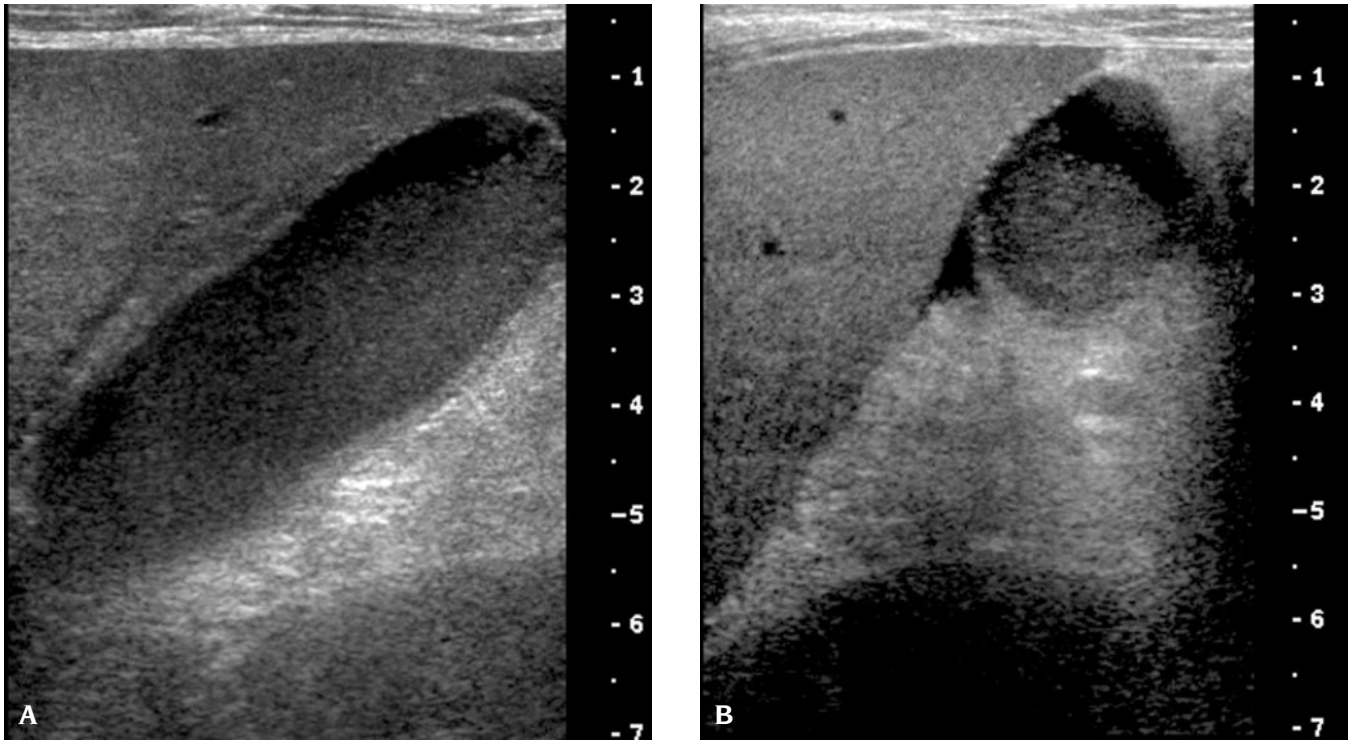

FIGURE 61-4 Ultrasonographic image of biliary sludge. *A* illustrates a child's gallbladder filled with sludge. Sludge does not form acoustic shadows (contrast this with the shadows created by gallstones in Figure 61-5). Sludge moves slowly within the gallbladder when the patient moves during the examination, and the sludge can be seen in a different position within the gallbladder in *B*. Courtesy of Dr. Harriet J. Paltiel, Children's Hospital, Boston.

has a greater than 95% sensitivity and specificity for detecting gallstones.[66]

Cholecystitis on ultrasonography is often associated with a thickened gallbladder wall (> 3 mm), an enlarged gallbladder, gallstones or sludge, and a positive Murphy sign.[64] In addition, signs of potential complications of acute cholecystitis should be sought, such as gangrene, which is suggested by irregularities in the gallbladder wall, or emphysema and perforation, which is suggested by pericholecystic fluid.[65] In chronic cholecystitis, the gallbladder may have all of the above findings or may even appear normal. In adults and very rarely in children, adenomyomatosis or strawberry gallbladder, which is due to diffuse or focal prominence of Rokitansky-Aschoff sinuses (hyperplastic mucosa extensions into the muscular layer), can cause chronic pain.[67] Hydrops of the gallbladder, also referred to as acute alcalculous cholecystitis, is characterized on ultrasonography by a distended gallbladder without evidence of obstruction or bile duct dilatation. The bile is usually anechoic.

Computed Tomography and Magnetic Resonance Imaging

Other radiologic investigations have a role in the diagnosis of specific complications. Computed tomography (CT) is used to image the pancreas, which may be inflamed sec-

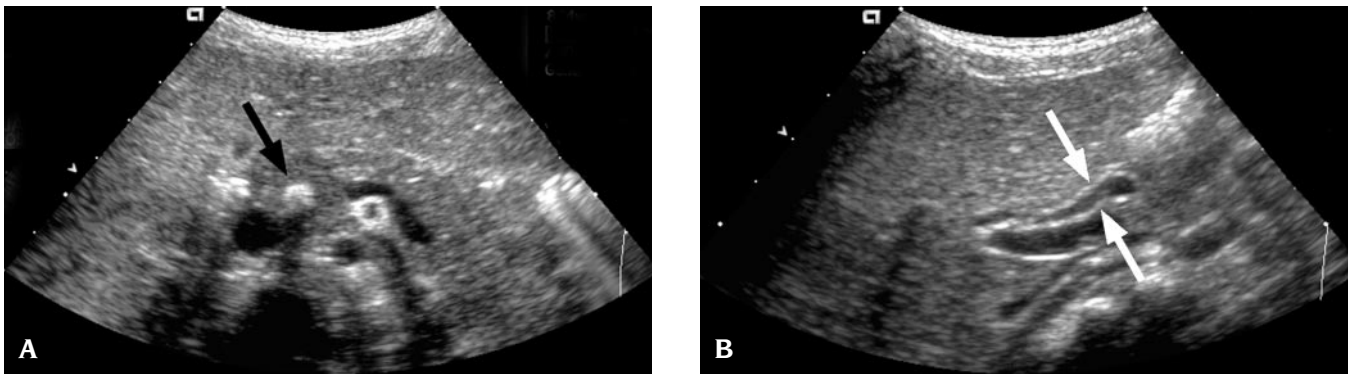

FIGURE 61-5 Ultrasonographic images of a gallstone in the common bile duct. *A,* A transverse image of the pancreas demonstrates an echogenic focus (*black arrow*) in the distal common bile duct with distal shadowing in keeping with a stone. *B* is a longitudinal oblique image of the liver hilum demonstrating dilation of the common bile duct (*between two white arrows*) down to the level of the pancreas. ondary to gallstone obstruction of the pancreatic duct, and is also useful for imaging the biliary tree when complications of acute cholecystitis are suspected. It is not as reliable as ultrasonography for detection of gallstones, which may exhibit the same radiographic density as bile and therefore may not be seen on CT.[63] Magnetic resonance imaging of the pancreas and biliary tree (magnetic resonance cholangiopancreatography) is superior to CT for investigation of the anatomy of the hepatobiliary tree and the pancreatic duct. However, ERCP is still the investigation of choice to define the extrahepatic and pancreatic duct systems because there is not only excellent imaging, but therapeutic interventions, such as retrieval of impacted stones from the common bile duct and sphincterotomy, are also possible. ERCP is discussed further under surgical procedures.

Radionuclide Hepatobiliary Scintigraphy

Radionuclide imaging or scintigraphy plays a role in both the diagnosis of biliary disease and assessment of function. For acute cholecystitis in adults, hepatobiliary scintigraphy (HBS) has both a higher specificity and sensitivity. In a meta-analysis of 27 studies containing almost 3,000 patients, the sensitivity of HBS is 90% and the sensitivity is 97%.[66] The rates for ultrasonography diagnosis are 91% and 79%, respectively. However, the main role of HBS is when ultrasonographic findings are equivocal for acute cholecystitis. A positive test of cholecystitis by HBS is based on a lack of gallbladder visualization. An intravenously administered radioactive pharmaceutical, usually technetium 99m hepatic iminodiacetic acid, is secreted from the liver into the hepatic bile ducts but is unable to enter the gallbladder if the cystic duct is obstructed. The isotope instead enters the small intestine.[68] If the gallbladder is not seen in the first 60 minutes, there are two options: delayed imaging at 4 hours or the more popular administration of morphine. Morphine administration increases pressure at the sphincter of Oddi and forces bile into the gallbladder if the cystic duct is patent. The morphine protocol is more specific, equally sensitive, and completed within 90 minutes.[68] Despite the increased specificity of HBS, ultrasonography is still the test of choice because it allows for evaluation of gallbladder anatomy as well as other abdominal organs. Ultrasonography is also less invasive and less expensive and involves no exposure to radioactivity.

Radionuclide imaging also can play a role in the diagnosis of both acute and chronic alcalculous cholecystitis. A prospective study comparing ultrasonography and radionuclide imaging in adults with acute alcalculous cholecystitis found a sensitivity of 70% and a specificity of 100% for radionuclide scanning in association with ultrasonography.[69] Gangrene and perforation, both complications of acute acalculous cholecystitis, can be identified on HBS by spill of radionuclide into the peritoneal cavity.[68] HBS is useful for diagnosis of chronic alcalculous cholecystitis, also referred to as gallbladder dyskinesia or spasm. Cholecystokinin (CCK) is administered during the study. Poor contractility of the gallbladder in response to CCK is the hallmark of chronic acalculous cholecystitis. If the gallbladder ejection fraction is less than 35% in a patient with a clinical history suggestive of chronic alcalculous cholecystitis, there is a greater than 90% positive predictive value.[68] False decreases can occur in patients with diabetes and celiac disease and in pregnancy, as well as in those receiving morphine and octreotide. Sphincter of Oddi spasm or bile duct dyskinesia has clinical symptoms similar to those of chronic alcalculous cholecystitis and an abnormal response to CCK—sphinchter contraction rather than dilatation. However, the best test for this condition is sphincter manometry. Finally, HBS is useful postcholecystectomy to detect bile leak complications.

Miscellaneous Imaging Techniques

The other available modalities to investigate the anatomy of the biliary tree are used much more rarely nowadays. Oral cholecystography has been superseded by ultrasonography for the detection of gallstones, and T tube cholangiography is performed infrequently in this era of laparoscopic cholecystectomies. Highly specialized interventions such as transhepatic cholangiography for investigation of strictures are still performed in the proper clinical setting.

Role of ERCP

ERCP in children is not a trivial procedure because general anesthesia is generally required in young children and infants.[70] The techniques of this procedure are reviewed in detail in Chapter 67.5, "Endoscopic Retrograde Cholangiopancreatography." The roles of ERCP in gallbladder disease in children are to remove common bile duct stones in choledolithiasis, measure sphincter of Oddi pressure, and, occasionally, delineate anatomy. Children undergoing ERCP because of biliary pathology have been reported to have higher complication rates than do adults. In one reported series of 15 such children, 6 presented with pancreatitis and 1 with bleeding post-ERCP.[70] A second group emphasized the role of ERCP with sphincterotomy and stone removal in children with common bile duct stones.

ERCP is also used to perform manometry at the sphincter of Oddi to make the diagnosis of SOD. A sphincterotomy can be performed at the same time if the diagnosis is confirmed.

Choice of Imaging Methods

The best imaging method for a child with suspected gallbladder disease depends on the suspected condition. The imaging methods of choice for a number of different gallbladder diseases are outlined in Table 61-2.

SURGICAL MANAGEMENT OF CHOLELITHIASIS

Laparoscopic cholecystectomy is currently the procedure of choice in children requiring cholecystectomy.[71] There is evidence to indicate that laparoscopic cholecystectomy patients have a shorter hospital stay and less analgesic requirements than their open cholecystectomy counterparts.[72] Open cholecystectomy is reserved for the few children in whom laparoscopic cholecystectomy is a relative contraindication or when it cannot be completed safely.

TABLE 61-2 IMAGING METHODS OF THE HEPATOBILIARY TRACT FOR DIFFERENT CLINICAL SITUATIONS

	IMAGING METHOD OF CHOICE					
DISEASE PROCESS	ULTRASONOGRAPHY	RADIONUCLIDE IMAGING	CT	MRI/ MRCP	ERCP	MISCELLANEOUS
Cholelithiasis	+++					
Acute cholecystitis	+++	++ (may need delayed imaging and/or intravenous morphine)				
Acute acalculous cholecystitis	++	+				
Chronic acalculous cholecystitis	+	+++ (with CCK)				
Sphincter of Oddi spasm	+	++ (with CCK)			+++ (sphincter manometry)	
Biliary leak postcholecystectomy	+	+++	+			
Bile duct obstruction	+++	++	++	+++	+++	Depending on site of obstruction, intraoperative cholangiogram or transhepatic cholangiogram may be required

CCK = cholecystokinin; CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic rseonance imaging.

Laparoscopic cholecystectomy is performed under general anesthesia with the patient in the supine position. An insufflation needle is introduced into the peritoneal cavity, with great care to prevent inadvertent visceral or vascular injury,[73] or a trochar may be introduced under direct vision to prevent damage to adjacent structures. After insufflation of the peritoneal cavity with carbon dioxide, a camera is introduced that allows the introduction of additional working ports under direct vision. Calot triangle is exposed by retracting the gallbladder up and over the liver[71] and freeing pericholecystic adhesions. Blunt dissection of the cystic duct is begun at the neck of the gallbladder, and the cystic duct–common duct junction is delineated. Clips are carefully applied to the cystic duct prior to its division before turning attention to the cystic artery, which is then clipped and ligated. The peritoneum of the gallbladder is then incised and is then freed from the gallbladder bed using hook cautery,[71] and the gallbladder is removed.

Children may also display gallstones in the common bile duct choledocholithiasis. Preoperative findings suggestive of this are listed in Table 61–3. Waldhausen and colleagues recommend routine use of intraoperative cholangiography.[74] They ultimately identified common bile duct stones in 18 of 100 patients studied and found preoperative suspicion of choledocholithiasis in 20 patients. The suspicion was based on finding one or more of the following abnormalities: ultrasonographic evidence of a dilated common or intrahepatic bile duct or identification of a specific common duct stone (6 patients), biochemical abnormalities consisting of elevated liver function tests (9 patients), elevated amylase and lipase (10 patients), or conjugated hyperbilirubinemia (2 patients). Fifteen of the 20 patients suspected preoperatively were confirmed to have evidence of choledocholithiasis based on intraoperative cholangiography or ERCP; no stones were found in five. Three additional children in their series were found to have cholangiographic evidence of choledocholithiasis, which had not been predicted on preoperative evaluation. They concluded that intraoperative cholangiography should be performed routinely and ERCP should be reserved for patients in whom common duct stones are identified and the surgeon prefers not to perform laparoscopic or open common duct exploration. However, Newman and colleagues do not recommend routine intraoperative cholangiography but rather preoperative blood work, ultrasonography, and ERCP as indicated.[75] In their series of 117 children undergoing cholecystectomy, 14 were suspected to have common bile duct stones, of which 8 patients were confirmed at the time of ERCP. One child was found at the time of surgery to have a common bile duct stone not identified preoperatively. Therefore, 7 children were incorrectly identified in this series of 117 children (6 false-positives and 1 false-negative) as having or not having stones in the common bile duct on the basis of preoperative examination and bloodwork. These authors do not recommend routine intraoperative cholangiography because only 9 of 117 children actually had stones in the common bile duct, and 8 of these were suspected preoperatively.[75]

TABLE 61-3 PREOPERATIVE FINDINGS SUGGESTIVE OF COMMON BILE DUCT STONES

Jaundice
Elevated canalicular enzymes
Pancreatitis
Dilated common bile duct on ultrasonography
Dilated intrahepatic bile ducts on ultrasonography

Laparoscopic cholecystectomy is associated with 3 to 4 times the risk of injury to the biliary tree compared with open cholecystectomy.[76] The key factor is prevention of this serious complication by correctly identifying the cystic duct and artery. If a biliary injury is recognized intraoperatively, it is recommended to convert to an open surgical approach to repair the injury.[76] If injuries of this nature are not recognized immediately, however, they may present days or months later with the triad of fever, pain, and jaundice. ERCP can play a vital role in the diagnosis and treatment of these complications.[77] If the common bile duct or one of its major branches is transected, a hepaticojejunostomy by an experienced hepatobiliary surgeon is the standard of care.

Contraindications to Laparoscopic Cholecystectomy

Recently, absolute contraindications for laparoscopic cholecystectomy have dramatically decreased as operative skills, experience, and equipment have developed. Hemodynamic instability, irreversible coagulopathy, and third-trimester pregnancy remain as absolute contraindications.[78] Situations that require special expertise but do not preclude laparoscopic cholecystectomy are acute gallstone pancreatitis, prior upper abdominal surgery, and second-trimester pregnancy.[79]

Medical Management of Cholelithiasis

The advent of laparoscopic cholecystectomy has essentially eliminated medical management of gallstones. Moreover, because medical therapy targets cholesterol gallstones only, children were generally unsuitable candidates, and, indeed, no reported studies have been performed in children. Nonsurgical therapy consists of either administration of bile salts or extracorporeal shock wave lithotripsy. Ursodeoxycholic acid and chenodeoxycholic acid are two bile salts that have been used. Both of these bile salts decrease cholesterol secretion into bile so that bile becomes desaturated of cholesterol.[80] Chenodeoxycholic acid in therapeutic doses leads to diarrhea in 50% of patients and dissolved gallstones in only 14.5% of adult patients treated for 2 years.[81] Ursodeoxycholic acid treatment is associated with less diarrhea and better stone dissolution rates than chenodeoxycholic acid, up to 40% at 2 years,[80] but is rarely used for this indication now. Extracorporeal shock wave lithotripsy has been used in association with administration of bile acids to disintegrate stones. This strategy did lead to dissolution of both solitary and multiple stones in 91% of patients, but the gallbladder remains in place, and stones can therefore recur.[82]

NONGALLSTONE DISEASES OF THE GALLBLADDER

Acalculous Cholecystitis

Acalculous cholecystitis, an uncommon condition in children, can be divided into two distinct clinical entities: acute, with symptoms of less than 1 month in duration, and chronic, with symptoms lasting more than 1 month.[83] Acute acalculous cholecystitis is characteristically associated with a concurrent systemic infection or recent surgery or trauma, whereas the chronic form is not. The condition appears to develop when the gallbladder either contracts or cannot empty its contents. Specific risk factors are prolonged fasting, parenteral nutrition, and sepsis. Children with acute alcalculous cholecystitis present with fever, right upper quadrant pain, and vomiting and exhibit abdominal tenderness on examination.[83,84] Leukocytosis and elevated bilirubin are also common. Ultrasonography diagnosis of acute acalculous cholecystitis requires gallbladder wall thickness greater than 3.5 mm, hydrops, sludge, and pericholecystic fluid.[83] These children often have associated illnesses such as infections like *Salmonella typhi*[85,86] or infective endocarditis[87] or a systemic disease such as Kawasaki disease.[83] A history of recent surgery or trauma is common. Treatment of acute acalculous cholecystitis involves serial examinations, gallbladder ultrasonography, and cholecystectomy when indicated by deteriorating clinical or ultrasonographic findings.[84] The histopathologic findings of gallbladders resected from children with acute acalculous cholecystitis range from edema and focal hemorrhage to gangrene.[83] For children who can be managed conservatively by active observation and antibiotic administration, the gallbladder will eventually return to normal function.

In contrast, children with chronic acalculous cholecystitis are generally female, are otherwise healthy, have a history of right upper quadrant pain that may be associated with nausea and vomiting, and have normal serum white cell counts and bilirubin.[83] The gallbladder is normal on ultrasonography, and the test of choice for diagnosis is a CCK-stimulated HBS.[60] This test measures the gallbladder ejection fraction, which is decreased with chronic acalculous cholecystitis. In adults, less than 35% is considered diagnostic; a comparable figure is not known in children.[68] Two reported series of children have shown good reduction in symptoms in children postcholecystectomy. In one study, following laparoscopic cholecystectomy, 70% of children had complete resolution of symptoms and 18% had partial relief.[61] In a second study, cholecystectomy, either laparoscopically or open, led to complete resolution of symptoms.[83]

Gallbladder Masses

Gallbladder masses are, fortunately, very rare in children so are discussed only briefly.

Benign Masses of the Gallbladder. Benign masses of the gallbladder are extremely rare in children and are usually polyps.[88,89] There are four main types of polyps: cholesterol ones, which arise from infiltration of lipid-laden macrophages into lamina propria; inflammatory polyps composed of granulation and fibrous tissue; adenomyoma, which arise when adenomyomatosis is confined to the fundus of the gallbladder; and adenomas.[90] Lipomas can also be found rarely in the gallbladder.[90,91] Adenomas of the gallbladder are usually solitary and may be associated with gallstones. It is not clear if they are premalignant, like adenomas of the colon. Patients with polyps of all types can present with symptoms and signs suggestive of biliary

colic, and ultrasonography may not be able to distinguish polyp type. Endoscopic ultrasonography may play a role in increasing preoperative identification of the polyp type. In a study of 182 Chinese patients aged 15 to 84 years, the sensitivity of transabdominal ultrasonography at detecting polyps was 90.1%. Of the 182 patients, 172 had polyps at the time of surgery, of which 159 were benign lesions and 13 were malignant.[91] These authors suggest surgical resection of polypoid lesions greater than 1 cm in diameter and of solitary lesions and in those older than 50 years.[91] Gallbladder polyps have been reported in three patients with Peutz-Jeghers syndrome in Germany, and conservative management is recommended unless there are symptoms suggestive of biliary colic.[92]

Malignant Tumors of the Gallbladder. Gallbladder carcinoma arises in those with a history of acute or chronic cholecystitis. It appears that chronic inflammation is necessary for this tumor to develop; it is, therefore, rare in childhood and adults under 50 years. Incidental adenocarcinoma of the gallbladder is found in 0.1 to 0.5% of adults undergoing laparoscopic cholecystectomy for gallstones and 1 to 2% of those undergoing open cholecystectomies.[93] For most patients with gallbladder cancer, however, the prognosis is poor because only 5% survive 5 years after diagnosis.[93,94] Approximately 80% of gallbladder carcinomas are adenocarcinomas and are associated with abnormal expression of *TP53*, the tumor suppressor gene.[95] Squamous cell adenocanthoma accounts for the remaining 20% of gallbladder cancers.[94] Radical cholecystectomy, ERCP placement of stents into the hepatic and common bile ducts if necessary, and palliative radiotherapy all play a role. For those found to have incidental adenocarcinomas confined to the mucosa and with lymph node metastases at the time of cholecystectomy, the cholecystectomy itself can be curative.[94]

Congenital Abnormalities of the Gallbladder. Congenital anomalies of the gallbladder are also rare, and although they may predispose the patient to inflammation and cholelithiasis, they are often found only incidentally during abdominal imaging or surgery.

Absent Gallbladder. The gallbladder can be absent, without any apparent symptoms, or can be associated with other conditions, such as extrahepatic biliary atresia. In biliary atresia, the gallbladder either fails to vacuolize from a solid state during development or postnatally becomes obstructed or obliterated. Because the mechanism of biliary atresia is unknown, the cause of the absent or "rudimentary" gallbladder also remains speculative. The gallbladder may appear to be absent in cystic fibrosis, in which recurrent attacks of cholecystitis can lead to fibrosis and/or atrophy of the gallbladder.[96]

Double Gallbladder. There are a number of forms of this anomaly. There can be a true duplicate set of gallbladders, each with its own cystic duct, which arise from an outpouching of the hepatic or common bile duct. If the pouch derives from the cystic duct, there are two gallbladders but only one cystic duct. A bilobed gallbladder appears to be similar, with two gallbladder fundi but only one cystic duct, but this anomaly arises from a duplication of the single bud, which normally develops into the gallbladder. All of the above anomalies are rare and are usually asymptomatic.[97]

Miscellaneous. The gallbladder can be abnormally folded during development, and the appearance on cholecystograms of the folded gallbladder is that of a type of bonnet or "phrygian cap," for which the condition is named.[97] The gallbladder empties and functions normally.[2] The development of ducts can also be abnormal, and 20% of people have an aberrant insertion of the cystic duct into the common hepatic duct.[97] The cystic artery, which usually arises from the right hepatic artery, can arise aberrantly from the left. These anomalies are of great importance during cholecystectomy. Finally, the position of the gallbladder can vary; in situs inversus, the gallbladder is in a normal relationship with the liver, but the liver is now on the left side of the abdominal cavity. The gallbladder can appear to be buried in the liver or it can be excessively mobile, which increases the risk of torsion. The latter two anomalies are important for radiologic interpretation.

CONCLUSION

Gallbladder disease in children is an uncommon, although not rare, problem. Clinicians are reporting increased numbers of cholecystectomies in children. It is not yet clear if this represents a true increase in the incidence of gallstones in children or more ready access to laparoscopy. However, the current epidemic of childhood obesity is likely to lead to an increased frequency of cholesterol gallstone disease either in adolescence or early adulthood, and we will all become more familiar with this disease.

CHAPTER 62

CONGENITAL ANOMALIES

Dominique M. Jan, MD

Congenital abnormalities of the pancreas are rare. These anomalies are more commonly discovered at endoscopy, at surgery, or by imagery. This chapter focuses on the congenital malformations of the pancreas, which could lead to clinical findings.

EMBRYOLOGY OF THE PANCREAS

Human pancreatic development has been known since the work of Streeter in 1942.[1] The pancreas forms as a result of the fusion of the two buds, which arise from the dorsal and ventral aspects of the distal foregut. Owing to craniocaudal development, the dorsal pancreas develops ahead of the ventral pancreas. The ventral bud forms the dominant pancreatic and the bile duct. The ventral pancreas rotates clockwise around the duodenal axis. The rotation of the duodenum is the result of duodenal growth. In the normal course of development, between the 8 and 12 mm stages (the fourth to sixth week), the common duct and the right portion of the ventral bud are carried dorsally around the circumference of the duodenum to lie adjacent to the dorsal pancreatic bud. This rotation is the result of duodenal growth, during which all enlargement is on the ventral side only. Thus, the dorsal pancreatic bud forms the anterior part of the head of the pancreas, the body, and the tail of the pancreas.[2] The ventral pancreatic bud forms the posterior part of the head of the pancreas and the posterior part of the uncinate process. The ventral bud is divided into right and left portions; the left portion atrophies, whereas the right portion is moved posteriorly by its connection to the bile duct. The dorsal and the ventral duct systems fuse so that most of the longer dorsal duct drains into the proximal part of the ventral duct to form the main pancreatic duct (duct of Wirsung). If the proximal portion of the dorsal duct remains, it forms an accessory duct (duct of Santorini). The fusion of the ducts occurs during the second month of development. Failure of the dorsal and ventral ducts of the fetal pancreas to fuse leads to pancreas divisum.

More recently, tissue culture and recombination experiments have shown that commitment to a pancreatic fate occurs before morphologic evidence of pancreatic development as early as embryonic day 5-8 in mice and stage 11 in chickens.[3] Experiments in mouse and chicken embryos have revealed that permissive signals secreted by adjacent mesodermal structures (notochord, aorta, and cardiac mesoderm) are important for the pancreatic program. The dorsal foregut (giving rise to the pancreas) is in close contact with the notochord. The ventral foregut is in close contact with the cardiac mesoderm (Figures 62-1 and 62-2).

Initial bud formation relies on different genes dorsally and ventrally. The expression of the homeobox gene *Hlxb9* is necessary to the dorsal bud formation.[4] The gene is active by controlling the expression of signaling molecule produced in the notochord (fibroblast growth factor 2 and activin-βB).[5] The mesenchymal tissue adjacent to the buds is important for all of the embryologic processes, expansion, branching, and differentiation.

The only gene clearly demonstrated to be causal to congenital anomalies of the pancreas formation is the gene coding for the homeodomain protein PDX1. It is expressed in the endoderm of the foregut at the regions where the ventral and the dorsal buds will form. In PDX1 null mutant mice, the ventral bud forms but fails to grow, and the dorsal bud grows but never forms a functional pancreas. Mutation in this protein has been identified in a patient with pancreas agenesis.[6]

Annular pancreas is usually sporadic, but familial descriptions have been reported with an apparent autosomal dominant transmission. Inactivation of a signaling molecule Sonic hedgehog (Shh) has been described as a potential mechanism that can lead to annular pancreas.[7] Shh is expressed in the endoderm in the regions lateral to the PDX1-expressing endoderm.

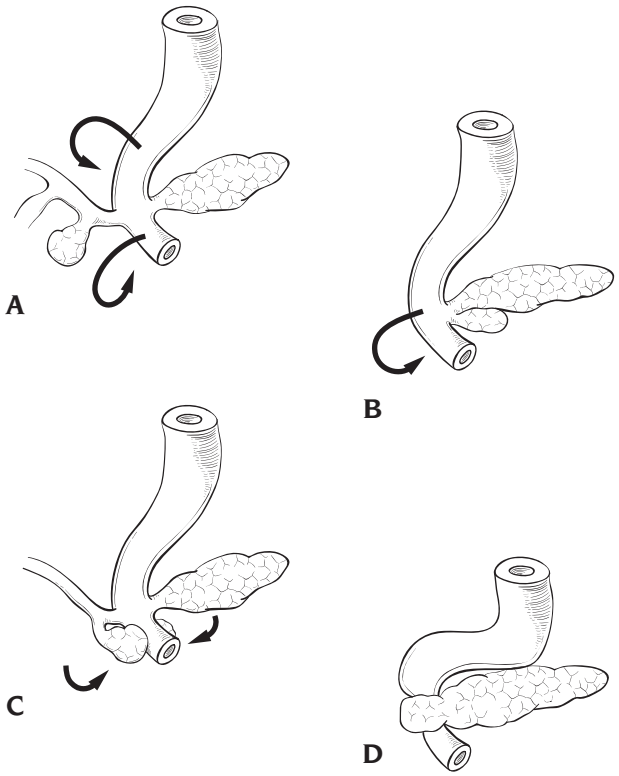

FIGURE 62-1 Embryology of the pancreas. *A*, Eight to 12 mm stage; *B*, fusion of the ducts; *C*, malrotation of the right portion of the ventral bud; *D*, annular pancreas.

Pancreas divisum, which is the most common anomaly of the pancreas, affects 5 to 6% of the population. Inappropriate fusion of the ventral and pancreatic buds has been reported in mice heterozygous for null alleles of Shh.[7]

Aberrant localization of pancreatic tissue affects 0.6 to 2% of the population.[8] The most common sites of pancreatic heterotopias are the stomach, duodenum, and Meckel diverticulum. Because inhibition of Shh leads to pancreatic ectopia in chickens, this signaling molecule may be involved in this anomaly in humans.[9]

ANNULAR PANCREAS

Annular pancreas is the complete encirclement of the second part of the duodenum in a ring-like fashion by a thin, flat band of pancreatic tissue. The annular tissue is histologically normal, containing both acini and islet cells. The anomaly may be associated with partial or complete duodenal obstruction. The annular pancreas occurs with a frequency of 1 in 20,000 births but is more commonly found in neonatal duodenal obstruction (8–21%).[10]

Pathogenesis

Annular pancreas may be the result of a hypertrophy of the normal pancreas tissue by failure of atrophy of the left ventral bud. The fixation of the ventral pancreas before the onset of rotation leads to formation of the annulus.[11] This theory and its chronology are supported by most of the fetal evidence reported. The ventral origin of the annulus has been confirmed immunohistochemically.

Pancreatic tissue often penetrates the muscularis of the duodenum. A large duct is usually present that connects to the Wirsung duct.

Annular pancreas is associated with a number of other congenital malformations in more than 75% of children.[12] This suggests that the defect of annular pancreas is the result of an early embryologic malformation.

Clinical Presentation

Symptomatic annular pancreas may present at any age, from birth through adult life. Approximately one-third of the cases are symptomatic during the neonatal period and half during the first year of life.[12,13] The age at presentation is determined by the degree of duodenal obstruction and by coexistent malformations.

The diagnosis of annular pancreas associated with duodenal obstruction may be suggested antenatally by polyhydramnios. The diagnosis of duodenal obstruction may be confirmed by antenatal ultrasonography.[14]

In the newborn period, the diagnosis is based on the typical appearance of a double-bubble sign of gastric and duodenal obstruction on supine and upright radiographs of the abdomen. Contrast studies are not necessary for the diagnosis unless the differential diagnosis of volvulus with malrotation is discussed.

In children beyond the neonatal period and in adults, symptoms differ because they are more likely recurrent vomiting secondary to partial duodenal obstruction and chronic gastric distention, pain as the result of mild pancreatitis, or peptic ulcers, as have also been described in patients with annular pancreas.[9] In older patients, different investigations may help the diagnosis. Upper gastrointestinal studies are useful, and ring-like smooth symmetric narrowing of the duodenum is observed in the majority of symptomatic children. Contrast-enhanced computed tomography allows direct visualization of the annular pancreas. More recently, magnetic resonance cholangiopancreatography (MRCP) has been used to visualize the pancreatic ducts and the bile duct and can demonstrate the pancreatic duct of the annular portion of the pancreas.[15] In teenagers and adults, diagnosis has also been achieved using endoscopic ultrasonography.[16]

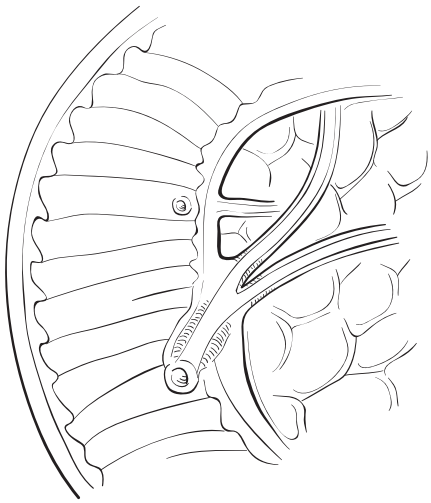

FIGURE 62-2 Normal patterns of the pancreatic ducts.

Management

Surgical management of annular pancreas is mostly concerned with relief of duodenal obstruction. The definitive diagnosis is made at the time of the laparotomy. Direct dissection of the annular ring is not recommended. Such attempts may be technically difficult, and the division of the annular pancreatic duct is associated with a high risk of pancreatic peritonitis or postoperative pancreatitis, fistulae, and late fibrosis. A large duodenoduodenostomy is recommended as a bypass operation. However, the morbidity is high with duodenal functional obstruction owing to the remaining dilated proximal duodenum. Duodenoplasty of the proximal duodenum and diamond-shaped duodenoduodenostomy may reduce the complication rate. The long-term prognosis is excellent.[13]

ECTOPIC PANCREATIC TISSUE

Pathogenesis

Ectopic pancreas is defined as the presence of pancreatic tissue lacking anatomic and vascular continuity with the main body of the pancreas. Islands of pancreatic tissue may be found in many sites and have been reported in 0.5 to 1.5% of autopsies.[17] Ectopic pancreatic tissue has been located most commonly in the pylorus, duodenum, Meckel diverticulum, and, less frequently, in the colon, appendix, gallbladder, and anomalous bronchoesophageal foregut fistulae.

Ectopic pancreatic tissue has been observed in knockout mice for homeobox gene *Cdx2*. Inhibition of Shh signaling also leads to ectopic pancreas in chickens.[18] The pathogenesis remains unclear because many theories are not demonstrated. A hypothesis regarding ectopic migration of pancreas precursor to in situ error of stem cell differentiation is still controversial. This theory is supported by the expression of PDX1, a marker of pancreatic progenitor cells, in the antral stomach, duodenum, and small bowel, the main localizations for ectopic pancreas.

Clinical Presentation

In most cases, ectopic pancreas remains asymptomatic. It is an incidental finding during surgery for another indication. Because the ectopic pancreas may occasionally cause complications, management remains controversial. Some recommend no further investigations and management; others recommend local resection as ileal resection of the Meckel diverticulum to avoid any further bleeding.

The most common clinical findings are gastrointestinal hemorrhage secondary to mucosal ulcerations close to the pancreatic tissue,[19] pain secondary to pancreatitis and obstruction in prepyloric localization in newborns, intussusceptions, and exceptional malignant transformation of the ectopic tissue in papillary neoplasm.[20,21]

Diagnosis

The diagnosis could be made endoscopically or radiographically in antral or prepyloric localizations. In other localizations, diagnosis is made at the time of surgery. A definitive diagnosis is made histologically.

Management

The treatment of symptomatic ectopic pancreas is surgical. Excision is indicated as Meckel diverticulectomy or antral or ileal resection.

PANCREATIC AGENESIS AND HYPOPLASIA

Complete agenesis of the pancreas is a lethal condition that has been reported in the literature. Lack of insulin leads to intrauterine growth retardation, hyperglycemia, coma, and a rapid fatal issue.[22]

Partial anatomic pancreatic agenesis is unlikely to be symptomatic because the endocrine and exocrine functions are normal. Agenesis of the dorsal pancreas has been described in diabetes and pancreatitis.[23] Magnetic resonance imaging can assist in making the diagnosis.

Agenesis of the acinar tissue occurs in Shwachman syndrome, autosomal recessive disorder with exocrine pancreas deficiency, growth retardation, skeletal anomalies, and bone marrow dysfunction.[24] The prognosis is poor until bone marrow transplant.

DUCTAL ANOMALIES

Any variation of the normal patterns of the dorsal and ventral ducts leads to a number of common ductal anomalies. Some anomalies are pure anatomic variations without any clinical significance, for example, the absence of the duct of Santorini or the absence of a connection between the accessory duct and the main duct. Two ductal anomalies have been implicated in the pathogenesis of clinical disease: the failure of the fusion of the dorsal and ventral ductal systems, which results in a ductal pattern known as pancreas divisum,[25] and the pattern of the junction with the common bile duct.

PANCREAS DIVISUM

Pathogenesis

The ducts remain separated, and the dorsal pancreas, which is the main drainage of the pancreas, empties into the duodenum via the smaller accessory papilla. Multiple variants of the divisum anomalies have been described anatomically or after endoscopic retrograde cholangiopancreatography (ERCP).[26] The small accessory duct leads to functional obstruction of the pancreas and pancreatitis (Figure 62-3).

Clinical Presentation

The importance of the abnormalities lies in its presumed relationship with documented pancreatitis not attributable to alcohol, infection, or biliary tract disease. Because there is a large gap between the anatomic incidence and the frequency of these documented cases of pancreatitis, the causal relationship remains controversial. Pancreas divisum was identified in 7.4% of all children with pancreatitis and 19.2% of children with relapsing or chronic pancreatitis.[27]

Diagnosis

Diagnosis of pancreas divisum depends on ERCP in children older than 3 years and/or MRCP to demonstrate the

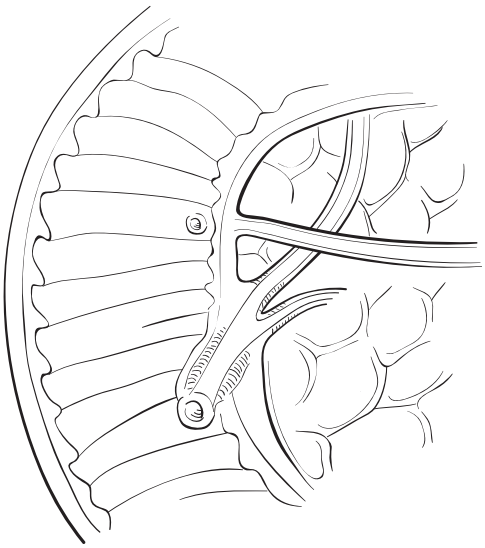

FIGURE 62-3 Ductal anomalies—pancreas divisum.

visualization of the duct of Santorini draining the pancreas. To confirm the diagnosis, the accessory papilla should be cannulated to visualize the duct of Santorini.[28]

Management

Because the causal relationship between pancreas divisum and pancreatitis is controversial, management is the subject of many discussions. Despite medical management of the episodes of pancreatitis, the visualization of a pancreas divisum leads to endoscopic treatment. Beneficial results could be expected by endoscopic enlargement of the accessory papilla. Surgical or endoscopic intervention is directed toward relief of ductal obstruction by a transduodenal sphincteroplasty.[29]

COMMON CHANNEL SYNDROME

Pathogenesis

Anomalies of the junctions of the common bile duct and the main pancreatic duct may be clinically significant. The extrahepatic bile duct is developed from the ventral pancreatic duct. Initially, the junction is extraduodenal and moves toward the duodenum wall. A failure of this progression toward the duodenum results in an abnormally long common pancreatobiliary channel. The junction remains outside the duodenum wall and is therefore not surrounded by the normal sphincter mechanism. The long common pancreatobiliary channel usually exceeds 10 mm in length compared with the normal estimated length of 5 mm in children. This may permit reflux of the pancreatic enzymes containing trypsin into the common duct, with resulting damage to the ductal wall. Occasionally, bile may reflux into the pancreatic duct as well.

Pancreaticobiliary reflux has been confirmed by dynamic MRCP after secretin stimulation.[30]

Clinical Presentation

Reflux of ductal contents in either direction may lead to two different clinical situations: choledochal cyst and pancreatitis. Common channel syndrome (Figure 62-4) is identified in 75% of the children with choledochal cyst. Recurrent pancreatitis is observed in 70% of choledochal cysts even after surgical disconnection of the bile duct from the pancreatic duct. Pancreatitis without choledochal cyst is related to bile reflux in the pancreatic duct with ductal ectasia.

Diagnosis

Abdominal ultrasonography is often diagnostic of choledochal cyst and is an indication for further imaging studies.

MRCP is noninvasive and can be performed in children without the use of contrast agents. It demonstrates the choledochal cyst, the common channel, and pancreatic ductal ectasia. Invasive imaging studies are mandated only if there is no clear evidence of congenital malformation and if the bile duct dilatation can be related to choledocolithiasis.

Percutaneous transhepatic cholangiography and ERCP are the most effective imaging studies to demonstrate the common channel.

In children less than 3 years of age, MRCP or percutaneous transhepatic cholangiography can be performed safely under general anesthesia. In older children, MRCP or ERCP can be discussed, but ERCP should be avoided in episodes of acute pancreatitis.

Management

Radical excision of the choledochal cyst and reconstruction by a Roux-en-Y hepaticoenterostomy is the treatment of choice for choledochal cyst.

Good results can be achieved with hepaticoenterostomy.[31] Postoperative complications are uncommon. Cholangitis and pancreatitis are the most frequent complications and could lead to imaging reassessment for anastomotic stricture or hepatic duct or pancreatic duct calculi. Malignancy of the biliary enteric anastomosis has been reported even many years after radical excision.[32]

Pancreaticojejunostomy and/or endoscopic sphincteroplasty may be curative in exceptional common channel syndrome without choledochal cyst but with pancreatic ductal ectasia.

FIGURE 62-4 Ductal anomalies—common channel syndrome.

OTHER CONGENITAL ANOMALIES

Congenital Pancreatic Cysts

Congenital pancreatic cysts are uncommon. Unilocular or multiple congenital cysts are lined by an epithelium. The presentation is variable, including asymptomatic cysts, abdominal masses, and pancreatitis. The cysts may be associated with other anomalies, such as polydactyly and anorectal malformations. Multilocular cysts may be an isolated pancreatic lesion, as well as part of von Hippel-Lindau disease, with hereditary cerebellar cysts, hemangiomas of the retina, and kidney and liver cysts.[33]

Enteric Duplication Cysts

Intrapancreatic or juxtapancreatic gastric or duodenal duplications with ductal communications are uncommon. Symptoms may include failure to thrive, abdominal pain, and episodes of pancreatitis. The lesion may be recognized by ultrasonography, upper gastrointestinal studies, and MRCP.

Exploration is necessary to excise the lesion and to alleviate recurrent episodes of pancreatitis. Excision of the duplication is performed close to the duodenal wall without pancreaticoduodenal resection.[34]

CHAPTER 63

TUMORS

Assad Butt, MB, BS, DCH(Lon), MRCP, CPCH

Pancreatic tumors and lesions that may mimic tumors rarely occur in childhood. They can present major diagnostic and therapeutic challenges. Pancreatic cancer in adults is the fifth leading cancer in the United States and has the poorest survival rate of the major malignancies, accounting for more than 25,000 deaths annually. In contrast, childhood pancreatic cancer represents less than 5% of all malignancies affecting children under the age of 15 years.[1,2]

Recent advances in genetics and immunohistochemistry have resulted in better understanding of the underlying pathogenetic mechanisms and biologic behavior of these lesions. Improvements in imaging techniques, including the application of newer modalities such as endoscopic ultrasonography (EUS) and magnetic resonance cholangiopancreatography (MRCP), have helped with better localization, improved noninvasive characterization, and tissue sampling of lesions.[3–5]

The World Health Organization classification of pancreatic tumors is currently one of the most widely accepted. This classification is based on the nature of the tissue of origin and relative malignant potential of the tumor (Table 63-1).[6] Although not all of the tumor subtypes have been reported in children, this classification provides a useful framework for considering the differential diagnosis and discussion of pancreatic tumors in children.[7]

PRIMARY EPITHELIAL EXOCRINE TUMORS

Benign and malignant exocrine tumors of the pancreas can be either cystic or solid and can arise from either ductal or acinar tissue. There is a spectrum of biologic behavior and tumor aggressiveness between different tumor groups.

CYSTIC TUMORS

Pancreatic cystic tumors are an important group clinically because other cystic lesions of the pancreas may mimic them. Pseudocysts are the most common cystic lesions encountered in childhood, accounting for about 75% of pancreatic cystic lesions. They occur either secondary to trauma or chronic pancreatitis resulting from other causes and are discussed in detail in Chapter 64, "Pancreatitis." Their diagnosis may be confused with cystic neoplasm and may result in inappropriate management.[8] The investigation and differential diagnosis of cystic neoplasia are considered below.

SEROUS CYSTADENOMA

Two types of serous cyst adenoma exist: serous microcystic adenoma and serous oligocystic adenoma. Both rarely occur in children.

Serous microcystic adenomas have a female predominance and are more commonly found in the pancreatic body and tail.[9] One-third of these lesions are asymptomatic and found incidentally, whereas the remainder have symptoms related to pressure of the tumor on adjacent structures.[7] The lesions are benign tumors consisting of numerous small cysts arranged around a central stellate scar. They are lined by epithelial cells and show evidence of ductular differentiation.[10] No specific tumor markers identify this lesion. Radiographs may show calcification in some patients. Computed tomography (CT) reveals a well-demarcated multiloculated cyst, on occasions demonstrating the central stellate scar.

Surgical excision of the tumors is usually unnecessary unless the patients are symptomatic. However, the histologic diagnosis must be confirmed.[7]

Serous oligocystic adenomas are benign tumors with an equal sex predominance that occur more rarely in children than the serous microcystic adenoma. The etiology is unknown; however, it is of interest that two reports in children have isolated cytomegalovirus from adjacent pancreatic tissue.[11,12]

Most tumors are located in the head and body of the pancreas and are composed of a few relatively large cysts showing evidence of ductular differentiation. Infants usually present with a palpable abdominal mass. Resection is needed if lesions are symptomatic.

MUCINOUS CYSTADENOMAS

This benign cystic pancreatic tumor is closely related to a spectrum of mucinous cystic tumors that includes mucinous cystadenocarcinoma and consequently has a definite malignant potential. There is a strong female preponderance. The majority of tumors are located in the tail of the pancreas.[9] The tumors usually consist of a solitary large unilocular cyst composed of mucin-secreting epithelial cells. Because of the malignant potential, wide surgical excision, including the associated capsule, is always recommended.[10]

TABLE 63-1 CLASSIFICATION OF PANCREATIC TUMORS

PRIMARY	EXAMPLE OF TUMOR TYPE
EPITHELIAL	
Exocrine	
Benign	Serous cystadenoma, mucinous cystadenoma (premalignant), mature cystic teratomas, papillary cystic tumor
Borderline malignant	Papillary cystic tumor
Malignant	Mucinous cystadenocarcinoma, ductal adenocarcinoma, acinar adenocarcinoma, pancreatoblastoma
Endocrine	
Benign	Insulinoma (90–95%), gastrinoma (40%), VIPoma (50%), GRFoma (67%), glucagonoma (40%), somatostatinoma (25%)
Borderline malignant	No pediatric example exists
Low-/high-grade malignant	Insulinoma (5–10%), gastrinoma (50%), VIPoma (33%), GRFoma (33%), glucagonoma (60%), somatostatinoma (75%), MEN type I (associated with gastrinoma, insulinoma, and VIPoma in decreasing frequency, respectively), islet cell carcinoma (functional or nonfunctional lesions)
NONEPITHELIAL	
Benign	Fibrous histiocytoma, juvenile hemangioendothelioma, lymphangioma, glomus tumors, myofibromatosis
Malignant	Rhabdomyosarcoma, lymphosarcoma, lymphomas
SECONDARY	
Malignant	Adenocarcinoma (local spread from stomach, intestine, biliary tract), malignant melanoma, leukemia, renal and lung tumors (hematogenous spread)
TUMOR-LIKE LESIONS	
Exocrine	Pancreatic cysts, chronic pancreatitis, ductal changes (eg, squamous metaplasia, mucinous cell hypertrophy, ductal papillary hyperplasia, adenomatoid duct hyperplasia), acinar changes (eg, focal acinar transformation), heterotopic pancreas, heterotopic spleen in pancreas, hamartomas, inflammatory pseudotumors
Endocrine	Islet cell hyperplasia, islet cell dysplasia, persistent hyperinsulinemic hypoglycemia of infancy (nesidioblastosis)

Adapted from Kloppel H et al.[6]
GRF = growth hormone releasing factor; MEN = multiple endocrine neoplasia; VIP = vasoactive intestinal polypeptide.

CYSTADENOCARCINOMA

SEROUS CYSTADENOCARCINOMA

This entity has not been reported in the pediatric literature.

MUCINOUS CYSTADENOCARCINOMA

The clinicopathologic features of this malignant tumor are similar to that of its benign counterpart, the mucinous cystadenoma. However, the tumor is invasive, tending to spread locally in the same way as ductal adenocarcinoma. The incidence is half that of mucinous cystadenomas. The prognosis is excellent if resection is complete.[9,10]

MATURE CYSTIC TERATOMAS ("DERMOID CYSTS")

These lesions are benign extragonadal germ cell cysts derived from all three germinal layers and may include hair, teeth, cartilage, sebaceous material, and sweat glands. They are rarely found in the pancreas but can occur anywhere in the substance of the pancreas or be attached to it.[13–15] Excision is the treatment of choice.

PAPILLARY CYSTIC TUMOR

Papillary cystic tumors of the pancreas are exceptionally rare neoplasms in children. Since their original description by Frantz in 1959, more than 400 cases have been reported in the English literature (mean age 23.9 years; range 2–74 years). By 1999, approximately 90 cases were reported in children (age group < 18 years).[16] Such cases represent 8 to 17% of all pediatric pancreatic neoplasms.[17] The tumors occur most frequently in young females (91% of cases), especially adolescent girls, and there may be a preponderance in Asian and black patients.[16–18] There is no conclusive evidence for the role of sex hormones in the pathogenesis of papillary cystic tumors; however, they may have an influence on tumor growth. Patients typically present with vague gastrointestinal systems such as upper abdominal discomfort or pain caused by an enlarging and often palpable abdominal mass. Because of slow tumor growth, patients often remain asymptomatic until the tumor has enlarged considerably or is detected incidentally on ultrasound imaging for an unrelated indication. There is usually no evidence of endocrine or exocrine dysfunction, and liver function and endocrine tests are normal.[16,17,19]

The tumors are slow growing and of low malignant potential. The body and tail are more frequently affected (64%) than the head of the pancreas, with a well-circumscribed tumor mass of average diameter between 8 and 10 cm.[16] Macroscopically, the tumors are round or oval, encased by a fibrotic capsule and showing intermingling solid and overt cystic-hemorrhagic areas on the surface. Microscopically, typical features are sheets and cords of polygonal cells comprising pseudopapillary structures with fibrovascular stalks or pseudorosettes.[16] Immunohistochemically, they may express various markers, including neuron-specific enolase (91/108 cases), α_1-antitrypsin (101/132 cases), vimentin (47/65 cases), progesterone (11/31 cases), and estrogen (3/56 cases), as well as other neuropeptides.[17] Most studies have not demonstrated reactivity for pancreatic hormones; importantly, this distinguishes papillary cystic tumors from nonfunctioning endocrine tumors, which may look similar on microscopic histologic assessment.[16]

Tumor invasion of adjacent organs has been reported but is rare.[20,21] The treatment of choice is complete excision of the lesion. Overall, more than 95% of patients are cured. Long disease-free intervals have been recorded after

initial resection even in patients whose tumors have either spread locally or metastasized.[21,22] More aggressive tumors are seen in older patients, tumors with a high deoxyribonucleic acid (DNA) index, aneuploidy, frequent mitotic figures, and/or nuclear atypia.[23] The origins of this tumor remain enigmatic. In a limited number of cases, chromosomal abnormalities have been found that are known to be associated with oncogenes. The chromosomal analyses have shown unbalanced translocations between chromosomes 11 and 14, loss of the X chromosome, and trisomy 3.[23] Recent studies suggest that there are abnormalities in the β-catenin or adenomatous polyposis coli (APC) gene pathways, influencing the pathways of neoplastic progression in papillary cystic tumors.[24,25] In Abraham and colleagues' study, a series of 20 papillary cystic tumors were analyzed by immunohistochemistry and molecular genetic techniques.[25] Almost all papillary cystic tumors harbored alterations in the APC–β-catenin pathway. Nuclear accumulation of β-catenin protein was present in 95% (19/20 cases), and activating β-catenin oncogene mutations were identified in 90% (18/20 cases) of the papillary cystic tumors. These findings are similar to those alterations recently identified in other nonductal pancreatic neoplasms (pancreatoblastomas and acinar carcinomas). In contrast, genetic alterations commonly found in pancreatic ductal neoplasms (ductal adenocarcinoma) were absent or detected only invariably.[25]

APPROACH TO INVESTIGATION AND DIAGNOSIS OF CYSTIC TUMORS

A precise diagnosis of all pancreatic cystic lesions is of key importance to exclude cystic pancreatic neoplasia. A more detailed discussion of non-neoplastic lesions is considered in Chapter 62, "Congenital Anomalies of the Pancreas."

Ultrasonography is the most useful initial diagnostic test and can confirm the cystic nature of the lesions. Endoluminal ultrasonography has been recently proposed for delineating small cystic lesions and obtaining tissue samples by fine-needle aspiration to aid specific diagnosis and thus help differentiate benign from potentially malignant lesions (Figure 63-1). One recent adult study suggests high sensitivity (91%), specificity (60%), and accuracy (82%) for EUS in identifying malignant or potentially malignant pancreatic cystic lesions compared with surgical histopathology.[4] The study included 34 patients (16 men, 18 women; mean age 55 years) who underwent surgery for suspected pancreatic cystic lesions based on CT and transabdominal ultrasonography. In addition to EUS, other assessments did not improve overall evaluation of the lesions. The respective sensitivity, specificity, and accuracy were (1) cyst fluid cytopathology, 27%, 100%, and 55%, and (2) carcinoembryonic antigen, 28%, 25%, and 27%. Although this approach has been applied recently to children and shows promise, it needs further evaluation.[3]

CT and/or magnetic resonance imaging (MRI) have an established role in determining the nature of a cyst and its precise relationship to the pancreatic duct and surrounding tissues.[26–28] The advent of MRCP has provided a further tool for evaluation. One recent study suggests that this modality has a distinct advantage over endoscopic retrograde cholangiopancreatography in the diagnosis of mucin-producing tumors of the pancreas and cystic lesions. MRCP provides a better image of the entire lesion, including the distal part that is obstructing the pancreatic duct.[5] Use of findings from multiple modalities can be helpful in formulating a differential diagnosis. Selective celiac and gastroduodenal angiography have been suggested as useful diagnostic tools in selected patients. [29]

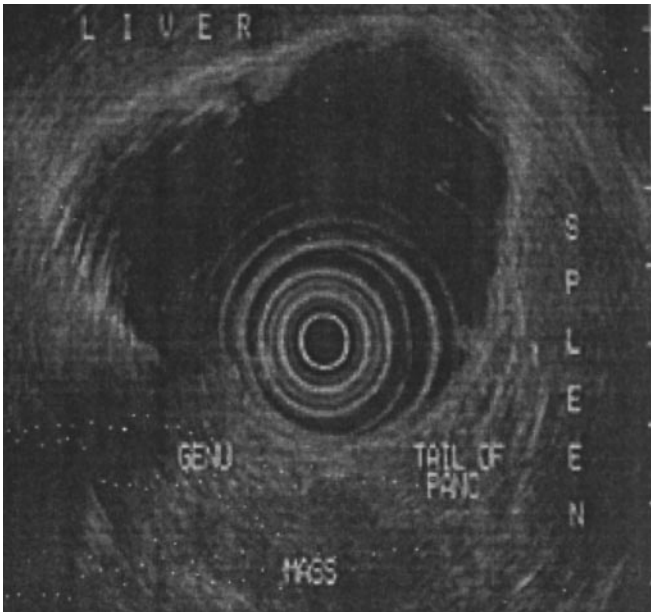

FIGURE 63-1 Papillary cystic neoplasm in a young girl as visualized via endoscopic ultrasonography. Reproduced with permission from Victor Fox, The Children's Hospital, Boston.

Despite advances in imaging techniques, definitive preoperative diagnosis is not possible in many cases (Figure 63-2). In a recent multi-institutional review of 398 cases of cystadenomas and cystadenocarcinomas of the pancreas, 93% of cases required surgery to establish a definitive diagnosis.[30] The study reported cases of serous cystadenoma

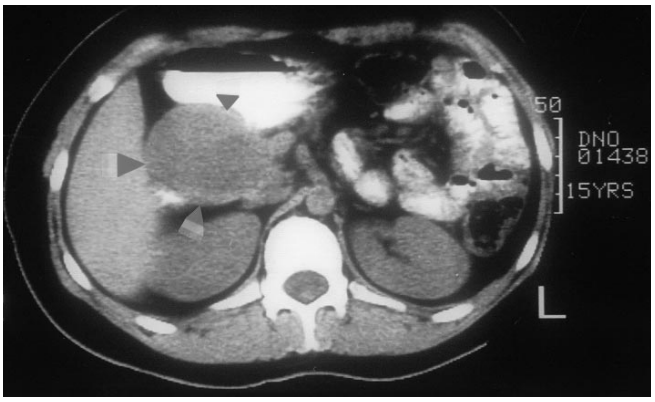

FIGURE 63-2 Appearance of a tumor in the head of the pancreas seen on an unenhanced computed tomographic scan. A definitive diagnosis of papillary cystic tumor was established postoperatively. Reproduced with permission from Professor L Spitz, The Institute of Child Health, Great Ormond Street Children's Hospital, London.

(n = 140), mucinous cystadenoma (n = 150), and mucinous cystadenocarcinomas (n = 78).[30] In approximately one-third of each group, the tumor was asymptomatic at presentation. Preoperative diagnostic accuracy was poor: 20% in cases of serous cystadenoma, 30% in cases of mucinous cyst adenoma, and 29% in those diagnosed with mucinous cystadenocarcinoma. Furthermore, even the utility of intraoperative frozen section allowed for definitive histologic diagnosis in only 50% of cases of serous and mucinous cystadenomas and 62% of cases of mucinous cystadenocarcinoma. Consequently, conservative management was warranted in only 7% of cases who had asymptomatic well-documented serous cystadenoma based on a combination of findings from spiral CT, EUS, and/or diagnostic aspiration of cyst.[30]

ADENOCARCINOMA

Adenocarcinoma of the pancreas exists in two malignant forms arising from ductal or acinar tissue. Ductal adenocarcinoma is by far the most common malignant pancreatic tumor in adults compared with acinar adenocarcinoma, which occurs in only 11%. In contrast, the incidence in children is more evenly distributed, with 53% of the carcinomas of ductal origin and 47% of acinar origin. The total number of pediatric cases reported in the English literature is very small, accounting for only 30 cases in total up to 1983.[31,32]

A combination of genetic and environmental factors most likely contributes to the pathogenesis of pancreatic adenocarcinoma. Genetic predisposition is suggested by an increased incidence in patients with hereditary pancreatitis, as well as a report of four otherwise healthy siblings of an index case of pancreatic ductal carcinoma who also developed this condition.[33]

A number of other conditions have also been linked to a potential increased risk of developing pancreatic carcinoma. These have included hamartomatous polyposis syndromes such as Peutz-Jeghers syndrome, as a direct result of functional deletion of tumor suppressor genes,[34] and celiac disease or dermatitis herpetiformis. However, an increased risk is not observed in children and adolescents with celiac disease. Epidemiologic studies have suggested an increased risk with environmental or other factors, such as men exposed to degreasing agents and women who smoke or have uterine myomas or prior oophorectomy.[35] In addition, higher social class, increased consumption of animal fat and protein, and wine consumption are potential risk factors.[35] With emergence of the field of transplant in recent years, an increased risk of developing de novo malignancies in this group should also be considered. In a series of 1,151 organ allograph recipients, 1,813 de novo malignancies were found, of which 755 involved the hepatobiliary-pancreaticoduodenal area.[36] Whereas lymphomas comprise the majority (63% of cases), pancreatic carcinomas accounted for 11% of the total.[36,37] Down syndrome shows an interesting tumor profile; whereas most solid tumors are underrepresented, pancreatic tumors are in excess.[38] Patients with cutaneous malignant melanoma have an increased risk of subsequent primary carcinoma.[39]

Ductal Adenocarcinoma

The malignant and aggressive nature of ductal adenocarcinoma relates to its ability to spread along the ducts to the capsule of the pancreas, adjacent lymph nodes, and retroperitoneal space.[31] Patients typically present with abdominal pain and weight loss. More than half of the patients present with obstructive jaundice. Additional symptoms include those of gastrointestinal bleeding, pancreatitis, and depression.[40]

The tumors are usually located in the head of the pancreas. They often generate a dense fibrotic reaction, resulting in a compact hard retroperitoneal mass. CT often demonstrates these lesions as irregular heterogeneous enhancing lesions without a visible capsule.[41] Histologically, they appear as moderately well-differentiated ductal carcinoma cells containing mucin but lacking zymogen.[7,40] Immunohistochemically, they are almost all positive for carcinoembryonic antigen.[7]

Cytogenetic studies show specific chromosomal abnormalities, including the loss of 9p, 17p, and 18q, as well as gains of 8q and 20q. Analysis of pancreatic fluid obtained at the time of endoscopic retrograde cholangiopancreatography by fluorescent in situ hybridization in 12 affected patients revealed a loss of 18q in 92%.[42] Further studies have shown that 70% of these mutations resulted in activation of oncogenes (ie, Ki-*ras*, C-*erb*B12) or in activation of tumor suppressor genes (*TP53*, *MTS1*, *Smad4*, $P16^{INK4}$).[42] One study found Ki-*ras* gene mutations at codon 12 in about 90% of cases and abnormal expression of the C-*erb* B12 oncogene in nearly 20% of cases.[43] A recent report suggests that a genetic diagnosis of ductal adenocarcinoma can be made by analysis of pancreatic fluid collected endoscopically for Ki-*ras* mutation analysis of both the supernatant and sediment of pancreatic fluid.[44] Other studies have shown alterations in those factors that may promote (*bax*) or block (*bcl-2*) apoptosis.[45] Studies have also shown an important role for tumor growth factor (TGF)-β and its signaling proteins in (1) allowing for tumor cell anchorage–independent growth,[46] (2) enhancing tumorigenicity by the TGF-β signaling inhibitor *Smad7*,[47] and (3) influencing disease progression (overexpression of type 2 TGF-β receptor may be a marker that correlates with disease progression and is associated with decreased patient survival).[48] Finally, recent studies have suggested an increased expression of inducible nitric oxide synthase in human pancreatic cancer, which correlates positively with the degree of apoptosis as expressed by the apoptotic index. These findings could, in the future, provide the basis for the development of potential therapeutic strategies.[49]

Only 10 to 20% of cases are amenable to curative surgical resection. A Whipple procedure is typically performed when the tumor is confined to the head of the pancreas. In addition to removal of the tumor, en bloc resection of the distal stomach, duodenum, and common bile duct is performed. Subsequently, continuity is restored by fashioning a pancreaticojejunostomy, choledochojejunostomy, or gas-

trojejunostomy.[40] In general, the 3-year survival rate is approximately 2%, with a mean survival after diagnosis of 4 to 6 months.[50] The core prognosis is related to a delay in diagnosis because 85% of tumors have metastasized at the time of diagnosis.[51] Palliation with chemotherapy, either single agent or in combination, and use of external beam radiation are of value for a limited duration only. A limited experience with high linear energy transfer particle (neutron or heavy iron) radiation therapy has produced significant decreases in tumor size but no improvement in patient survival.[40] A number of patients have gained some relief from intractable peritoneal pain with celiac plexus neurolysis.[52]

Acinar Adenocarcinoma

Acinar adenocarcinoma has already metastasized in most patients by the time a diagnosis is made. The tumor typically presents more commonly in males and in a reported age range from 3 to 90 years.[53,54] Symptoms at presentation are attributable to local expansion of the tumor or metastases. About 15% of patients present with a syndrome involving polyarthralgia, extrapancreatic fat necrosis, and eosinophilia.[53]

The tumor is a well-circumscribed nodular mass that occurs evenly throughout the pancreas. Ultrasonography shows a midrange echogenic mass. Dual-phase helical CT usually reveals large encapsulated lesions of lower attenuation with or without calcified and necrotic areas.[41] Histologically, acinar tumor cells are arranged in a ribbonlike configuration and contain eosinophilic cytoplasm and periodic acid–Schiff–positive zymogen granules on electron microscopy. Electron microscopic features can help distinguish acinar adenocarcinoma from islet cell tumors of the pancreas, which can look similar on routine light microscopy. In addition, immunostaining properties can distinguish between these two entities, which have also been reported to coexist as mixed acinar–islet cell carcinomas associated with insulin secretion.[55,56] Immunostaining of granules for various pancreatic enzymes is typically positive, including trypsin and lipase.

Cytogenetic studies show that these tumors typically lack those cell markers associated with ductal adenocarcinoma (ie, Ki-*ras* and *TP53*).[57] A recent study suggests that acinar adenocarcinomas are genetically distinct from their ductal counterparts, with demonstration of frequent allelic losses on chromosome 11p and alterations in the APC–β-catenin pathway.[58] It is of interest that similar genetic alterations have also been described in pancreatoblastoma (see the following section).

Treatment is directed at complete excision of the primary lesion and offers the only possible chance of cure. The prognosis is generally more favorable than that for ductal adenocarcinoma. Chemotherapy and radiotherapy are used mainly for palliation.[7]

PANCREATOBLASTOMA

Pancreatoblastoma was originally described by Becker in 1957. Subsequently, 65 pediatric cases have been reported in the literature and 4 cases in adults.[59] Although rare, it is the most common pancreatic neoplasm in childhood. It usually presents in early childhood (mean age approximately 4 years), but this tumor can occur at any age from the neonatal period to adulthood.[60] The tumor is more common in males (male-to-female ratio 1.3:1), and those of Asian descent account for approximately 50% of reported cases.[60,61] There is a reported association of pancreatoblastoma with Beckwith-Wiedemann syndrome (three reported cases).[61,62]

Clinically, most patients present with an incidental abdominal mass. Associated pain, weight loss, and obstructive jaundice are rare.[60] A number of patients have diarrhea of undetermined etiology on presentation. Cushing syndrome and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) have also been reported concurrently with pancreatoblastoma.[61]

Radiologic studies help determine tumor site and extent of disease. Ultrasonography reveals solid lobulated pancreatic masses with mixed echogenicity.[61] Fine-needle aspiration guided by ultrasonography has been useful in confirming the diagnosis.[61] CT typically reveals large firm, lobulated masses (7–8 cm in diameter) and provides more detailed information.

A review of 59 cases showed that the tumor can occur in any region of the pancreas, and typical features include hemorrhage (94% of cases), capsule formation (92% of cases), and necrosis (90% of cases).[63] All neonatal cases demonstrated cystic changes.[63] MRI, as with other pancreatic neoplasms, demonstrates high signal intensity on T_2-weighted images, with more variable intensity on T_1-weighted images.[64] Gadolinium enhancement is reported to be helpful in distinguishing pancreatoblastoma from other pancreatic tumors.[7] CT and/or MRI will usually correctly make a preoperative diagnosis of pancreatoblastoma.[65] Although a pancreatoblastoma is a malignant tumor, the course is more favorable than with pancreatic acinar cell carcinoma as a result of the presence of a surrounding capsule. Consequently, metastatic spread occurs rarely. Sites of metastases at diagnosis or at the time of recurrence are hepatic (21/69 patients), pulmonary (3/69), and bone (2/69).[59]

Serum α-fetoprotein (AFP) is elevated in nearly 80% of cases, with a median level of 1,280 ng/mL (range 30–138,000 ng/mL).[59] When elevated at diagnosis, evaluation of serum AFP levels is useful to follow the course of the disease, including monitoring for tumor recurrence. However, one reported case in the literature describes a boy with a pancreatoblastoma and a high level of AFP at diagnosis whose tumor recurred as metastatic lesions without a concomitant increase in serum AFP level above normal limits.[66] Yolk sac tumor or hepatoblastoma should also be considered in the differential diagnosis of patients with high AFP levels. One report has suggested that pancreatic AFP (yolk sac origin) can be differentiated from liver AFP (as seen with hepatoblastoma) by using lectin-affinity immunoelectrophoresis.[67]

Histologically, the tumor consists of a soft solid mass, which is usually surrounded by a fibrous capsule that

becomes infiltrated in advanced cases. The tumor is composed of epithelial tissue with acinar differentiation, squamoid cell nests, and occasional endocrine cells. Rarely, cases have pronounced mesenchymal elements, including chondroid and osteoid tissue. Recent cytogenetic studies have provided insights into the possible pathogenesis of pancreatoblastomas. One report has demonstrated an association with chromosome 11p loss of heterozygosity and insulin-like growth factor 2.[68] Another suggests that pancreatoblastomas are genetically distinct from pancreatic ductal adenocarcinomas but bear a close resemblance in molecular pathogenesis to heptatoblastomas. In addition, a link is proposed between familial adenomatous polyposis and pancreatoblastoma. [69]

Treatment is by excision, often involving pancreaticoduodenectomy. If complete resection is achieved initially or after preliminary chemotherapy for reduction of tumor size, 80% achieve complete remission (21/24 cases).[61] Of 10 children who had marginally resectable tumor or partial resection, only 5 survived.[61] Because often tumors cannot be completely resected at diagnosis, preoperative chemotherapy has been employed with some success; however, there is no consensus regarding optimal chemotherapeutic regimens. In one report, a regimen including cisplatinum and doxorubicin documented good tumor response in 9 of 10 children who received the chemotherapy, with the 6 subjects remaining disease free for a median time of 28 months after initial diagnosis.[59] However, chemotherapy provides only transient benefit and must always be followed by surgery. Local radiotherapy after surgery is recommended in patients with a marginally resectable tumor or with tumor spillage during resection.[59] Prognosis is generally better in children. Overall, about 70% of patients are well at 1 year, and tumor-free survival after 5 years is approximately 30%.[7] A tumor-free follow-up of 28 years after surgery has been reported.[70]

PRIMARY EPITHELIAL ENDOCRINE TUMORS

Pancreatic endocrine tumors are a rare and diverse group of lesions that account for a greater proportion of all pancreatic tumors in children than in adults. The tumors may be either functioning or nonfunctioning. Although many of the tumors exhibit features of multihormonality, the specific clinical syndromes that are caused by these neoplasms are predominantly attributable to the systemic effects of only one of their secretory products. (Table 63-2). Advances in our ability to detect the various hormones that are secreted in excess by these tumors have resulted in major progress in our understanding and diagnosis of these challenging tumors. The diagnosis often rests more on the identification of humoral factors than on tissue biopsy. There is a wide overlap in biologic behavior and in the spectrum of benign and malignant potential of these tumors. Descriptions of gastrin-producing tumors (Zollinger-Ellison syndrome), VIPomas (vasoactive intestinal polypeptide; Verner-Morrison syndrome), and carcinoid tumors can be found in Chapter 47, "Secretory Tumors." Glucagonomas, somatostatinomas, and growth hormone–releasing factor adenomas are listed in Table 63-2 to illustrate their main biologic features but are not discussed in the text because they have not been reported in the pediatric age range.

Recent studies have shown new insights into the factors that might influence or predict the biologic behavior of these tumors. One report has suggested that assessment of tissue mitotic rate and necrosis correlates strongly with survival.[71] Other studies have suggested allelic losses on the X chromosome in foregut endocrine tumors, including pancreatic neoplasia, shown by X chromosome loss of heterozygosity.[72,73] A study using the technique of comparative genomic hybridization, which allows for the simultaneous evaluation of the entire tumor genome, has shown a variety of types of chromosomal imbalances in 96% of cases (25/26 patients). These abnormalities discriminated to some extent between sporadic foregut and midgut tumors and reveal new distinct candidate regions in the human genome that are associated with sporadic endocrine tumors.[74]

INSULINOMA

Insulinomas are the most common functioning pancreatic endocrine tumors. Benign tumors usually account for between 90 and 95% of cases. The first description of a patient with an insulinoma syndrome was in 1902, predating the discovery of insulin by Banting and Best in 1922.[75] A large review of patients with insulinoma from 1974 included 1,067 cases (mean age 45.5 years; 68% of patients in the age range of 30 to 60 years; female predominance in a ratio of 3:2).[76] The reported incidence is of 4 cases per 1 million person-years.[76]

Clinically, patients present with symptoms of hypoglycemia, including neuropsychological symptoms such as loss of consciousness, lethargy, confusion, dizziness, blurred vision, epilepsy, and coma, occurring in up to 92% of patients.[76] Amnesia is also reported in 41% of cases.[77] Irreversible central nervous system damage owing to hypoglycemia was evident in 6.8% of patients. Symptoms related to catecholamine response, such as palpitations, tachycardia, and hypertension, were also common. In addition, patients may complain of hunger, vomiting, or epigastric pain. One study documents obesity in 47% of cases.[76]

Hypoglycemia may be a feature of a number of other clinical conditions. The presence of hypoglycemic symptoms, abnormally low serum glucose, and relief of symp-

TABLE 63-2 ENDOCRINE TUMORS OF THE PANCREAS

TUMOR TYPE	MAJOR CLINICAL FEATURE(S)
Insulinoma	Hypoglycemia, altered mental state
Gastrinoma	Gastric acid hypersecretion, peptic ulceration, steatorrhea
GRFoma*	Achromegaly
Glucagonoma*	Hyperglycemia, mild diabetes mellitus, necrolytic erythematous migratory rash
Somatostatinoma*	Hypochlorhydria, weight loss, mild diabetes mellitus, steatorrhea, cholelithiasis
VIPoma	Severe watery diarrhea, achlorhydria, hypokalemia

*These tumors have not yet been reported in the pediatric age group

toms with glucose infusion (Whipple triad) are supportive of the diagnosis.[75] The diagnosis can be aided by inducing fasting hypoglycemia, with measurement of insulin levels. Insulin levels are typically greater than 6 μU/mL despite a serum glucose level less than 40 mg/dL.[75] In the presence of hypoglycemia, an absence of urinary ketones or elevated free fatty acids supports the diagnosis. Other supportive tests include the quantification of proinsulin, which is less than 24% of serum insulin in controlled subjects and greater than 24% in 90% of patients with insulinoma.[78,79] The classic fasting period is 72 hours because previous data suggest that all patients will become symptomatic with hypoglycemia by this time.[75] However, recent evidence suggests that with current available insulin and proinsulin assays, a 48-hour fast is sufficient for a definitive diagnosis and should now become the standard.[80]

The C-peptide suppression test has been advocated as a screening test in suspected cases. In this test, injected porcine insulin fails to suppress endogenous C-peptide levels in affected patients. Despite the various means to establish a diagnosis, there is a delay from the time of presentation of a mean of 37.4 months.[75] In unusual cases in which Munchausen syndrome by proxy is suspected, quantification of C-peptide, which is produced in equimolar concentrations with endogenous insulin but is absent in pharmaceutical insulin, and measurement of serum and urine levels of oral hypoglycemic agents should be performed.

Ninety-eight percent of insulinomas are located within the pancreas.[81] Extrapancreatic sites include the duodenum, ileum, and lungs.[82] The lesions are typically small (90% less than 2 cm in diameter), solitary (83%), and nearly equally distributed between the head, body, and tail of the pancreas.[76,83] The presence of multiple tumors should raise the suspicion of multiple endocrine neoplasia (MEN) type I, as discussed later in this chapter.

One of the major challenges in the management of insulinomas is the difficulty of preoperative localization because of their small size. In different series, 20 to 60% of tumors are not visualized prior to surgery.[84] A multiinstitutional study from 1990 reported the sensitivity of localizing a tumor by various noninvasive and invasive modalities as follows: abdominal ultrasonography, 39%; CT, 33%; arteriography, 62%; and transhepatic portal venous sampling, 89%.[84] A report of 11 cases assessed by the same modalities showed similar sensitivities. In addition, newer techniques of MRI, EUS, and the arterial stimulation test with venous sampling were also reported, showing sensitivities of 30%, 50%, and 91%, respectively.[85,86] More recent experience with EUS shows promise. Evaluation of 54 endocrine tumors of the pancreas, including 29 cases of insulinomas, showed an overall sensitivity and accuracy of 93% in locating the tumor.[87] Some reports have suggested that extensive invasive investigations to achieve preoperative localization of the tumor are unnecessary because a combination of intraoperative palpation (sensitivity greater than 90%) and intraoperative ultrasonography will detect nearly all solitary lesions.[88–90]

Initial treatment of insulinoma is dietary, involving the use of frequent snacks and complex carbohydrates to prevent hypoglycemia. Pharmacologic means may be used to treat hypoglycemia in patients with inoperable or metastatic disease or in those instances in which a tumor cannot be localized. Diazoxide acts by directly inhibiting beta-cell release of insulin and by increasing glycogenolysis by inhibition of cyclic adenosine monophosphate phosphodiesterase.[75,83] Diazoxide is effective in 60% of patients but has major side effects that are usually dose related, such as sodium retention, nausea, and hirsutism.[82] Other alternatives include octreotide, which is shown to be efficacious in 40 to 60% of cases, and verapamil, which reduces insulin release by calcium channel blockade.[82]

The treatment of choice is surgical removal of the tumor. Most surgeons advocate enucleation of these firm adenomas with their pseudocapsule rather than resection. In circumstances when the tumor is not localizable intraoperatively, medical treatment with possible re-exploration at a future date is favored over blind distal resection of the pancreas because 32% of lesions are located in the head of the pancreas. Tumor infiltration is indicative of a malignant state, which warrants resection rather than enucleation. Metastases occur typically to local lymph nodes or the liver. Malignant lesions are usually greater than 2.5 cm in diameter, in contrast to a typical insulinoma, which is between 0.5 and 1 cm.[90] Complications of resection can be seen in up to 55% of cases and include pancreatitis, fistula formation, pseudocyst formation, bleeding, and infection.[84] In addition to aggressive resection, malignant insulinomas have shown variable response to antihormonal chemotherapy and radiotherapy.[7,75] Postoperatively, rises in serum glucose can be seen within 20 minutes of resection in 70% of cases.[78] Consequently, intraoperative monitoring of glucose and immunoreactive insulin has been advocated to confirm that the insulinoma has been completely excised.[91] Hypoglycemia may last for up to 20 days postoperatively and therefore needs monitoring during this time.[76]

MEN TYPE I (WERMER SYNDROME)

MEN type I is a syndrome of malignant potential that involves synchronous or metachronous development of endocrine lesions in the parathyroid, pancreas, and anterior pituitary glands. Less common are associated lesions in the gastrointestinal tract, thymus, lungs, and other sites. In contrast, MEN type II involves the thyroid gland and adrenal medulla.

MEN type I is an autosomal dominant condition that can also occur sporadically. Patients may have primary hyperparathyroidism (88–97%), multiple duodenal pancreatic endocrine tumors (81–82%), and/or pituitary adenomas. Associated skin angiofibromas and collagenomas are common.[92] Of less frequent occurrence are thymic carcinoids, adrenocortical adenomas, thyroid adenomas, and subcutaneous lipomas.[93,94] Patients with MEN type I account for 17% of all patients with hyperparathyroidism, 33% of all patients with Zollinger-Ellison syndrome, 4% of patients with insulinoma, and a small fraction of patients with VIP-secreting tumors, somatostatinomas, and glucagonoma syndromes.[95]

The occurrence of MEN type I was first linked to a tumor suppressor gene (*mu*) at chromosome 11 q13 in 1988. Further studies revealed *MEN1* gene mutations in sporadic cases of gastrinoma (33%) and insulinoma (17%) and deletions of one of the MEN alleles in gastrinomas (93%) and insulinomas (50%).[96]

Pancreatic lesions are either functioning or nonfunctioning. The latter are usually numerous and are microadenomas. Of the functioning lesions, the majority are gastrinomas, followed by insulinomas and VIPomas.

Specific treatment is determined by the type of pancreatic lesion. Tumors are often multiple, especially gastrinomas, which are typically within the duodenum. Production of multiple hormones is documented in 57% of cases. However, 80% contain one predominant hormone, most commonly insulin.[97] The significant morbidity and mortality associated with these tumors and the possibility of testing for *MEN1* gene mutations have raised the issue of screening affected members and kindred. One recent study suggested that screening facilitates the identification of individuals who carry *MEN1* gene mutations and allows one to exclude nonmutant gene carriers from further investigations. This study included 45 members from 10 *MEN1* Swiss families.[98] Prospective biochemical and radiologic screening of carriers was undertaken and revealed the following abnormalities in asymptomatic *MEN1* gene carriers: nine cases of primary hyperparathyroidism, three cases of nonfunctioning pancreatic tumors, one case of gastrinoma, one case of a nonfunctioning microadenoma of the pituitary gland, and one case of macronodular adrenal hyperplasia. Earlier detection of *MEN1*-associated tumors may allow for a reduction in future morbidity and mortality. A similar approach has also been recently applied in families presenting with familial hyperparathyroidism in which genetic screening for *MEN1* mutations was carried out with the suggestion that positive genetic screening may predict disease and allow early detection and appropriate treatment before initiation of symptoms.[99]

A number of biochemical and radiologic investigations have been suggested to detect lesions associated with MEN type I. These include serum prolactin and insulin (IGF-I) for pituitary lesions, serum parathyroid hormone and total serum calcium (corrected for albumin level) for the parathyroids, and serum glucose, insulin, proinsulin, glucagon, gastrin, and plasma chromogranin A for the pancreatoduodenal tumors. In addition, a standardized meal or secretin simulation test analyzing serum polypeptides and gastrin is recommended.[100] Studies have suggested the use of fasting human pancreatic polypeptide levels as an additional screening tool. One study of 202 patients with MEN type I revealed its sensitivity to be 95% and specificity to be 88% in the detection of islet cell tumors.[101] Advances in EUS are promising for tumor localization, but other imaging modalities have been inadequate for tumor screening.[102] The risk of metastasis appears to be related to tumor size, with a 25% risk with 2 cm lesions and a 60% risk with 3 cm lesions. However, this relationship remains controversial.[103]

A recent single-institution retrospective review of 233 patients with MEN examined outcome. This revealed that 28% of patients died of causes related to MEN type I, most commonly metastatic islet cell malignancy. The remaining patients died of causes unrelated to MEN type I, most commonly coronary artery disease and nonendocrine malignancies (14% each). The overall 20-year survival of MEN type I was 64% compared with an age- and gender-matched comparison group of 81%.[104] The authors suggest that earlier diagnosis and appropriate treatment of potentially malignant tumors may lead to a reduction in premature mortality.

ISLET CELL CARCINOMA

Islet cell carcinomas arise from functional pancreatic lesions associated with hypoglycemia (see above) or the Zollinger-Ellison syndrome (Chapter 47). They are usually associated with MEN type I, which was discussed earlier. Nonfunctioning islet cell carcinomas occur more commonly in children than in adults. Diagnosis is often delayed because these tumors present as an abdominal mass with a high incidence of metastases.[7]

There is a reported association between von Hippel-Lindau (VHL) disease, a hereditary cancer syndrome, and pancreatic islet cell tumors.[105] VHL disease is caused by germline mutations of the VHL tumor suppressor gene located on chromosome 3p25. The syndrome is characterized by the development of vascular tumors of the central nervous system and retina, clear cell renal carcinomas, pheochromocytomas, endolymphatic sac tumors, and benign cysts affecting a variety of organs, in addition to pancreatic islet cell tumors.[106–107] In one report, solid pancreatic lesions were detected in 12% of patients with VHL disease.[105] Studies suggest that larger primary tumors (greater than 2–3 cm) are associated with hepatic metastases. These may be prevented by early detection and resection.[105,108] Furthermore, analysis of germline VHL mutations may help predict the occurrence of metastatic disease. Eighty percent of such patients showed mutations in exon 3 (4/5 patients) compared with 46% (18/39 patients) without metastatic disease.[108] A malignant islet cell tumor has also been reported in a 12-year-old boy with tuberous sclerosis complex.[109]

PRIMARY NONEPITHELIAL TUMORS

A variety of benign nonepithelial tumors have been reported to occur in the pancreas in childhood (see Table 63-1).[110–114]

Malignant nonepithelial tumors such as rhabdomyosarcoma and lymphoma have all been described in children, albeit rarely.[115] Primitive neuroectodermal tumors are rarely described in solid organs. A recent case series (n = 7 cases) shows that primitive neuroectodermal tumors can sometimes arise as primary neoplasms of the pancreas, particularly in the pediatric and adolescent population (age range 6–25 years; mean 18 years).[116] Such cases demonstrate typical translocation chromosomal abnormality, that is, (t 11; 22) (q 24; q12), and characteristic immunohistochemical staining monoclonal antibody for O13 (CD 99, p30/32 MIC2).[116]

SECONDARY TUMORS

Secondary involvement of the pancreas by tumors results most commonly from hematogenous spread and includes malignant melanoma, renal tumors, lung tumors, and leukemia. Relatively few tumors invade the pancreas directly. They are usually adenocarcinomas of the stomach, intestine, or biliary tract, which are themselves rare in childhood.

TUMOR-LIKE EXOCRINE LESIONS

The most important entity in this group is pancreatic cystic lesions, which have been discussed earlier. Other lesions that may appear tumor-like include chronic pancreatitis, ductal changes (such as squamous metaplasia, mucinous cell hypertrophy, ductal papillary hyperplasia, and adenomatoid duct hyperplasia), acinar changes (such as focal acinar transformation), heterotopic pancreas, heterotopic spleen in the pancreas, hamartomas, and inflammatory pseudotumors.[7] Inflammatory pseudotumors are an important clinical group that pose diagnostic and therapeutic challenges because of their resemblance to malignant pancreatic lesions such as sarcoma. Consequently, complete surgical excision aided by radiologic surveillance appears to offer the best chances of successful management.[117]

TUMOR-LIKE ENDOCRINE LESIONS

This group of disorders comprises the entities of islet hyperplasia/dysplasia and persistent hyperinsulinemic hypoglycemia of infancy (PHHI), formally termed nesidioblastosis.

PERSISTENT HYPERINSULINEMIC HYPOGLYCEMIA OF INFANCY

PHHI, until very recently, was an enigmatic syndrome. New advances have helped define this entity at the molecular genetic and clinical levels, permitting a rational approach to classification, diagnosis, treatment, and prognosis.[118] The autosomal recessive form of PHHI is the predominant familial type, with an estimated incidence in the white European population of 1 case per 50,000 live births. However, in populations with a high rate of consanguinity, the incidence may be as high as 1 in 2,675 live births. Sporadic PHHI accounts for 95% of all cases.[118]

Remarkable progress in this field over the last 7 years has been achieved through fundamental investigations into the regulation of insulin secretion. This process is highly complex and integrated, involving regulation by nutrients, hormones, and the autonomic nervous system. These regulatory influences impinge on the pancreatic beta cell, where insulin secretion is ultimately regulated by an adenosine triphosphate (ATP)-sensitive potassium channel (K_{ATP}) that controls the polarity of the beta-cell membrane.[119] The pancreatic K_{ATP} channel consists of two protein subunits: the sulfonylurea receptor 1 (SUR 1) and the inward rectifying potassium channel (ie, Kir 6.2), whose distinct genes are located at adjacent loci on chromosome 11 (11p15.1).[120,121] Mutations in these K_{ATP} channel genes are now known to be responsible for some forms of familial PHHI.[122–124] Furthermore, other genes that are responsible for insulin secretion but are not themselves part of the channel have also been discovered, and mutations causing autosomal dominant forms of PHHI have been described.[125,126] However, the majority of cases of PHHI (greater than 95%) are sporadic, without identifiable gene mutations. Nevertheless, one study has shown that despite the inability to detect mutations with the *SUR1* gene, all five patients with sporadic PHHI investigated had absent K_{ATP} activity in their islets, attesting to the critical role of K_{ATP} channels also in the pathogenesis of sporadic PHHI.[127]

The clinical phenotype of PHHI associated with known molecular defects is summarized in Table 63-3, including a description of their management and prognosis. The

TABLE 63-3 PERSISTENT HYPERINSULINEMIC HYPOGLYCEMIA OF INFANCY: COMPARISON OF CLINICAL PHENOTYPES ASSOCIATED WITH KNOWN MOLECULAR DEFECTS

TYPE (MOLECULAR DEFECTS)	HYPOGLYCEMIA/ HYPERINSULINEMIA	ASSOCIATED CLINICAL, BIOCHEMICAL, OR MOLECULAR FEATURES	RESPONSE TO MEDICAL MANAGEMENT	RECOMMENDED SURGICAL APPROACH	PROGNOSIS
Sporadic (*?SUR1* or *Kir6.2* mutations)	Moderate/severe in first days to weeks of life; macrosomic at birth	Loss of heterozygosity in microadenomatous tissue	Generally poor; may respond to somatostatin better than to diazoxide	Partial pancreatectomy (microadenoma; 30–40% cases)	Excellent
				Subtotal greater than 95% pancreatectomy (diffuse hyperplasia; 60–70% cases)	Guarded; diabetes mellitus develops in 50% of patients; hypoglycemia persists in 33%
Autosomal recessive (*SUR/Kir6.2* mutations)	Severe in first days to weeks of life; macrosomic at birth	Consanguinity a feature in some populations	Poor	Subtotal pancreatectomy	Guarded

Adapted from Sperling MA and Menon RK.[118]

results of genotype-phenotype comparisons owing to mutations of the K_{ATP} channel have yielded mixed results. For example, for some mutations, there is a correlation between the severity of clinical disease and demonstration of parallel severity of dysfunction of the mutant channel in in vitro functional studies. The DeltaF1388 mutation has been associated with severe disease and the H125Q mutation with mild disease. In contrast, the N188S mutation, despite a phenotype associated with severe clinical disease, shows minimal channel dysfunction in vitro.[118]

In suspected cases, a diagnosis of hyperinsulinemia must initially be established. Hyperinsulinemia is generally considered to exist if the circulating insulin concentration exceeds 5 μU/mL when the corresponding glucose concentration in the same sample is less than 2 to 2.5 mM (< 45 mg/dL). Because insulin concentrations may not always be elevated at the time of hypoglycemia, an alternative test is the measurement of IGF binding protein 1 levels at the time of hypoglycemia. The secretion of this is acutely inhibited by insulin, and patients with PHHI have serum levels that are approximately 10 to 20% of the control level values.[118] This test supplements existing indirect evidence of severe hyperinsulinemia, including a brisk glycemic response to parenteral glucagons, exceeding 30 to 45 mg/dL from a baseline hypoglycemic glucose concentration and an exogenous glucose requirement greater than 15 to 20 mg/kg/min necessary to maintain euglycemia.[118]

Initial treatment includes the administration of intravenous glucose at high rates in severe PHHI in the neonatal period. Other pharmacologic measures can also be employed. Diazoxide acts to maintain patency of the K_{ATP} channel and may not respond because of the absence of functional pancreatic K_{ATP} channels seen in patients with mutations in *SUR1* or *KIR 6.2* genes.[128] Calcium channel blockers, particularly the long-acting somatostatin analog octreotide, may be more effective as medical therapy, with reports of success in as many as 50% of affected infants.[129]

Failure of medical management is common and a clear indication for surgical pancreatectomy in an attempt to avoid long-term neurologic sequelae of hypoglycemia. Surgery may be guided by the type of histopathologic lesion. Focal and diffuse histopathologic lesions characterize sporadic PHHI. Focal PHHI is characterized by focal adenomatous hyperplasia of islet-like cells, with small beta-cell nuclei packed closely together. In contrast, in diffuse PHHI, the islets of Langerhans cells throughout the pancreas are irregular in size, with hypertrophied insulin-secreting cells containing large, abnormal beta-cell nuclei.[118] It has been proposed that a histologic index of beta-cell nuclear crowding may provide a reliable discrimination between the diffuse and focal adenomatous forms of sporadic PHHI, that is, focal lesions showing more nuclear crowding than diffuse—hence intraoperatively providing the ability to distinguish and potentially guide the extent of pancreatectomy necessary.[130] Further guidance to predict between the two histologic lesions has been applied preoperatively using the technique of transhepatic retrograde pancreatic venous catheterization with measurement of insulin concentration at multiple sites.[118] In diffuse hyperplasia, uniformly high insulin concentrations without evidence of a gradient are seen. With localized lesions, a distinct gradient in insulin concentrations is observed. However, only a few centers have developed the expertise and experience to perform this catheterization procedure with a high degree of safety and success. Despite pre- and perioperative evaluations, the long-term outcome following subtotal pancreatectomy remains questionable because of persistent hypoglycemia and development of insulin-dependent diabetes in a high proportion of patients (see Table 63-3).[131]

CHAPTER 64

PANCREATITIS

1. *Acute and Chronic*

David C. Whitcomb, MD, PhD
Mark E. Lowe, MD, PhD

Clinical understanding and treatment of pancreatic diseases lag behind understanding and treatment of many other important diseases. This delay arises from a combination of factors making it difficult to study the pancreas, including its inaccessible location, hesitation of clinicians and researchers to use invasive testing methods, poorly understood pathophysiologic processes, and limited treatment options. However, a number of recent advances in cell biology and genetics have provided the critical tools to unravel some mysteries of pancreatic pathophysiology and have provided genetic susceptibility testing, which also allows for better classification of pancreatic diseases. In addition, high-quality abdominal imaging techniques, including magnetic resonance cholangiopancreatography (MRCP), now provide critical anatomic information with minimal risk. These advances, framed within the context of acinar and duct cell physiology, provide the foundation for future treatment and prevention of pancreatic diseases.

PATHOPHYSIOLOGY OF ACUTE PANCREATITIS

The pancreas is a gland serving three primary functions: production of a bicarbonate-rich fluid by the duct cells, which helps neutralize gastric acid entering the duodenum; synthesis of digestive enzymes within acinar cells with eventual delivery into the duodenum to help digest complex nutrients; and production of hormones by islet cells to regulate nutrient storage and use related to meals. Although each of the functions and cell types differs, their interrelationship remains critical for normal organ function.

Most of the pancreas is composed of acinar cells. The duct cells connect the acinar cells to the duodenum and flush the digestive enzymes out of the pancreas after acinar cell secretion. The islet cells function independently of the acinar cells, but the acinar cells must remain in close proximity to the islet cells to maintain normal gene expression profiles. This is accomplished through the insular-acinar portal system, in which blood vessels extend from the islets to the acinar cells so that insulin-rich fluid continually bathes the acinar cells.

Acinar Cells Synthesize and Store Trypsinogen

The acinar cells synthesize and store digestive enzymes until they are stimulated to secrete the enzymes into the ducts. All of the major digestive enzymes are synthesized by all acinar cells. All enzymes, except amylase and lipase, are synthesized as proenzymes (zymogens) that require activation by cleavage of an activation peptide by trypsin. Trypsinogen (the proenzyme form of trypsin) is activated by the intestinal brush border enzyme enterokinase or by another trypsin molecule (Figure 64.1-1). Trypsinogen also slowly autoactivates, possibly because trypsinogen has some trypsin-like activity.[1] Because trypsinogen is synthesized in the same cell, is stored in the same subcellular compartment as the other enzymes, and has the potential to become active trypsin, there is always the danger of premature trypsinogen activation with subsequent activation of other digestive enzymes and digestion of the pancreas itself. Trypsin not only activates itself, it also inactivates itself through autolysis, a process that is regulated by calcium.[2–4] High calcium concentrations and pH are optimal for trypsin survival in the duodenum[5] but favor autolysis within the acinar cells when calcium concentrations are low. Thus, a number of critical mechanisms are found throughout the pancreas that protect acinar cells, the duct, and the pancreas itself from premature trypsinogen activation.

Pathophysiology of Calcium Signaling

Calcium is the most important second-messenger signaling system within the acinar cells. Activation of the acinar cell through the major receptors results in increases in intracellular calcium, which, in turn, activates protein synthesis and zymogen secretion. With physiologic stimulation, intracellular calcium levels rise and slowly oscillate within well-controlled concentrations.[6b] The process begins with opening of calcium channels on the basolateral membrane, which allows calcium to enter the cell and causes release of intracellular calcium stores. Basolateral calcium is rapidly transported through the rough endoplasmic reticulum to the apical membrane, where it initiates secretion of the zymogen granules into the duct lumen.[7] With hyperstimulation, the calcium levels rise above critical levels, followed

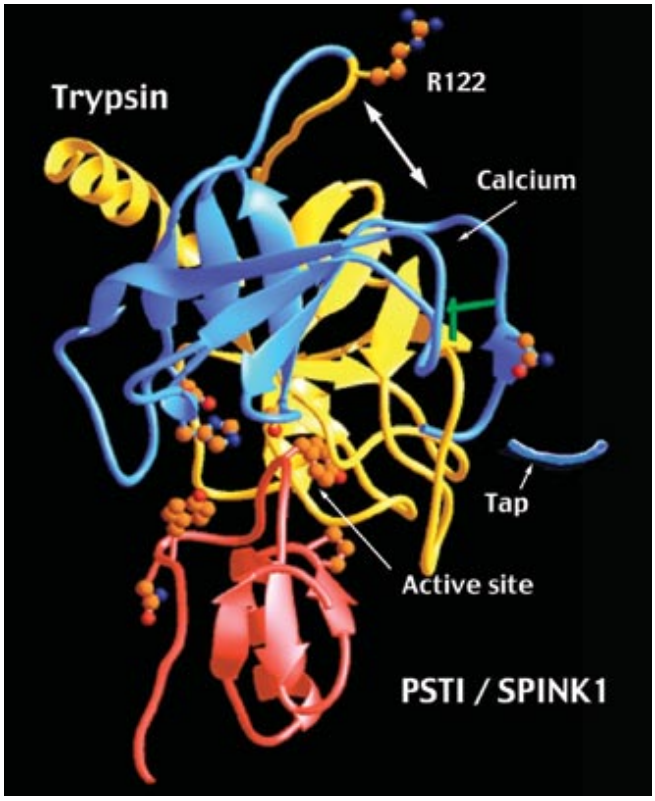

FIGURE 64.1-1 Crystallography-based model of trypsin (yellow and blue) attacking pancreatic secretory trypsin inhibitor/serine protease inhibitor, Kazal type 1 (PSTI/SPINK1-red) at the active site (*long arrow*). The critical regulatory site for trypsinogen activation is shown after cleavage of trypsinogen activation peptide (TAP). The critical regulatory region of trypsin is the flexible autolysis loop *(line with two arrowheads)* with the target amino acid residue R122 shown in the exposed conformation. The calcium binding loop is shown without calcium, which would stabilize the autolysis loop in a conformation protecting R122 from attack by another trypsin (see CD-ROM for color image).

by sustained activation of trypsin.[6b,8] The link between extracellular calcium, acinar cell stimulation, and trypsinogen activation has also been demonstrated in animal models.[9,10] Finally, exposure of the acinar cell apical membrane to bile acids (especially taurolithocholic acid 3-sulfate) causes extended calcium signals near the secretory granules, which leads to trypsin activation.[11] These observations link calcium dysregulation with acute pancreatitis.[12]

Duct Cells Normally Flush Secreted Digestive Enzymes out of the Pancreas

The ductal cells make up less than 5% of the total pancreatic mass but are responsible for the large volume of bicarbonate-rich pancreatic fluid. This function is critical for sweeping digestive enzymes released from the acinar cells out of the pancreas and into the duodenum. The intralobular ductules penetrate the acinus and include the centroacinar cells. Pancreatic bicarbonate secretion is derived from the centroacinar and proximal duct cells.

Duct cells are polarized cells that maintain a significant electrical membrane potential. The basolateral membrane contains ion channels and transporters that participate in regulating chloride, bicarbonate, sodium, and potassium, as well as the sodium-potassium adenosine triphosphatase ion pump that drives secretion. The most important transporter is the sodium-2 bicarbonate cotransporter, which uses the sodium electrochemical gradient to transport bicarbonate into the cell. The apical membrane also contains channels and transporters, with the most important being the cystic fibrosis transmembrane conductance regulator (CFTR). CFTR is both a chloride and a bicarbonate channel, and the opening or closing of this channel determines duct cell fluid secretion.[13] Mutations in the CFTR reduce the fluid-secreting capacity of the pancreas, increasing the risk of having active trypsin within the pancreas for prolonged periods of time. This is especially dangerous because calcium levels within the duct lumen are elevated, thus eliminating the trypsin autolysis protective mechanism. Unregulated trypsinogen activation in the duct and failure to flush the enzymes because of mutations in the CFTR may also lead to both acute pancreatitis and chronic pancreatitis, as is seen in patients with cystic fibrosis (CF), atypical CF, or forms of CFTR-associated polygenic pancreatitis.[14,15]

Other Protective Mechanisms

The vast majority of mechanisms that are protective against acute pancreatitis center on control of trypsin. This includes preventing trypsinogen activation, inhibiting active trypsin, destroying trypsin, or sweeping trypsin out of the pancreas. Identification of specific mutations in several genes proved the importance of several of these mechanisms. As noted above, the first protective mechanism is the synthesis of trypsinogen in an inactive form (trypsinogen) with an activation site located in the target organ, which is the duodenal lumen. Several mutations in cationic trypsin gene enhance trypsin activation,[16] and these mutations increase susceptibility to acute pancreatitis.

If trypsinogen is activated within the acinar cells, it is inhibited by pancreatic secretory trypsin inhibitor (also known as serine protease inhibitor, Kazal type 1 [SPINK1]). This peptide is a specific trypsin inhibitor and an acute-phase protein.[17] Mutations in *SPINK1*, which likely reduce its ability to inhibit trypsin, are associated with pancreatitis in children, some familial pancreatitis, and various forms of tropical pancreatitis. These mutations are common, seen in 2% of most populations.[18] Although intracellular SPINK1 is a highly effective trypsin inhibitor, the number of trypsinogen molecules greatly outnumbers the number of SPINK1 molecules, so that the inhibitory capacity is limited.[1] If more trypsinogen is activated than SPINK1 can inhibit, then other mechanisms must be employed.

Studies in hereditary pancreatitis drew attention to the trypsin self-destruct mechanism.[19] The trypsin molecule has two globular domains held together by a single side chain. This side chain is critical to trypsin regulation. In the middle of the side chain is an arginine, or target amino acid for trypsin attack. Biochemical studies demonstrate that this site is sensitive to trypsin hydrolysis, and cleavage of the site is the first step in trypsin autolysis. The importance of this site and autolysis mechanism is demonstrated by patients with hereditary pancreatitis who have muta-

tions altering the amino acid sequence at R122 (eq. R122H) and recurrent acute pancreatitis when trypsin cannot be destroyed within the acinar cells. Calcium protects trypsin from autolysis by protecting the R122 site from attack.[4,20] So trypsin autolysis only occurs in compartments with low calcium concentrations.

Summary

Some of the mysteries surrounding acute pancreatitis are beginning to be solved. This allows the construction of conceptual models that help organize knowledge about pancreatic physiology, pathophysiology, and pancreatic disease.[4] Acute pancreatitis can be thought of as an event that occurs when trigger factors drive trypsinogen activation beyond the protective mechanisms. Key molecular events occur within the acinar cell in relation to loss of calcium regulation with intracellular hypercalcemia and, therefore, elimination of trypsin autolysis protective mechanisms. Trypsin that is activated outside the acinar cell in which calcium levels are already elevated must be flushed quickly out of the duct by a CFTR-dependent mechanism or inhibited, eliminated, or corraled by other means. These factors are important in understanding susceptibility to acute pancreatitis. Once initiated, the resulting immune response and a variety of complications become the primary concern.

ACUTE PANCREATITIS

Acute pancreatitis is defined clinically as the sudden onset of abdominal pain associated with a rise in digestive enzymes in the blood or urine. The mechanism appears to involve the premature activation of trypsinogen because trypsinogen activation is among the earliest biochemical changes in experimental pancreatitis. Trypsinogen activation peptide is one of the earliest markers of acute pancreatitis in humans; endoscopic retrograde cholangiopancreatography (ERCP)-associated pancreatitis can be attenuated by pretreatment with trypsin inhibitors (eg, gabexate), and mutations that enhance trypsinogen activation, diminish trypsin inactivation, or limit trypsin clearance from the ducts are associated with acute pancreatitis. Second, acute pancreatitis is associated with a vigorous immune response, which contributes to the severity of the pathologic condition. By the time acute pancreatitis is recognized clinically, the trypsinogen activation and autodigestion phase may be over, and the inflammatory consequences dominate the clinical picture.

The prevalence of acute pancreatitis in children appears to be increasing.[21–23] The reason for this observation is unclear but does not appear to be simply related to referral bias or improved methods for diagnosis.[23]

Etiology of Acute Pancreatitis

A number of factors are able to trigger an attack of acute pancreatitis. In adults, the vast majority of cases are associated with gallstones, alcohol abuse, hypercalcemia, hypertriglyceridemia, medications, and blunt trauma. This profile appears to differ in children. Recently, a number of single and multicenter studies have investigated the etiologies of acute pancreatitis in children (Table 64.1-1). Acute pancreatitis associated with severe systemic illnesses is striking, accounting for about 20% of reported cases.[23] In some cases, acute pancreatitis may be overlooked in the intensive care unit setting.[24] However, the contribution of

Benifla and Weizman[51] is a review of 18 pre-1999 studies from the United States (*n* = 9), the United Kindom (*n* = 5), Canada, Taiwan, Hong-Kong, Switzerland, and Israel. DeBanto et al[21] is from a multicenter (*n* = 6) study in the midwestern United States. Lopez[22] includes outpatient (Dallas, TX), Werlin et al[23] is from a referral center in Milwaukee, WI, and Alvarez Calatayud et al[117] is from Madrid, Spain.

pancreatitis to the overall severity of these diseases cannot be calculated from these reports, and it appears that deaths owing to acute pancreatitis in children alone are now uncommon (< 2%).[21,23] Hemolytic uremic syndrome is identified as the most common of all systemic diseases, causing acute pancreatitis in children.[21,23] The mechanism of pancreatitis is unknown and likely multifactorial, noting that uremia itself is a risk factor for pancreatic injury.[25–27] Although not classified separately in most case series, acute pancreatitis after organ transplant is also common.[23]

Gallstones are an important cause of acute pancreatitis in children. Choi and colleagues reported gallstones in 16 (29%) of 56 cases in a recent report from Korea.[28] In previous studies, gallstones were often included with structural abnormalities of the pancreas and biliary system as "biliary." This etiology should not be overlooked because therapeutic ERCP may be indicated.

Structural abnormalities also increase the risk for acute pancreatitis. The most common is pancreas divisum, but other abnormalities in the pancreatic or common bile duct (eg, choledochal cysts, choledochocoeles, and partial pancreas divisum) have been identified in children with otherwise unexplained acute pancreatitis.[23]

Infectious acute pancreatitis in North America and Europe is primarily viral in etiology. This includes mumps (39% of cases of pediatric acute pancreatitis reported in a Scottish study[29]), enterovirus, Epstein-Barr virus, hepatitis A, cytomegalovirus, rubella, coxsackievirus, varicella, rubeola, measles, and influenza virus.[21,23,30–33] Children with human immunodeficiency virus (HIV) frequently develop acute pancreatitis, usually from a secondary infection such as cytomegalovirus, *Mycobacterium avium intracellulare*, *Pneumocystis carinii*, and *Cryptosporidium parvum*, as well as from HIV medications.[34,35] Bacterial infections also occasionally cause acute pancreatitis.[30] In third world countries and tropical regions, acute pancreatitis is often associated with helminth infections such as *Ascaris lumbricoides*.[36–38] These cases can be severe, complicated, and difficult to treat.[39]

A variety of mediations are associated with acute and recurrent acute pancreatitis.[31,40,41] The strongest evidence in adults includes azathioprine or 6-mercaptopurine, thiazide diuretics, sulfonamides, furosemide, estrogens, and tetracycline, with suggestive evidence for L-asparaginase, iatrogenic hypercalcemia, chlorthalidone, corticosteroids, ethacrynic acid, phenformin, and procainamide.[41] Table 64.1-2 lists medications associated with acute pancreatitis in children.[21,23] The anticonvulsant valproate is the most common medication reported in these series. Grauso-Eby and colleagues reported 4 cases (1 fatal) from their institution, plus 29 others from the literature.[42] The median age was 8.9 years (range 1–18 years), and the mean dose was 45.6 mg/kg/d (range 20–85 mg/kg/d), with approximately equal doses in fatal and nonfatal cases. Seventy-one percent were taking multiple antiepileptic drugs, and children were taking valproate for a mean of 19 months (range 1 month to 10 years).[42] However, Pellock and colleagues reviewed over 3,000 patients treated with valproate from 34 studies and found only 2 documented cases of acute pancreatitis and a similar number of cases of amlyase elevations in valproate-treated versus placebo-treated patients.[43] Furthermore, in over 2,000,000 reports to the Toxic Exposure Surveillance System compiled by the American Association of Poison Control Centers, acute pancreatitis was noted in only one of the four subjects with fatal valproate ingestion.[44] These data indicate that the association of valproic acid with acute pancreatitis is idiosyncratic but remains an important cause of pancreatitis in children. The other major causes of medication-associated pancreatitis in children are L-asparaginase and prednisone.

Trauma is a common cause of acute pancreatitis in children and is responsible for nearly 20% of cases (see Table 64.1-1). In the majority of cases, the trauma is blunt and accidental (eg, bicycle handlebar), but child abuse makes up a proportion of cases.[23] A major concern in these cases is pancreatic duct transection, which may require surgical intervention.

Post-ERCP pancreatitis is reported in several series.[21,23] Newer imaging modalities such as high-resolution computed tomography (CT) and MRCP, are, therefore, replacing ERCP as a diagnostic tool. ERCP, however, remains invaluable for therapeutic interventions.

Familial pancreatitis includes hereditary pancreatitis and other forms of pancreatitis that occur in families with an incidence that is higher than expected in the population by chance alone.[45] Atypical CF with compound heterozygous CFTR mild-variable mutations or CFTR mutations plus modifying factors, such as *SPINK1* mutations, are the most common cause of familial pancreatitis in our experience (D. Whitcomb, unpublished, 2003). Note that genetic testing was not available for cationic trypsinogen gene testing before 1996,[19] and for *SPINK1* gene testing before 2000,[46,47] and the role of CFTR testing was previously unclear.[4,48,49] There is no association between α_1-antitrypsin mutations and acute pancreatitis.[50] As genetic testing and better diagnostic testing become more widely available, the percentage of children with familial or gene mutation–associated pancreatitis will rise, whereas the idiopathic category will continue to fall.[23,51]

An evaluation of a child with acute pancreatitis should include measurement of calcium and triglyceride levels because these causes must be addressed to prevent recurrence. Pancreatitis is occasionally seen in a number of other metabolic disorders, such as diabetic ketoacidosis[21–23] and inborn errors of metabolism[52] (Table 64.1-3).

Recurrent Acute Pancreatitis

Recurrent acute pancreatitis is seen in about 10% of children after a first episode of acute pancreatitis.[23,51] Recurrent acute pancreatitis is most commonly seen in patients with structural abnormalities, idiopathic pancreatitis, or familial pancreatitis.[23,51] A careful evaluation aimed at identifying reversible causes should be undertaken. In addition to avoiding another attack of acute pancreatitis, one should consider the prevention of chronic pancreatitis through eliminating known risk factors. Theoretically, the progression to chronic pancreatitis may be slowed by the use of antioxidants (which may also reduce the frequency and severity of recurrent symptoms in hereditary pancreatitis patients[53]), but these approaches are currently unproven.

Diagnosis of Acute Pancreatitis

The diagnosis of pancreatitis is currently based on the syndrome of sudden onset of typical abdominal pain plus elevation of amylase or lipase to at least three times the upper limit of normal levels.[21–23,30] The diagnosis of acute pancreatitis can be difficult because no readily available test confirms the diagnosis. Although there have been multiple attempts to determine the sensitivity and specificity of elevations in both enzymes in adults, the studies all suffer from the absence of a method to separately and absolutely document pancreatitis. It is clear that both enzymes can be normal when there is radiographic and clinical evidence of pancreatitis. Also, both enzymes can be elevated by other conditions unrelated to pancreatitis. The level of elevation is also not diagnostic, although the higher the level is above the upper reference limit, the more likely it is that there will be pancreatic inflammation. Levels just above the upper reference limits may still be secondary to pancreatitis, especially in patients presenting several days after the onset of symptoms.

Other pancreatic products, such as phospholipase A_2, trypsin, trypsinogen activation peptide, and elastase, are elevated in pancreatitis, but none have found widespread use in the clinical laboratory setting. Serum transaminases are elevated in some patients, and the combination of elevated amylase or lipase and elevated serum transaminases may be more predictive of pancreatitis than elevated amylase or lipase alone.

Diagnostic testing for acute pancreatitis begins with a high index of suspicion, such as unexplained abdominal pain or vomiting. Pain is usually epigastric, in the right upper quadrant, or in the left upper quadrant, with radiation through to the back. However, back pain can occur alone, and pain may localize to other areas of the abdomen. Nausea and vomiting are common and may be the dominant clinical features. Other less common clinical signs include fever, tachycardia, hypotension, jaundice, and abdominal signs such as guarding, rebound tenderness, and a decrease in bowel sounds.[51] Occasionally, the diagnosis is first suspected because of feeding intolerance when feeds are introduced in patients with systemic illnesses.

Transient fever or jaundice can be present. Jaundice or elevated transaminases should raise the possibility of biliary tract involvement. Rarely, patients present with ascites or an abdominal mass. Epigastric tenderness is a useful but nonspecific and unreliable sign.

CT and abdominal ultrasonography of the pancreas are primarily used to document pancreatitis, determine the severity or identify complication (eg, pseudocysts), determine if there is underlying chronic pancreatitis, or identify other causes of unexplained signs or symptoms (Figure 64.1-2). Ultrasonographic findings include enlargement of the pancreas, altered echogenicity of the pancreas, dilated main pancreatic duct, gallstones, biliary sludge, dilated common and intrahepatic bile ducts, pancreatic calcification, choledochal cysts, and fluid collections, either peripancreatic or cystic. A CT scan will show similar findings, except that abnormal attenuation is seen rather than altered echogenicity. The CT scan is usually done several days into a severe course of acute pancreatitis when the patient fails to improve. There is experimental evidence indicating that CT contrast given early in the course of acute pancreatitis may diminish already tenuous blood flow to ischemic areas of the pancreas and thereby extend the region of necrosis. Although this is difficult to prove in humans, most experts agree that there is no diagnostic utility for a CT scan in the early phases of acute pancreatitis.[23] MRCP may be helpful in defining abnormalities of the ductal system, but its utility in pediatric patients has not been carefully studied. ERCP should be reserved for patients with unexplained recurrent episodes of pancreatitis, prolonged episodes of pancreatitis when a structural defect or duct disruption is suspected, or in some cases of gallstone pancreatitis.

Medical Management of Acute Pancreatitis

The mainstay of current treatment of acute pancreatitis in children is analgesia, intravenous fluids, pancreatic rest, and monitoring for complications.[23,30] Full attention must be paid to fluid balances because patients are usually kept without food and may lose fluids from the vascular compartment from a capillary leak syndrome and "third spacing." Fluid

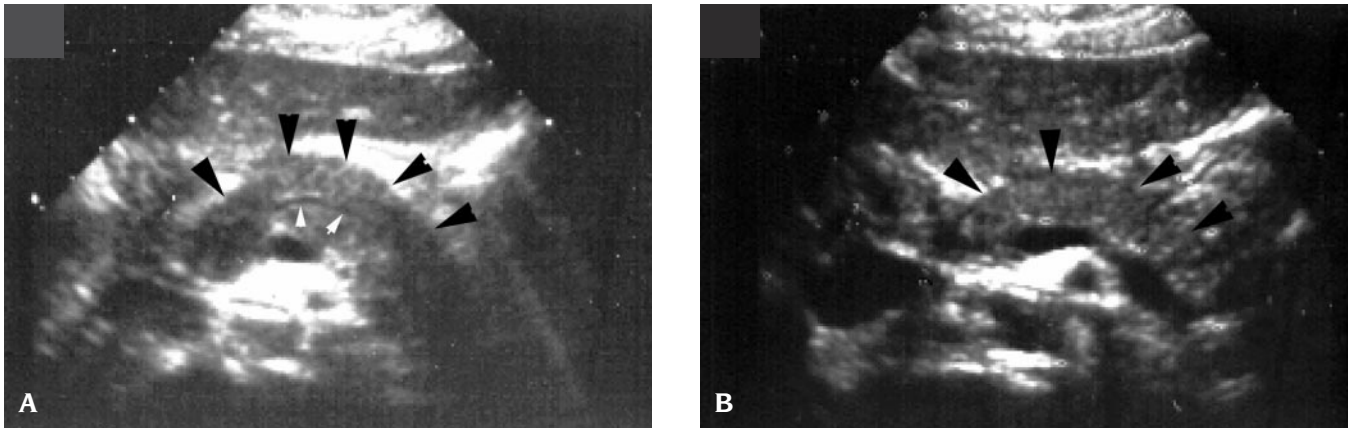

FIGURE 64.1-2 Ultrasonographic changes of pancreatitis. *A*, Sonogram of the pancreas in a 10-year-old boy who presented with epigastric pain and vomiting. He had a serum lipase 20 × upper reference limit (URL) and a serum amylase 6 × URL. The pancreas is edematous, and the main pancreatic duct is dilated. The upper edge of the pancreas is marked by *black arrowheads*, and the main pancreatic duct is indicated by *white arrowheads*. *B*, Sonogram of a normal pancreas. The same patient presented with periumbilical pain 2 months later. His serum lipase and amylase levels were normal. A sonogram showed a normal pancreas and did not visualize the main pancreatic duct, a normal finding in children. The *arrowheads* mark the upper edge of the pancreas.

losses are exaggerated if a nasogastric tube is used to decompress the stomach as a treatment for vomiting. Volume expansion early in the course of acute pancreatitis is important for both cardiovascular stability and preventing development of pancreatic necrosis. Meperidine 1 to 2 mg/kg intramuscularly or intravenously is used for pain control.[30] Enteral or total parenteral nutrition is often unnecessary in mild cases but should be instituted early if a severe or prolonged course is anticipated. Until recently, parenteral nutrition was considered the only option, but several studies show that adult patients with acute pancreatitis tolerate jejunal feedings with fewer complications than those given parenteral nutrition.[54] Antibiotics are usually unnecessary except for the most severe cases, especially if significant pancreatic necrosis is present.

Severity of Acute Pancreatitis

Acute pancreatitis can be life threatening, although death does not appear to occur as often in children (without other systemic diseases) as it does in adults.[23] Death occurs by several mechanisms, with some occurring early and others late. The early causes of death are cardiovascular collapse and respiratory failure. The cardiovascular collapse occurs with the combination of a vascular leakage syndrome with third spacing of fluid, vomiting, and having the patient receive nothing by mouth. If recognized, this complication can be treated with fluid resuscitation, guided, when necessary, by following central venous pressure. The respiratory failure is associated with an adult respiratory distress syndrome–like situation that results from leakage of fluid into alveolar spaces and inflammation. Early recognition of this complication and management of patients at high risk within an intensive care setting can be lifesaving.

Late life-threatening complications of acute pancreatitis are related to infected pancreatic necrosis and multisystem organ failure, although pancreatic necrosis appears to be uncommon in children—1 case of 380 from 7 centers (0.3%).[21,23] Judicious use of antibiotics and attention to nutrition may help limit these late complications.

Global Acute Pancreatitis Scoring Systems

Acute pancreatitis is usually divided into mild and severe forms. Originally, mild acute pancreatitis was defined as pancreatitis limited to peripancreatic fat necrosis and interstitial edema, whereas severe pancreatitis included additional features.[55,56] Other clinically based systems also have been developed, which define mild and severe according to the absence or presence of major complications requiring prolonged treatment or specific interventions or an increased likelihood of death.[57–60] Thus, mild pancreatitis includes the majority of cases, which have minimal complications, a short clinical course requiring minimal supportive treatment, and complete recovery. It is the physician's responsibility to make a rapid assessment of the patient's condition and to predict the risk of a mild or severe clinical course. To assist the physician in this decision, a number of severity criteria have been developed, including Ranson's scores,[57,58] Glasgow score,[59] the Acute Physiology and Chronic Health Evaluation (APACHE) II score,[61,62] and Pediatric score.[21] Although these criteria add little to the assessment of the experienced physician, they remain useful in reminding one to carefully consider the major systems impacted during the more severe attacks of acute pancreatitis. In general, the signs and organic symptoms of each of these systems reflect the magnitude of the inflammatory response to acute pancreatitis rather than measure the actual amount of pancreatic injury.

Ranson's criteria were developed in adults,[57,58] and several criteria (eg, age > 55 years and fluid deficit > 6 L) are not applicable to children.[21] The Midwest Multicenter Pancreatic Study Group analyzed the criteria of the Ranson and Glasgow scores, plus additional criteria, and developed a scoring system for children.[22] The seven severity factors included age (< 7 years), weight (< 23 kg), admission white blood cell count (>18.5 x 10^9/L), admission lactate dehy-

drogenase (> 2,000 IU/L), 48-hour fluid sequestration (> 75 mL/kg/48 hours), and a 48-hour rise in urea (> 5 mg/dL). If each criterion is assigned a value of 1 point, then the outcome of patients with 0 to 2 points was 8.6% severe, 1.4% death; with 2 to 4 points was 38.5% severe, 5.8% death; and with 5 to 7 points was 80% severe, 10% death.[21] The accuracy of this system was validated in three centers. Of note, young age and low weight are major risk factors. Severity was also often associated with severe systemic diseases (see Table 64.1-1, DeBanto [severe]), a pattern also noted by others.[22,23]

Complications of Acute Pancreatitis

A number of non–life-threatening complications of acute pancreatitis are recognized. These include both local and systemic complications (Table 64.1-4). Local complications include fluid collections, pancreatic necrosis (sterile or infected), pancreatic abscess, duct rupture, duct strictures, bleeding, and pseudocyst formation.

Pancreatic necrosis, which is a segmental pancreatic infarction, remains a major concern because it is associated with serious complications. This complication probably occurs in less than 5% of adult patients and less than 1% of children. The risk of pancreatic necrosis appears to increase with vascular leakage, as reflected by an elevated hematocrit in nearly all patients with pancreatic necrosis. The combination of intravascular volume depletion, inflammation, and high hematocrit therefore leads to blockage of pancreatic blood flow and infarction. The diagnosis is made by contrast-enhanced CT with demonstration of a segment of pancreatic gland without perfusion.

Complications of pancreatitis may require specific treatment. Pancreatic pseudocysts occur in children. Pseudocysts can be observed over time for spontaneous resorption or may require drainage. Currently, both endoscopic internal drainage and external drainage by interventional radiologists offer viable options to surgery. The chronicity, size, location, and complexity of the pseudocysts all contribute to decisions about the optimal choice for treatment. Abscesses often can be treated with external drainage and intravenous antibiotics, and only rarely is surgical drainage necessary. Surgery is usually necessary for traumatic rupture of the duct, although endoscopic stenting across the disrupted duct is another option.

TABLE 64.1-4 COMPLICATIONS OF ACUTE PANCREATITIS

LOCAL	SYSTEMIC
Edema	Shock
Inflammation	Pulmonary edema
Fat necrosis	Pleural effusions
Phlegmon	Acute renal failure, coagulopathy
Pancreatic necrosis	Hemoconcentration
Sterile	Bacteremia, sepsis
Infected	Distant fat necrosis
Abscess	Vascular leak syndrome
Hemorrhage	Multiorgan system failure
Fluid collections	Hypermetabolic state
Pseudocysts	Hypocalcemia
Duct rupture and strictures	Hyperglycemia
Extension to nearby organs	

Surgical Management of Acute Pancreatitis

The role of surgery in the management of acute pancreatitis is limited to débridement of infected pancreatic necrosis and cholecystectomy to prevent recurrent gallstone pancreatitis. The differentiation of infected from sterile pancreatic necrosis should be based on fine-needle aspiration for bacteriology.[63–65] Surgery in severe pancreatitis is usually deferred for at least 2 weeks to permit proper demarcation of pancreatic and peripancreatic necrosis to occur and to provide the optimal operative conditions for necrosectomy.[65] This approach decreases the risk of bleeding and minimizes surgery-related loss of vital tissue, which can predispose the patient to surgically induced endocrine and exocrine pancreatic insufficiency.

If acute pancreatitis is caused by gallstones or biliary sludge, then a cholecystectomy should be performed to avoid recurrence of gallstone-associated acute pancreatitis. It has been recommended that cholecystectomy should be performed as soon as the patient has recovered and, ideally, during the same hospital admission in mild gallstone-associated acute pancreatitis, whereas cholecystectomy may need to be delayed after an episode of severe acute pancreatitis. Endoscopic sphincterotomy is an alternative to cholecystectomy in selected cases.

CHRONIC PANCREATITIS

Chronic pancreatitis is a syndrome of destructive, inflammatory conditions that encompasses the many sequelae of long-standing pancreatic injury.[66] Thus, acute pancreatitis is an *event*, whereas chronic pancreatitis is a *process*.[4] Histologic changes from the normal pancreatic architecture include irregular fibrosis, acinar cell loss, islet cell loss, and inflammatory cell infiltrates.[67–69] Clinical diagnosis currently depends on identifying defined clinical, functional, morphologic, and histologic features that characterize the final common pathologic pathway of a variety of pancreatic disorders.[45,66]

Etiology of Chronic Pancreatitis

In adults, chronic pancreatitis is usually associated with prolonged ingestion of large amounts of alcohol (~ 70%) or appears to be idiopathic (~ 20%).[66] In children, chronic pancreatitis is usually associated with genetic conditions such as typical or atypical CF or hereditary pancreatitis or is idiopathic. The incidence of chronic pancreatitis appears to be increasing in children, perhaps reflecting better diagnostic tools or following an apparent rise in recurrent acute pancreatitis.

Current research suggests that chronic pancreatitis is better defined as a complex process beginning with acute pancreatitis and progressing to end-stage fibrosis as the result of recurrent and chronic inflammatory processes. As with acute pancreatitis, susceptibility and the rate of progression are influenced by both genetic and environmental factors. To date, genetic susceptibility factors for chronic

pancreatitis are the same as the susceptibility factors for recurrent acute pancreatitis (ie, *PRSS1*, *SPINK1*, and *CFTR* mutations). Several genetic modifiers have been reported in abstract form, but further research must be completed before their role in chronic pancreatitis can be clearly defined.

Recently, a new classification system has been developed to organize and understand the factors associated with chronic pancreatitis (Table 64.1-5). The TIGAR-O system allows multiple factors to be assessed in a single patient either as risk factors (before chronic pancreatitis develops) or as etiologies (after pancreatitis develops). This approach also allows the clinician to identify factors that can be modified to reduce risk (eg, smoking cigarettes or drinking alcohol). The common etiologies of chronic pancreatitis in adults (eg, alcohol, hypertriglyceridemia) are reviewed elsewhere.[66]

TABLE 64.1-5 ETIOLOGIC RISK FACTORS ASSOCIATED WITH CHRONIC PANCREATITIS: TIGAR-O CLASSIFICATION SYSTEM (VERSION 1.0)

TOXIC-METABOLIC
Alcoholic
Tobacco smoking
Hypercalcemia
Hyperparathyroidism
Hyperlipidemia
Chronic renal failure
Medications
Phenacetin abuse (possibly from chronic renal insufficiency)
Toxins
Organotin compounds (eg, di-n-butyltin dichloride)
IDIOPATHIC
Early onset
Late onset
Tropical
Tropical calcific pancreatitis
Fibrocalculous pancreatic diabetes
Other
GENETIC
Autosomal dominant
Cationic trypsinogen (codon 29 and 122 mutations)
Autosomal recessive/modifier genes
CFTR mutations
SPINK1 mutations
Cationic trypsinogen (codon A16V, D22G, K23R)
α_1-Antitrypsin deficiency (possible)
AUTOIMMUNE
Isolated autoimmune chronic pancreatitis
Syndromic autoimmune chronic pancreatitis
Sjögren syndrome–associated chronic pancreatitis
Inflammatory bowel disease–associated chronic pancreatitis
Primary biliary cirrhosis–associated chronic pancreatitis
RECURRENT AND SEVERE ACUTE PANCREATITIS–ASSOCIATED CHRONIC PANCREATITIS
Postnecrotic (severe acute pancreatitis)
Recurrent acute pancreatitis
Vascular diseases/ischemic
Postirradiation
OBSTRUCTIVE
Pancreatic divisum
Sphincter of Oddi disorders (controversial)
Duct obstruction (eg, tumor)
Preampullary duodenal wall cysts
Post-traumatic pancreatic duct scars

Trypsinogen Mutations

Trypsinogen mutations are responsible for pancreatitis in the majority of hereditary pancreatitis kindreds. The most common mutations include the cationic trypsinogen (*PRSS1*) R122H and N29I mutations, although a variety of other mutations are occasionally seen. Recommendations for genetic testing and genetic counseling have been published.[4,70,71] Hereditary pancreatitis caused by *PRSS1* mutations usually presents as recurrent acute pancreatitis in childhood with a median age of 10 years but a range of less than 1 year to 60 years of age.[16,72–74] The chronic pancreatitis in *PRSS1* mutation–associated hereditary pancreatitis usually follows the onset of recurrent acute pancreatitis by 10 years, although only half of the patients with recurrent acute pancreatitis develop chronic pancreatitis, and the clinical course is highly variable. Occasionally, patients will present with chronic pancreatitis without a clear history of acute pancreatitis. The most important clinical clue is a family history of pancreatitis or unexplained abdominal pain lasting for 1 to 3 days in adults from previous generations, although, in some cases, no other history of pancreatitis is seen.[75] The diagnosis is confirmed by genetic testing of the *PRSS1* gene, but about 30 to 40% of smaller hereditary pancreatitis families do not have identifiable mutations in the *PRSS1* gene.[75]

CFTR-Associated Pancreatitis

CF is the most important cause of chronic pancreatitis in children. CF is caused by severe mutations in both CFTR gene alleles ($CFTR^{sev}/CFTR^{sev}$). However, over 1,200 CFTR mutations have been identified, which are organized into five or six classes depending on the effect of the mutation on CFTR expression and function.[76] Some mutations (class IV) are mild or variable ($CFTR^{m\text{-}v}$), and compound heterozygous genotypes ($CFTR^{sev}/CFTR^{m\text{-}v}$) result in total CFTR function that is a fraction of normal (eg, 5%). These genotypes are associated with atypical CF, in which some CFTR-dependent organs are spared from severe CF-associated injury, whereas others are affected.[77,78] For example, the $CFTR^{sev}/CFTR^{m\text{-}v}$ genotypes have been associated with idiopathic chronic pancreatitis (ICP).[14,15] However, these studies also have an excess of patients who appear to be *CFTR* mutation heterozygous, whereas parents of CF patients (who are obligate *CFTR* mutation carriers) do not have an excess incidence of pancreatitis.[79]

CFTR mutation–associated pancreatitis can be divided into four mechanistic subtypes of CFTR-associated mechanisms.[4] Type 1 is CF with a $CFTR^{sev}/CFTR^{sev}$ genotype. Type 2 is atypical cystic fibrosis with a $CFTR^{sev}/CFTR^{m\text{-}v}$ genotype. Of specific interest are *CFTR* mutations that specifically block bicarbonate conductance but not chloride conductance.[80,81] These mutations may specifically target the pancreas over other organs because bicarbonate secretion by the pancreatic duct cells is central to pancreatic fluid secretion. Type 3 is $CFTR^{sev}$ or $CFTR^{m\text{-}v}$ plus a second pancreatitis modifier or susceptibility gene in a

polygenetic condition such as the CFTR^{sev}/SPINK1 N34S allele. Type 4 is CFTR^{sev} or CFTR^{m-v} plus a strong environmental risk factor such as alcohol.

Early- and Late-Onset ICP

Layer and colleagues observed that the age at onset of ICP is bimodal.[82] In early-onset ICP, calcification and exocrine and endocrine insufficiency develop more slowly than in late-onset idiopathic and alcoholic pancreatitis, but pain is more severe. In contrast, in late-onset ICP, pain is absent in 50% of patients.[82]

The etiology of early-onset ICP is being resolved. Witt and colleagues first identified the *SPINK1* N34S and other *SPINK1* mutations in children with ICP.[46] Pfützer and colleagues recently identified *SPINK1* mutations in about 25% of patients with ICP, but 87% of patients with *SPINK1* mutations developed pancreatitis before age 20 years.[47] A similar pattern was seen by Ockenga and colleagues.[83] However, 1 to 4% of representative populations have the high-risk *SPINK1* N34S allele, and the phenotype of heterozygous and homozygous genotypes is identical.[18,47] Thus, *SPINK1* mutations probably cause increased susceptibility to recurrent acute and chronic pancreatitis with homozygous mutations or as part of a polygenic condition with another genetic risk factor, such as type 3 CFTR-associated pancreatitis. Other genetic factors that increase susceptibility to pancreatitis or that modify the clinical course of recurrent acute pancreatitis toward rapid fibrosis likely will be defined in the near future.

Diagnosis

The diagnosis of chronic pancreatitis can be made by histologic or morphologic criteria alone or by a combination of morphologic, functional, and clinical findings.[69,84–87] Functional abnormalities alone are not diagnostic of chronic pancreatitis because these tests do not differentiate chronic pancreatitis from pancreatic insufficiency without pancreatitis.[66] Pancreatic insufficiency should be considered as either an end stage of destructive chronic pancreatitis or as arising from an independent condition, such as Shwachman-Diamond syndrome.[88,89]

Abdominal Imaging

Four imaging procedures are commonly used for the evaluation of pancreatic disease: CT, ERCP, endoscopic ultrasonography (EUS), and magnetic resonance imaging (MRI) or MRCP. Chronic pancreatitis with calcifications also can be identified on abdominal radiography or by transabdominal ultrasonography, and, when present, the diagnosis of chronic pancreatitis can be made with 90% confidence.[90] These techniques are used as inexpensive initial screening techniques in some centers.[90] However, abdominal radiography and transabdominal ultrasonography lack the sensitivity of CT, ERCP, and EUS.[85] EUS and MRI or MRCP are less widely available and require more technical expertise, and their precise role in evaluation of chronic pancreatitis in children remains to be fully defined.[91] At some centers, MRCP[92] (especially with secretin[93]) has replaced ERCP in most cases used for diagnosis in children, although ERCP remains a valuable tool for therapy and in some diagnostic cases.[23] Each of these newer technologies offers significant advantages and promise over ERCP or CT, but they also have limitations.

Pancreatic Function Testing

Several functional tests have been developed to diagnose chronic pancreatic insufficiency. As noted above, pancreatic insufficiency is a sign of chronic pancreatitis but is not diagnostic. The pancreas has marked functional reserve, so it must be damaged severely before functional loss is clinically recognized.[94] Invasive tests of pancreatic function (eg, the "tubed" secretin test) are the gold standard for determining exocrine pancreatic function.

Pancreatic function testing serves three purposes: to diagnose exocrine pancreatic insufficiency, to aid in the evaluation of chronic pancreatitis, and to provide a basis for rational treatment.[45,95] Mechanistically, pancreatic insufficiency reflects either impaired enzyme synthesis capacity, altered release of enzymes and bicarbonate into the intestine, or intraluminal impairment of pancreatic enzyme function or mixing.[96] Pancreatic function tests are difficult to compare between centers because they often use different stimulants and measure different parameters.[96] Furthermore, few centers perform direct testing of pancreatic exocrine secretion.

Noninvasive function tests to detect pancreatic insufficiency are also used infrequently because they are insensitive and have high false-positive rates.[95] Currently, there are two noninvasive pancreatic function tests available at many centers: fecal elastase 1 (FE-1) and "functional" MRCP. The FE-1 is an excellent test for moderate to severe chronic pancreatitis in adults[97] but is less accurate in mild to moderate chronic pancreatitis.[98] FE-1 reaches normal levels by day 3 in term newborns and by 2 weeks in infants born before 28 weeks of gestation.[99] The sensitivity and specificity of FE-1 and fecal chymotrypsin have been assessed in subjects with severe and mild steatorrhea.[100] Although FE-1 had superior performance characteristics in patients with mild steatorrhea, the ability to identify patients with moderate pancreatic insufficiency without steatorrhea remains a major limitation. The possibility of having a "functional" MRCP is very attractive because both structural and functional data could be gathered in one test. A functional MRCP protocol has been published,[101] but the sensitivity and specificity compared with those of direct testing must be demonstrated because the concentration of bicarbonate compared with the volume of pancreatic fluid is a critical discriminator in exocrine pancreatic function testing.

Genetic Testing

Genetic testing for pancreatic diseases is becoming an important part of medical practice. The results of genetic testing are highly accurate, but positive results for the major autosomal dominant, high-penetrance mutations (eg, *PRSS1* R122H) have broad implications for the patient's future health, family, employment, and insurability.[48,71,102,103] The purpose of genetic testing can be divided

into two general categories: diagnostic and predictive.[4] Diagnostic testing is done when a patient has symptoms of a disease, and a genetic test is done to determine the underlying cause(s). Examples include *CFTR* mutation testing in suspected typical or atypical cystic fibrosis or *PRSS1* (cationic trypsinogen) gene testing in suspected hereditary pancreatitis. Predictive testing is genetic testing in subjects without evidence of pancreatic disease. In general, predictive genetic testing in children is not indicated for *CFTR* or *SPINK1* mutations and is not recommended for *PRSS1* mutations unless there are first-degree relatives with a known *PRSS1* mutation, adequate genetic counseling has been offered, and the child can participate in the decision to undergo testing.[70] General guidelines are outlined in Tables 64.1-6 and 64.1-7.

Genetic testing is now commercially available for the *PRSS1* (cationic trypsinogen) R122H and N29I mutations.[66] The primary indications for cationic trypsinogen mutation testing include recurrent idiopathic acute pancreatitis, ICP, verification of a clinical suspicion in a family member of a kindred with known mutations, to help a patient understand or validate his or her condition, and to assist individuals in making lifestyle decisions (eg, reproduction, diet, smoking) based on the known risk of pancreatitis and potential pancreatic cancer.[66,71,104]

Genetic testing is also used in children with unexplained pancreatitis or episodes of pancreatitis-like pain when there is a significant concern about the possibility of hereditary pancreatitis. Identification of an established pancreatitis-associated gene mutation can be valuable in expediting an expensive and prolonged evaluation of recurrent pancreatitis in children.[45] A positive test result in a clinically unaffected person is interpreted as conferring a significant increased risk of pancreatitis, with this risk possibly diminishing with age. A negative test result in a family with a known mutation essentially eliminates the risk of this genetic form of pancreatitis. If a mutation has not been previously identified in the family, then a negative test result in an unaffected person is considered noninformative because one cannot distinguish whether the tested individual is free from genetic risk or whether he or she has inherited a different pancreatitis-predisposing gene mutation.[66] In families with hereditary pancreatitis, alcohol, emotional stress, and fatty foods are reported to precipitate pancreatitis attacks,[72] and smoking increases the risk of pancreatitis[105–107] and pancreatic cancer.[108] Testing for the purpose of encouraging mutation-positive older children to avoid these excesses is advocated by some caregivers. However, avoidance of fatty foods, alcohol, and tobacco represents excellent general medical advice and therefore provides no compelling reason for genetic testing.[71] In either case, the personal desires of older children to postpone testing or to proceed with testing to relieve their own anxieties and learn more about their own personal health must be carefully considered. Ownership of test results in children must be addressed.[66,70]

Testing for *SPINK1* mutations in individuals with early-onset chronic pancreatitis may provide important information on the predisposing causes of pancreatitis for the concerned patient.[66] However, most experts do not advocate genetic testing for *SPINK1* mutations at this time.[48,49,70] Furthermore, because less than 1% of patients with a heterozygous *SPINK1* mutation alone are likely to develop pancreatitis, the major reasons are lacking to undertake presymptomatic testing. Homozygous *SPINK1* N34S genotypes are strongly associated with chronic pancreatitis and, therefore, are likely a dominant factor in the etiology of otherwise ICP. Heterozygous *SPINK1* mutations alone are likely not disease causing[47,109] but rather act as a cofactor with other genetic mutations as part of a polygenic disorder.

There has been much interest in testing patients with ICP for *CFTR* mutations. The problem is that most panels are designed to test for the common CF-causing gene mutations, not pancreatitis-causing mutations. This area of research continues to develop, and pancreatitis-specific panels or total, low-cost CFTR gene analysis will be needed to fully interpret the CFTR genotype–pancreatitis phenotype relationship. On the other hand, pancreatitis may be the first sign of CF or atypical CF, and these children should, therefore, undergo a full evaluation for cystic fibrosis.

TABLE 64.1-6 INDICATIONS FOR GENETIC TESTING FOR *PRSS1* MUTATIONS

Recurrent (2 or more) attacks of *acute* pancreatitis for which there is no explanation (eg, anatomic anomalies, ampullary or main pancreatic strictures, trauma, viral infection, gallstones, alcohol, drugs, hyperlipidemia)
Unexplained (idiopathic) *chronic* pancreatitis
A family history of pancreatitis in a first-degree (parent, sib, child), second-degree, (aunt, uncle, niece, nephew), or third-degree (grandparent, first cousin) relative
An unexplained episode of documented pancreatitis occurring in a child who has required hospitalization and where there is significant concern that hereditary pancreatitis should be excluded
For a patient with pancreatitis eligible for an ethics committee/institutional review board–approved research protocol

Adapted from Ellis et al.[70]

TABLE 64.1-7 PREGENETIC TEST PATIENT INFORMATION FOR *PRSS1* MUTATIONS

Prior to genetic testing, patients should understand
Why the test has been suggested and provide documented informed consent
The implications of finding a pancreatitis-related mutation in the *PRSS1* gene for the health and medical care of that patient
How their genetic test result will be communicated to them and who else will be informed of their result (ie, the clinician who has requested that test, other involved pancreatic specialists, the family doctor, hospital medical records, insurance carrier)
The availability of genetic counseling after the test result is known
The pancreatic cancer risk and the possible adverse health, life insurance, and employment consequences for the patient (if not safeguarded against by state or national legislation)
The implications of a positive genetic test result for their relatives
Whether or not they wish for their test sample to be used for any research project and by what (anonymized) route this will occur

Adapted from a consensus statement of the Consensus Committees of the European Registry of Hereditary Pancreatic Diseases, the Midwest Multi-Center Pancreatic Study Group, and the International Association of Pancreatology.[70]

Modifier Genes

The reason that some patients with recurrent acute pancreatitis rapidly develop chronic pancreatitis whereas others do not likely involves mutations in disease-modifying genes.[4] This area of research is currently evolving, and several interesting candidate genes are under investigation and verification.

Treatment

The major goals in treating patients with chronic pancreatitis differ with the stage and etiology of disease. Patients with recurrent acute pancreatitis are at risk of developing chronic pancreatitis.[23,110] Efforts should be made to identify the cause of recurrent acute pancreatitis to prevent the development of chronic pancreatitis. Systematic approaches have been published,[111] and a number of risk factors can be addressed by the physician.[66] Anatomic variants can be addressed by both endoscopic and surgical interventions.

In patients with rapidly progressing chronic pancreatitis from an untreatable cause (eg, severe genetic mutations), there are two prognostic concerns. The first is development of a chronic pain syndrome, and the second is development of insulin-dependent diabetes mellitus. There are many possible etiologies of pancreatic pain.[112] The concern is that prolonged exposure of pancreatic nerves to growth factors associated with pancreatic inflammation will cause irreversible central changes so that eventual pancreatic surgery for pain will be of limited value. A second concern is the development of diabetes through destruction of the pancreatic islet cells. Although early surgical intervention with islet cell autotransplant is a consideration in these patients, the problem of islet yield, especially if delayed until chronic pancreatitis is advanced, and long-term benefit remain important issues without clear answers.

In patients with advanced chronic pancreatitis, the objectives are to treat the pancreatic insufficiency resulting from the loss of pancreatic digestive enzymes and to treat pain and diabetes mellitus if they develop. The treatment for pancreatic digestive enzyme deficiency is enzyme replacement.[113,114] The goal is to provide enzyme supplements that restore digestive function.[96] Enzymes are given with all protein- and fat-containing foods and milk products, including predigested formulas and breast milk. Microspheres, minimicrospheres, and microtablets are preferable to granules because the acid-resistant enteric coating protects the enzyme from acid degradation in the stomach and protects against the mouth and perianal excoriations that were seen previously with uncoated enzyme powders.[115,116] Enzymes should be taken about 15 minutes before each meal or snack. For prolonged meals, additional enzymes should also be taken during the meal. Parents and adolescent patients should be taught to adjust the enzyme dosage according to the anticipated amount of fat in a meal.

Generic enzymes may not be bioequivalent to proprietary enzymes.[117] Therefore, apparent treatment failures should include an investigation of the brand of enzymes that was dispensed. Another cause of failure is destruction of the digestive enzymes by gastric acid. Although enteric coating of pancreatic enzymes may protect pancreatic enzymes in the stomach, the intestine remains more acidic (1–2 pH units) in patients with *CFTR* mutations than those with other types of pancreatitis because of a loss in duodenal bicarbonate secretion.[118,119] In the past, treatment of gastric and intestinal acidity included the use of sodium bicarbonate and histamine$_2$ receptor antagonists. However, the availability, efficiency, and safety of the proton pump inhibitors have resulted in widespread use of these products. Enteric-coated products remain effective when used with proton pump inhibitors. On the other hand, patients who do not have CF and retain significant pancreatic function could theoretically benefit from a more acidic duodenal pH so that pancreatic fluid secretion is stimulated and enzymes are rapidly washed out of the pancreatic duct. In this case, gastric acid suppression would be limited, and enteric-coated enzymes are mandatory.

The dose of enzymes is usually calculated according to lipase content. A usual dose of pancreatic enzymes contains 1,000 to 2,500 U lipase/kg/meal. Adequacy of treatment is typically determined on clinical grounds. Frequent, bulky, fatty stools; excessive bloating and flatus; excessive appetite; and inadequate growth velocity are indicators of inadequate treatment. Calculation of a coefficient of fat absorption is used for clinical studies but rarely in clinical practice. Although the human FE-1 test accurately predicts exocrine pancreatic insufficiency,[120–122] it is of no value in determining the adequacy of enzyme replacements of porcine origin because the test is specific for human elastase 1.

2. *Juvenile Tropical Pancreatitis*

C. S. Pitchumoni, MD, FRCPC, FACP, MACG, MPH
Viswanathan Mohan, MD, MRCP, PhD, DSC

Chronic pancreatitis is mostly a disease of adults secondary to 10 to 15 years of alcoholism. Although relatively rare, hereditary pancreatitis is the most common type of chronic pancreatitis in children of the developed countries of the world. In many Afro-Asian countries, a nonhereditary, nonalcoholic form of chronic calcific pancreatitis is the most common type of chronic pancreatitis in children and young adults.[1–8] Nutritional pancreatitis, tropical pancreatitis, juvenile tropical pancreatitis syndrome, tropical calculous pancreatopathy, Afro-Asian pancreatitis, and fibrocalculous pancreatic diabetes are other terms used in the literature to describe this entity.

DEFINITION

Tropical pancreatitis is a form of chronic pancreatitis characterized by recurrent abdominal pain, pancreatic calculi, and diabetes mellitus, occurring mostly among poor children and young adults of many developing nations (Figures 64.2-1 to 64.2-3). The affected individuals are generally emaciated and may show signs of malnutrition. The notable absence of other known causes of pancreatitis, the geographic prevalence of the disease in developing nations, and the scientific plausibility of pancreatic injury in malnutrition are the keys to implicating nutritional deficiency as the most likely etiologic factor for this otherwise enigmatic disease.

EPIDEMIOLOGY

Although isolated case studies have been reported in the Indian medical literature since 1930, the first clear description of this syndrome was made in 1959 by Zuidema from Indonesia.[1] This classic article described seven malnourished Indonesian patients with pancreatic lithiasis. The youngest, a 15-year-old girl, was markedly undernourished, weighing only 33.5 kg. Her main meal at home was rice, cassava (*Manihot esculenta*), and vegetables and seldom included fish, meat, or eggs. The oldest in the group was 28 years of age. None had a history of alcohol consumption. In six patients, diabetes mellitus dominated the clinical picture. Some of them had marked swelling of both parotid glands and thinning of scalp hair resembling kwashiorkor. In one case, autopsy showed fibrosed acinar tissue and stones in the duct. Zuidema subsequently reported on 45 patients from 12 to 45 years of age with the same clinicopathologic features.[1] The diabetes of the poor in Indonesia, Zuidema concluded, was a result of severe protein malnutrition.

In 1960, Shaper observed a similar syndrome in the indigenous population of Uganda, whose diet was rich in carbohydrate but low in protein and fat.[2] The youngest patient was 10 years old. Most patients had a history of moderate to severe recurrent abdominal pain, suggestive of pancreatitis. Shaper felt that the high-carbohydrate diet associated with severe protein deficiency led to increased demands for pancreatic enzymes while potentiating the effect of protein depletion.

The syndrome of chronic pancreatitis with pancreatic calculi and diabetes has subsequently been reported by different observers from many countries, such as Uganda, Nigeria, the republic of Congo, Malawi, Zambia, Ghana, the Ivory Coast, and Madagascar in Africa; Sri Lanka, Malayasia, Thailand, India, and Bangladesh in Asia; and Brazil in South America.[1] In support of the term tropical pancreatitis, the prevalence of this disease is almost restricted to latitude 30° north and south of the equator.

FIGURE 64.2-1 A 13-year-old boy with juvenile tropical pancreatitis. Note the emaciation and distended abdomen.

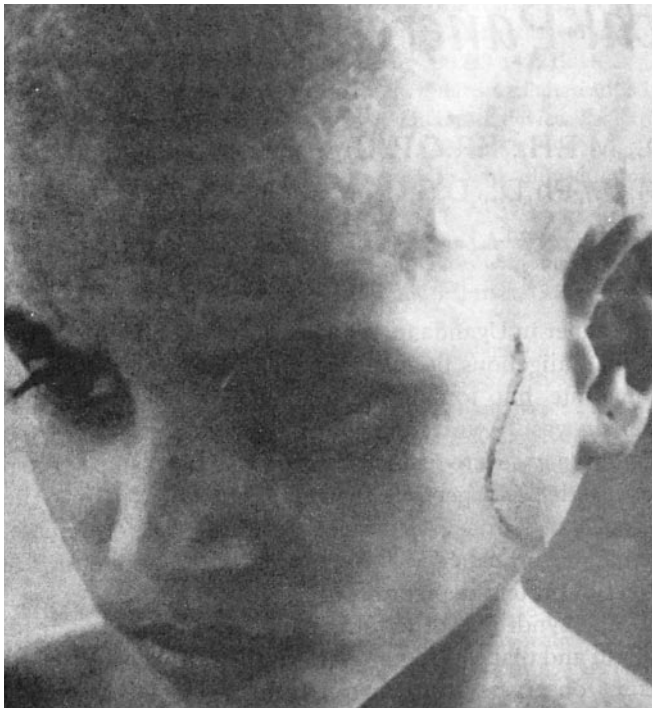

FIGURE 64.2-2 Parotid gland enlargement in the boy shown in Figure 64.2-1.

The largest series of cases of juvenile tropical pancreatitis to date is from the southwestern state of Kerala in India. This may be the result of an increased awareness and routine screening of young diabetics for pancreatic calculi with radiographic studies of the abdomen. Approximately 3,000 cases of this disease have been reported in the literature, more than 1,700 cases by GeeVarghese alone from the state of Kerala in India, where the disease was once noted to occur in endemic proportions.[5]

The true prevalence of this disease is not well established because the epidemiologic data are based exclusively on patients seen in major teaching hospitals that do not include those studied in nonteaching hospitals and outpatient clinics of private practitioners. On the other hand, the hospital data may give an erroneously high prevalence because most of the patients from villages tend to accumulate in the major teaching hospitals for treatment. The data can be further skewed because in many Afro-Asian countries, men seek medical attention more often and earlier than women. One epidemiology study in an endemic area in the state of Kerala reported a prevalence of 1 in 1,000 population.[9] In a referral diabetic center, tropical pancreatitis constituted 1% of all diabetic patients.[8] The disease currently appears to have decreased in its incidence in the state of Kerala in India, where, nearly three decades ago, it was noted to be frequent. A marked improvement in the socioeconomic status of the population in the state and an associated improvement in childhood nutrition may be reasonably assumed to be the reasons for this change in incidence.

FIGURE 64.2-3 Flat plate of the pancreas in a case of juvenile topical pancreatitis. The entire main pancreatic duct and even some ductules are packed with calculi. A ductogram is seen.

PATHOLOGY

The pathologic changes in the pancreas and other organs in tropical pancreatitis have been well studied in material obtained at postmortem or surgery.[8,10,11] Because pancreatic biopsy is not done in the early stages of the disease, our knowledge of the pathology is limited to the late stages. The histologic changes in the pancreas are almost identical to those of alcoholic pancreatitis.

The size of the pancreas varies inversely with the duration and severity of the disease. In advanced stages of the disease, the pancreatic gland is as small as the little finger, and the surface is irregular and nodular. Uneven shrinkage and fibrous adhesions cause displacement of the pancreas from its normal location. The parenchyma may be replaced by fat and become indistinguishable from surrounding adipose tissue. The pancreas is firm, fibrous, and gritty to the touch, although the consistency of the organ may vary in different regions of the gland depending on the presence of fibrous tissue, cysts, or stones. Radiologic examination of the dissected pancreas often reveals multiple calculi, which are not noted in antemortem radiologic studies (Figure 64.2-4).

Homogeneous areas; varying degrees of fibrous, cystic dilatation of the gland; and pancreatic calculi of different shapes and sizes distributed throughout the duct system characterize the cut-section. The major pancreatic duct may be eccentrically placed as a result of uneven destruction of the glandular tissue. Areas of stenosis and dilatation of the ducts can be seen in the same gland. Incomplete pancreatic obstruction at the ampulla of Vater is noted in a large majority of carefully dissected cases, corresponding to the location of a solitary calculus ("sentinel stone") and/or larger stones.[5]

Pancreatic calculi vary in color, size, and shape. The larger stones are nearer the head, progressively diminishing in size toward the tail. The stones range in size from small sand particles to calculi 4.5 cm long, weighing up to 20 g. The shape of a stone is influenced by its location; may be smooth, rounded, or staghorn-like; and may be incarcerated in the main pancreatic duct and major branches.

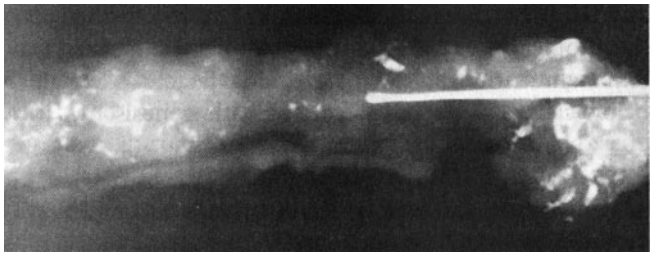

FIGURE 64.2-4 Radiologic study of the isolated postmortem pancreas. Note the numerous small radiodense areas, which are intraductal calculi. The probe is passed into the main duct to show the dilatation in relation to the shrunken pancreas.

Soft stones are formed by noncalcified protein plugs and caseous material. Sections of calcified stones show epithelial debris, fibrin, and mucinous material.

Pancreatic calculi are composed of 95.5% calcium carbonate and a small amount of calcium phosphate. Traces of magnesium, urate, and oxalate have been identified in some stones. X-ray diffraction studies of calculi have determined that calcium carbonate is found predominantly in the form of calcite and rarely in the form of vaterite.[12] Scanning electron microscopic studies and spectroscopic methods of analysis have shown that the calculi have an amorphous nidus and a cryptocrystalline periphery. The nidus is rich in iron, chromium, and nickel, and the periphery contains a number of trace elements and a preponderance of calcium.[13] These calculi are structurally and biochemically similar to stones obtained in other types of chronic pancreatitis. A nonenzymatic protein has been identified by some observers in the core of calculi. This protein, termed pancreatic stone protein (PSP), has been implicated in the pathogenesis of the disease and in calculus formation. The absence or decrease of PSP has been thought to promote nucleation of calcium carbonate and crystallization in chronic pancreatitis.[14] However, recent studies on PSP have given contradictory results, and the role of PSP in the genesis of calculi and the pathogenesis of disease is unclear.

Microscopically, the characteristic feature is diffuse fibrosis of the pancreas (Figure 64.2-5). The main duct, collecting ducts, and small ductules show marked dilatation with periductular fibrosis. Denudation of the ductular epithelium and squamous metaplasia are seen in some areas. The characteristic cellular infilitraton of the pancreas is composed of lymphocytes and plasma cells, distributed mainly around the ducts. Interlobular fibrosis is characteristic of early cases, and focal, segmental, or diffuse fibrosis is characteristic of more advanced cases. The acinar tissue shows varying degrees of atrophy and parenchymal destruction. Fibrous tissue is seen adjacent to relatively normal-looking parenchyma. As the disease advances, the islets become atrophic and are isolated and surrounded by dense fibrous tissue. In some instances, the islets appear even hypertrophied, and, as in other forms of pancreatic atrophy, a true nesidioblastosis is observed (Figure 64.2-6). Preliminary histochemical studies have identified those hyperplastic islets as B-cell nesidioblastosis. Immunohistochemistry has also shown

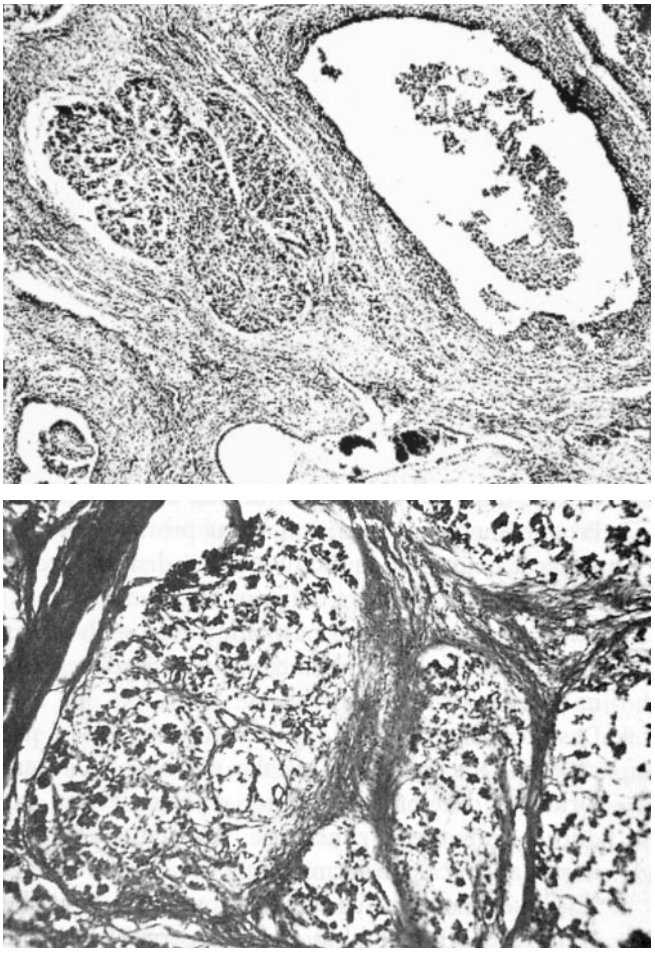

FIGURE 64.2-5 The pancreas shows extensive fibrosis, ductular dilatation, and intraductular calcium deposits. The intra- and interacinar fibrosis of the exocrine parenchyma produces the appearance of cirrhosis of the pancreas (hematoxylin and eosin).

reduced alpha cells and beta cells in the pancreas.[11,15] The vacuolation, ballooning, and glycogen infiltration of the islets characteristic of juvenile diabetes are seldom noted. The clinical significance of the islet cell hyperplasia is to be further studied.

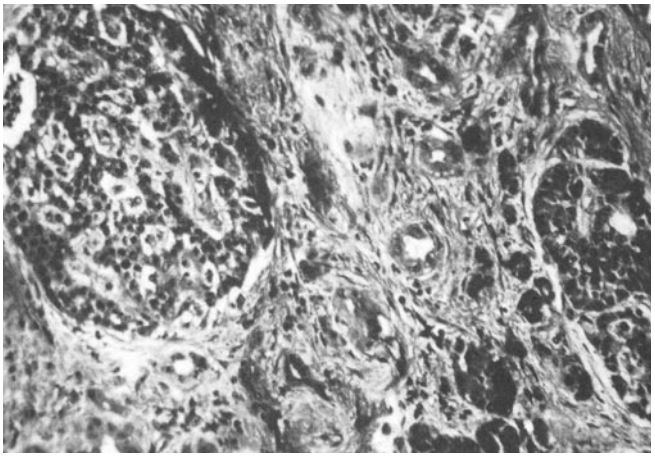

FIGURE 64.2-6 The islets show varying degrees of hypertrophy in the presence of fibrosis of the organ.

The high incidence of pancreatic carcinoma in patients of a relatively young age suggests that tropical pancreatitis is a premalignant disease similar to hereditary pancreatitis.[16,17] Other organs such as the liver and parotid glands show changes indicative of uncontrolled diabetes mellitus and/or malnutrition. The liver in the early stages shows glycogen infiltration of the cytoplasm and nuclei and fatty changes (and cirrhosis in more advanced cases). Parotid glands show hypertrophied acini, with varying degrees of round cell infiltration around the intralobular and interlobular ducts. The pathogenesis of parotid enlargement is probably a functional or compensatory hypertrophy as an adaptive mechanism to pancreatic exocrine insufficiency.[18]

ETIOLOGY AND PATHOGENESIS

The exact etiology of this disease has not yet been established. The etiologic factors proposed here are to be considered hypothetical, based on epidemiologic data, careful clinical studies, and biochemical evaluations. The hypotheses in consideration are as follows:

Malnutrition

The basis for considering malnutrition as a predisposing factor was the prevalence of the disease almost exclusively in the poor population groups of developing nations and the findings of malnutrition in many patients.[3–7] Protein malnutrition is known to cause pancreatic injury in experimental and clinical studies. In kwashiorkor, as well as marasmus, pancreatic structure and function are markedly altered.[17] Some of the histologic changes of the pancreas in kwashiorkor, such as atrophy of acinar cells, disorganization and loss of the acinar pattern, marked reduction in the amount of zymogen granules, vacuolization, epithelial metaplasia, cystic dilatation of the ducts, and an increase in fibrous tissue, mimic the histology of tropical pancreatitis.

A number of recent observations, however, speak against protein malnutrition as the sole or initiating factor of this disease[19]:

1. In India and Africa, the geographic prevalence of the disease does not correlate with that of kwashiorkor.
2. Protein-energy malnutrition, being prevalent in many tropical countries, is likely to be a denominator in most diseases affecting poor populations.
3. There are large pockets of malnutrition with relative infrequency or total absence of tropical pancreatitis in many parts of the world.
4. Despite some histologic similarities to tropical pancreatitis, the pathology of the pancreas in kwashiorkor is different. The latter disease seldom produces permanent pancreatic damage, and, more importantly, calculi formation is not a feature.
5. The disease currently is seen in some well-nourished children of affluent families, further complicating the malnutrition theory.

The advanced malnutrition noted in tropical pancreatitis studied three decades ago appears to be the consequence of the disease rather than its cause. It is thus clear that tropical pancreatitis is not secondary to isolated protein malnutrition, although nutritional factors as explained below cannot be excluded from its pathogenesis.

Free Radical Injury

Clinical protein-energy malnutrition is a complex syndrome complicated by deficiencies of a number of vitamins and trace elements, bacterial and viral infections and parasitic infestations, psychological stress, and hormonal and immunologic disturbances. The body's ability to scavenge the highly reactive free radicals is markedly impaired in malnutrition, whereas the endogenous and exogenous stimuli for free radical production are markedly enhanced. Chronic pancreatitis, alcoholic or tropical, has been hypothesized as one of the many diseases caused by unmitigated free radical injury.[20,21]

However, in view of the difficulties in studying free radical production and elimination in the pancreas, free radical injury as a mechanism of pancreatitis remains in the realm of hypothesis.

Trace Elements and Vitamin Deficiencies

Independent of their ability to scavenge free radicals, trace elements and vitamins participate in maintaining the integrity of acinar cell function and structure. Experimental studies indicate that a zinc-deficient diet results in acinar cell injury, copper deficiency induces selective and progressive atrophy of acinar cells, and selenium deficiency causes pancreatic fibrosis.[22] Vitamin A, riboflavin, folic acid, and vitamin D appear to be important for acinar cell integrity.[22] Although deficiency of these trace elements and vitamins may occur as part of the spectrum of human malnutrition, clinical pancreatic disease has not been proven to be secondary to micronutrient deficiency.

Dietary Cyanogens

The geographic distribution of tropical pancreatitis coincides with areas of consumption of cassava root (tapioca, *Manihot esculenta*), which is a source of carbohydrate for poor populations in parts of Nigeria, Uganda, Indonesia, Thailand, and the state of Kerala in India.[5]

Cassava root is known to contain cyanogenic glycosides: linamarin and lotaustralin.[23] Cyanide is normally detoxified in the body by conversion to thiocyanate, but this detoxification requires sulfur containing the amino acid methionine, which is deficient in cassava. A high-carbohydrate, low-protein diet was shown to cause pancreatic fibrosis in a recent experimental study, raising the possibility that the nutritional composition of the diet is important in pancreatic injury[24] rather than the source of carbohydrate or the presence or absence of cyanogen in the diet. Although tropical pancreatitis is prevalent in some parts of Africa and India where cassava is not consumed, it is not noted in some areas where cassava is consumed, as in the rural West African population.[25]

Genetic Factors

Many recent studies have looked for genetic abnormalities in all forms of chronic pancreatitis following the discovery of genetic mutations in hereditary pancreatitis.[26–28]

In the normal pancreas, a number of mechanisms work synergistically, preventing the premature activation of trypsinogen to trypsin. The central mechanism of acinar cell injury is autodigestion by active trypsin. Mutations of certain genes reduce the natural ability of the body to prevent the premature activation of trypsinogen. The most important mutations studied in relation to hereditary pancreatitis and, to a lesser extent, in other forms of pancreatitis are those involving the cationic trypsinogen gene (*PRSS1*), serine protease inhibitor Kazal type 1 (SPINK 1), and cystic fibrosis transmembrane conductance regulator (CFTR).[29] In light of what has been learned with regard to genetic abnormalities in hereditary pancreatitis, tropical pancreatitis is being currently evaluated for possible genetic mutations. On a small cohort of tropical pancreatitis patients, the frequency of CFTR mutations was lower than that reported in idiopathic chronic pancreatitis from the West.[30]

In two recent studies, one from India and the other from Bangladesh, it was noted that tropical pancreatitis was highly associated with the SPINK 1 *N34S* mutation.[31,32] The high prevalence of N34S mutation in patients with and without diabetes in the Indian study suggests that these two subtypes have a similar genetic predisposition.[31,32]

In conclusion, the etiopathogenesis of this syndrome remains enigmatic, and further studies are clearly needed. Its relationship to cystic fibrosis is an area that needs to be explored.

CLINICAL FEATURES

The cardinal manifestations of juvenile tropical pancreatitis are recurrent abdominal pain in childhood, followed by diabetes mellitus and pancreatic calculi by puberty and death in the prime of life. Improvement in the management of diabetes has resulted in a longer life span not noted in earlier observations. The calculated life expectancy after the onset of abdominal pain and diabetes is 35 and 25 years, respectively.[33]

The onset of the disease is insidious in early childhood, with recurrent attacks of upper abdominal or periumbilical pain before the thirteenth year (Table 64.2-1). The history is often elicited from the patient's mother, who attests to the number of school days lost. About 5% of juvenile diabetics with pancreatic calculi do not have abdominal pain.[5] The patient usually keeps the palm on the abdomen to indicate a wide area of pain as opposed to the finger tip, as in duodenal ulcer. The pain radiates to the lower end of the sternum, the left costal margin, and along the left side or posteriorly to the lumber spine. The episodes of pain last for days, not minutes or hours. The pain is usually aggravated by small amounts of food so that the patients refuse all food by mouth. In the early stages, the bouts of pain are severe and are associated with vomiting. As years pass, painful attacks become less intense but more prolonged. In an attempt to obtain relief, patients sit up, bend forward, or walk; curl up in the lateral decubitis position; clutch the skin of the abdomen; or apply hot water bottles to the area. Recent studies have noted a change in the age at onset of the disease. Only about 12% of patients report an onset before the age of 20 years.[7] The observed difference in the current series of cases from those reported earlier cannot be explained.[4,7]

An interval of several years may pass between the cessation of painful attacks and the onset of diabetes mellitus. Pancreatic pain totally disappears in a large number of patients either before or some years after diabetes develops, coinciding with "burning out the pancreas." It is uncommon for diabetes to precede abdominal pain.

Patients are often repeatedly treated with antihelminthics and antacids after the mistaken diagnosis of parasitic disease or peptic ulcer. Persistent abdominal pain in childhood of undetermined etiology has often led to diagnostic laparotomy. In the absence of demonstrable pancreatic calculi, there is no easily available test to establish the diagnosis of chronic pancreatitis at this stage of illness.

DIABETES MELLITUS

Most patients initially seek medical attention for diabetes mellitus, which becomes clinically manifest a few years after the onset of pancreatalgia. A pain-free period of 1 or 2 years and an apparent transient improvement in the clinical picture prior to the onset of diabetes are not unusual. The age at onset of diabetes from India is presented in Table 64.2-2.

The fasting blood glucose level ranges between 200 and 400 mg/dL, and postprandial blood glucose levels greater than 700 mg/dL are not rare. Pancreatic diabetes is characteristically brittle, with marked fluctuations of blood glu-

cose values with or without insulin therapy. Episodes of hypoglycemia are characteristic and may complicate the administration of even small doses of insulin. This may be a reflection of depleted glycogen reserves in the liver or decreased glucagon release from the pancreas. Spontaneous hypoglycemic episodes have been recorded without insulin therapy. True insulin resistance, defined as a daily requirement of over 200 U of insulin in the absence of infection or ketosis reported earlier, is no longer seen with the use of purified and human insulins.[8] Metabolic acidosis is uncommon, but ketosis may be seen in less than 5% of cases.[7]

C-peptide assay shows partial preservation of beta cells, which is responsible for the ketosis resistance.[8] Diabetic retinopathy and nephropathy do occur and are related to the duration of diabetes.[5,8] Other complications of pancreatic diabetes include neuropathy, recurrent urinary tract infections, and pyelonephritis. The liver is palpably enlarged in 40% of diabetics, although the only liver functional abnormality may be elevation of alkaline phosphatase, indicating fatty liver.[5] Autonomic nervous system dysfunction occurs with similar frequency and severity, as in patients with non–insulin-dependent diabetes mellitus.[34]

EXOCRINE PANCREATIC INSUFFICIENCY

Overt exocrine pancreatic insufficiency characterized by steatorrhea is the least striking clinical feature, attributable to the very low consumption of fat in the diet. However, on a diet of 100 g of fat, more than 70% of patients develop biochemical steatorrhea.[7]

Clinical and biochemical evidence of obstructive jaundice is a well-recognized complication secondary to stenosis and compression of the common bile duct, which is tunnelled in the head of the pancreas. Pancreatic pseudocysts are less uncommon than in alcoholic or biliary pancreatitis.

DIAGNOSIS

The diagnosis of chronic pancreatic injury in the early stages of the disease in young children is seldom made. Abdominal pain in childhood is often ignored or attributed to psychogenic causes or, in the tropics, to parasitic infestations. Endoscopic retrograde cholangiopancreatography (ERCP) or computed tomography (CT) will be helpful in earlier detection of the disease. An ERCP characteristically shows a markedly dilated main duct with a radiopaque and lucent calculi. Sonograms and CT scans of the abdomen help in identifying the calculi and the dilated ducts. Cost and limited availability, however, make it impractical to use CT scans and ERCP for the routine diagnosis of tropical pancreatitis. There are no sensitive and specific noninvasive blood or urine tests to diagnose chronic pancreatitis. Even in the developed nations of the world, the diagnosis of chronic pancreatitis in adults or children is often elusive and made very late, only after ductal changes or calculi develop.

On the other hand, the picture of a well-established case of tropical pancreatitis is so characteristic that a diagnosis based on clinical features alone is suspect. The onset of diabetes mellitus with a present or past history of recurrent abdominal pain in a young individual suggests chronic pancreatitis. Extreme emaciation, bilateral parotid gland enlargement, and a distended upper abdomen are seen only in patients with established and advanced disease. A peculiar cyanotic hue of the lips has been mentioned in early reports[3,4] but is noted infrequently in the majority of patients.[7]

The diagnosis is established by demonstration of pancreatic calculi on a flat-plate radiograph of the abdomen. The most common site of pancreatic calculi on the abdominal flat plate is to the right of the first and second lumbar vertebrae. The lateral extension is up to 2 to 5 cm to the right of these vertebrae. Calculi are most numerous in the head of the pancreas. In 30% of cases, the calculi form a cast of the main duct.[5] In the lateral film, the stones are located anterior to the vertebral body but posterior to the gallbladder area.

The diagnosis of tropical pancreatitis does not depend on the demonstration of pancreatic exocrine functional abnormality. Serum amylase determination is not often useful in the diagnosis of chronic pancreatitis except in acute exacerbations. The amylase is below normal in a large number of cases. Steatorrhea is manifest only on a high-fat test diet given prior to stool fat testing. Secretin cholecystokinin stimulation tests are expensive and time consuming and are seldom performed. Limited studies done in an academic setting have shown a marked decrease in volume and enzyme output. Bicarbonate secretion is normal in some studies but markedly reduced in others. The newer diagnostic tests—bentiromide test, pancreaolauryl test, and fecal chymotrypsin assays—are likely to be of limited value except in assessing exocrine insufficiency in late stages of the disease.

MANAGEMENT

The management of tropical pancreatitis consists of alleviation of abdominal pain, treatment of diabetes, prevention of complications, and correction of nutritional problems.

The treatment of acute episodes of painful attacks is similar to the treatment of other types of pancreatitis. The measures to "put the pancreas to rest" include no feeding by mouth and the use of intravenous fluids and electrolytes. Nasogastric suction may be needed in severe cases. The treatment of pain may require repeated injections of meperidine, but there is a danger of producing narcotic addiction. The role of large doses of orally administered enzyme therapy for pain in tropical pancreatitis is not well studied. The basis of such therapy is the experimental observation that orally administered proteases suppress endogenous enzyme production through a feedback inhibition.[35,36] Enzyme therapy may not help patients with tropical pancreatitis, a disease characterized by marked dilatation of duct and ductules. Success with enzyme therapy is limited to patients with nondilated ducts with functioning acinar cells. Empiric therapy with oral antioxidants appears to be effective in the management of pain in alcoholic pancreatitis.[37] Although not well proven, in view of its simplicity, antioxidant therapy is worth a trial in all patients. Endo-

scopic papillotomy with the removal of stones and the clearance of dominant strictures and obstructions has shown good results in carefully chosen patients.

Unremitting pain is an indication for surgical treatment. The best procedure is the exploration of the pancreatic duct, the removal of stones, and longitudinal anastomosis of the split surface of the pancreas to the jejunum (Puestow procedure).[38] The relief of pain, even with surgery, may be temporary.

The treatment of diabetes is with dietary manipulation using oral hypoglycemic agents and insulin therapy. The dietary management of diabetes in pancreatitis is complicated.[8] The associated malnutrition, malabsorption, and tendency toward hypoglycemia deserve consideration in prescribing a suitable diet. A nutritious diet supplemented with vitamins and minerals is needed, and it is not advisable to restrict the carbohydrate content of the diet below 300 g. The diet may have to be supplemented with adequate protein intake, and pancreatic enzyme preparations are also advised to correct malabsorption.

If the diabetes is mild, oral hypoglycemic agents may be used, especially in the first few years after the onset of diabetes. Insulin therapy is required to control hyperglycemia in the large majority of cases. Often a combination of insulin and oral hypoglycemic agents is used to reduce the cost of therapy with insulin alone. Supplementary pancreatic enzyme therapy in a preliminary study was shown to reduce marked fluctuations of blood sugar.[39]

SUMMARY AND CONCLUSIONS

Juvenile tropical pancreatitis is a type of chronic pancreatitis that occurs in children and young adults of many developing nations. Although the etiology is not established, malnutrition is an important epidemiologic association. Other proposed etiologic factors include unopposed free radical injury, trace element and vitamin deficiencies, and dietary cyanogen toxicity. Many recent studies have identified genetic markers, and an association with SPINK 1 and N34S mutation has been noted. The occurrence of abdominal pain in childhood followed by the onset of diabetes in an emaciated teenager is the typical clinical picture, and the radiologic demonstration of calculi in the pancreatic duct is the hallmark of the disease. Patient management involves the control of diabetes with an oral hypoglycemic agent and/or insulin. Painful attacks of pancreatitis require the use of analgesics or surgery. Nutritional management should include a diabetic diet with adequate complex carbohydrates and frequent small meals, supplemented with oral pancreatic enzymes.

Tropical pancreatitis is an enigmatic disease that requires further study to explain its etiopathogenesis. It may be one of the preventable forms of diabetes in children in the tropics.

CHAPTER 65

EXOCRINE PANCREATIC DYSFUNCTION

1. *Cystic Fibrosis*

Kevin J. Gaskin, MD, FRACP

Cystic fibrosis (CF) is an autosomal recessively inherited disorder caused by mutations of the cystic fibrosis transmembrane conductance regulator (CFTR) gene and characterized clinically by chronic suppurative lung disease and exocrine pancreatic failure. The early postmortem descriptions of CF in the 1930s recognized both the pulmonary and pancreatic components of the disorder,[1,2] establishing it as a separate entity to "celiac syndrome" (a collective term for malabsorptive disorders of children in that era). Later, di Sant'Agnese and others demonstrated that CF patients have elevated sweat salt concentrations,[3] and this has remained the mainstay of diagnosis until the present day. The CFTR gene was discovered in the late 1980s[4–7] with the subsequent demonstration that the gene product (CFTR protein) was a cyclic adenosine monophosphate (cAMP)-stimulated Cl^- channel.[8] Over the same era, there were many significant advances in clinical management, including antibiotic therapy for lung disease, microspheric pancreatic enzyme replacement therapy, and nutritional therapy, all of which enhanced median survival from 10 to nearly 40 years of age over the last half-century. This chapter addresses concepts of the pathophysiology of this disease, its genetics, and associated gastrointestinal and nutritional problems. The reader is referred elsewhere for reviews of respiratory disease[9] and reproductive tract complications.[10]

ETIOLOGY

The pathophysiologic basis of CF centers on the CFTR protein and its function in absorptive and secretory epithelial tissue. The *CFTR* gene was located on chromosome 7[4] and was subsequently cloned, and the sequence of the gene and protein product were determined in 1989.[5-7] CFTR is a membrane protein, and its secondary or domain structure, proposed by Riordan and others,[6] included two membrane spanning domains (MSD1 and MSD2), two nucleotide binding domains (NBD1 and NBD2), and a regulatory domain (R), as depicted in Figure 65.1-1. The CFTR protein functions as a phosphorylation-dependent Cl^- channel located in the apical membrane of epithelial cells, as evident from data showing (1) the expression of CFTR in cells that did not normally contain cAMP-dependent Cl^- channels and the subsequent demonstration of a Cl^- current activated by cAMP agonists,[11] (2) the demonstration of the similarity between Cl^- currents in cells expressing recombinant CFTR and in epithelial cells expressing native endogenous CFTR,[12] (3) mutations of CFTR altering Cl^- transport,[13] and, finally, (4) purified recombinant CFTR in planar lipid bilayers demonstrating Cl^- channel properties identical to those in native epithelia.[8]

CFTR is important in regulating electrolyte transport in absorptive and secretory epithelia.[14] Cholera toxin, for instance, stimulates massive chloride and subsequent fluid secretion from intestinal epithelia. The chloride secretion is mediated by a direct effect of the toxin on the cAMP-

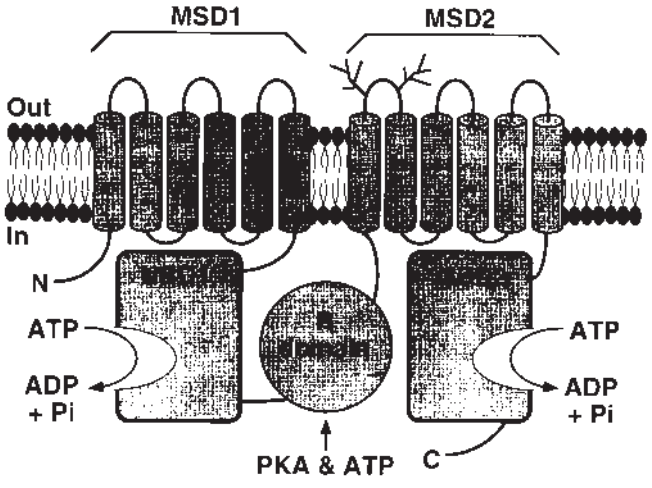

FIGURE 65.1-1 Schematic model of the cystic fibrosis transmembrane conductance regulator with membrane spanning domains (MSD1 and MSD2), nucleotide binding domains (NBD1 and NBD2), and regulatory domain (R). dependent CFTR channel, as confirmed recently by the demonstration that the highly specific CFTR inhibitor, thiazolidinone, markedly reduces Cl^- secretion in response to cholera toxin stimulation.[15] As seen in Figure 65.1-2, a simple model demonstrates that Cl^- accumulates intracellularly following entry via the Na^+-K^+-Cl^- cotransporter in the basolateral membrane. Recycling of Na^+ occurs by the basolateral Na^+-K^+ exchanger and of K^+ through independent K^+ channels, whereas Cl^- moves down its electrochemical gradient to the lumen following activation of the cAMP Cl^- channel in the apical luminal membrane. Na^+ is transported paracellularly in response to the lumen negative voltage set up by Cl^- transport. In absorptive epithelia, for example, in the sweat duct, CFTR functions in almost a reverse fashion to the above and is involved in electrolyte and fluid absorption. In addition to its function as a cAMP-dependent Cl^- channel, CFTR as an ABC transporter (adenosine triphosphate [ATP] binding cassette protein) can regulate other membrane channels and the transport of drugs, amino acids, and peptides.[16] These functions are summarized in Figure 65.1-3 and include cAMP Cl^- channel function, facilitation of ATP release, positive regulation of outwardly rectifying Cl^- channels (ORCC), negative regulation of epithelial Na^+ channels, regulation of intracellular vesicle trafficking, intracellular compartment acidification and glycoprotein processing, and modulation of renal outer medullary K^+ channel sensitivity to sulfonylureas. Moreover, release of ATP may further enhance or regulate ORCC via purinergic receptors, and other chloride channels, including Ca^{++} activated channels, appear to be regulated by external nucleotides.

Patients with CF have impaired chloride reabsorption from sweat ducts and, in general, elevated sweat chlorides greater than 60 mmol/L. Transport defects have also been demonstrated in vivo in both respiratory and pancreatic duct epithelium. In upper airway epithelium from CF subjects, the potential difference across the epithelium of 53 mV is about twice that observed in normal controls, and

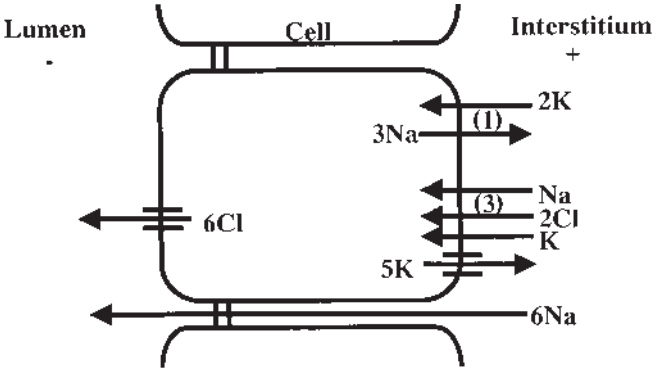

FIGURE 65.1-2 Chloride secretion via the cyclic adenosine monophosphate–activated Cl^- channel. Cl^- accumulates intracellularly via the Na^+-K^+-Cl^- cotransporter in the basolateral membrane. Na^+ is recycled via Na^+-K^+-adenosine triphosphatase and K^+ through independent K^+ channels. Cl^- moves down its electrochemical gradient following activation of the Cl^- channel and is secreted into the lumen, and Na^+ follows paracellularly owing to the lumen negative voltage set up by Cl^- transport.

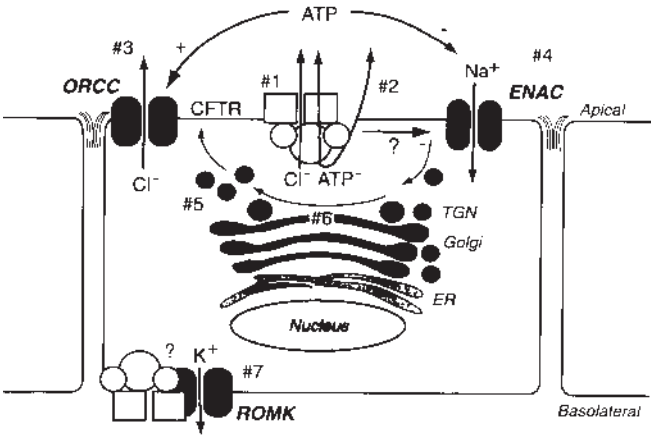

FIGURE 65.1-3 Cystic fibrosis transmembrane conductance regulator (CFTR) functions: (1) Cl^- channel function, (2) facilitation of adenosine triphosphate (ATP) release, (3) positive regulation of outwardly rectifying Cl^- channels (ORCC), (4) negative regulation of epithelial Na^+ channels (ENAC), (5) regulation of vesicle trafficking, (6) regulation of cell acidification and protein processing, (7) modification of renal outer medullary K^+ (ROMK) sensitivity to sulfonylureas. Reproduced with permission from Schwiebert EM et al.[16] ER = endoplasmic reticulum; TGN = trans-Golgi network.

this difference persists further down the airways, although perhaps of lesser magnitude.[17,18] Of interest, this difference in potential can be abolished by amiloride, a finding attributed to amiloride blocking the enhanced Na^+ reabsorption in CF airway epithelium.[19] These changes in electrolyte transport help explain the impaired fluid secretion and the relative dehydration and increased viscosity of respiratory secretions in CF, the latter having previously been attributed to an abnormality of mucus.

In the normal pancreas, the major driving force for pancreatic fluid production has been attributed to secretin–stimulated ductal bicarbonate (HCO_3^-) secretion. The conventional theory proposed that duct cell chloride secretion via CFTR increased duct luminal chloride concentration. Chloride was then exchanged with intracellular HCO_3^- via an apical cell membrane Cl^--HCO_3^- exchanger, with HCO_3^- being synthesized in the cell via carbonic anhydrase action on CO_2, the latter diffusing into the cell via the basolateral membrane.[20] Because pancreatic ductal CFTR Cl^- secretion was impaired in CF patients, Cl^- was not available for exchange with HCO_3^-, thus producing the characteristically low HCO_3^- secretion defined by in vivo pancreatic function studies.[21–23] Recently, the mechanisms of both HCO_3^- production and secretion via the Cl^--HCO_3^- exchanger have been questioned on the basis that (1) there is demonstrable Na^+ dependence of ductal HCO_3^- uptake at the basolateral cell membrane[24] and (2) there is a lack of inhibition of secretin-stimulated HCO_3^- secretion in the absence of luminal Cl^-.[25] The current model of secretion suggests that depolarization of the cell membrane potential, owing to Cl^- exit via cAMP CFTR activation, stimulates HCO_3^- entry via the basolateral electrogenically driven Na^+ HCO_3^- cotransporters and that HCO_3^- secretion into the lumen occurs predominantly via a conductive pathway. In

CF, the impaired Cl^- secretion and lack of cell depolarization inhibit HCO_3^- uptake and subsequent luminal HCO_3^- secretion. Although further work is required in this area, there is little question that pancreatic duct contents are relatively dehydrated and precipitate within the duct or ductule, leading to subsequent obstruction and proximal inflammation, with scarring and destruction of acinar tissue.[26] Furthermore, impaired HCO_3^- secretion may lead to polymerization and ductal precipitation of the zymogen granule–associated protein GP2, which normally undergoes a continuous exoendocytosis cycle to maintain the integrity of the zymogen granule.[27]

INCIDENCE, DIAGNOSIS, GENOTYPE

CF affects approximately 1 in 2,500 live births in white communities.[28] It is less frequent in African Americans, with a reported incidence of 1 in 15,300,[29] and is considered rare in Southeast Asians. The estimated carrier frequency of near 5% in white communities is extraordinarily high for a lethal gene and does suggest some survival advantage to mutation carriers. Quinton has postulated that carriers are protected against organisms causing toxigenic diarrheas,[30] as is evident by resistance to cholera toxin in heterozygotes of a CF mouse model.[31]

Classically, the diagnosis of CF is based on the clinical phenotype at presentation (lung disease, pancreatic insufficiency [PI]) and the presence of an elevated sweat chloride greater than 60 mmol/L. CF infants may have sweat chlorides in the borderline range of 40 to 60 mmol/L, and some normal adults could have values of up to 60 mmol/L. In addition, up to 20% of patients with milder disease and pancreatic sufficiency (PS; see later) may have sweat chloride values below 60 mmol/L, but average values even for this group are in the CF range at 85 mmol/L. In cases with borderline or even normal sweat chloride values, genotyping, nasal potential difference measurements, and quantitative pancreatic stimulation tests measuring HCO_3^- secretion are of value in determining the diagnosis.

CFTR is a large gene of 250 kb pairs containing 27 exons and encodes the CFTR protein of 1,480 amino acids. Over 1,200 mutations of the *CFTR* gene have now been described. The most common mutation, a basepair deletion in exon 10 resulting in a deletion of phenylalanine at position 508 on the CFTR protein, ΔF508, affects 66% of the CF chromosomes worldwide.[32] It is most frequent in northern Europeans (70–80%), is less frequent in southern Europeans (50–55%), and affects only a minority of Ashkenazi Jews (30%).[33] CFTR mutations have been categorized into five groups, as summarized in Figure 65.1-4, and are defined below[34]:

- Class I mutations reflect defective protein production, are associated with unstable messenger ribonucleic acid (mRNA), which is rapidly degraded, and involve nonsense, frameshift, and splice junction mutations.
- Class II mutations produce defective processing of the CFTR protein. ΔF508 is in this category, and improper folding of the molecule prevents trafficking to the apical membrane.
- Class III mutations involve defective regulation of the channel. Thus, although CFTR inserts correctly into the apical membrane, the mutation affecting the nucleotide binding fold impairs CFTR function.
- Class IV, mainly missense mutations involving organic residues in the membrane spanning part of the channel, insert normally into the apical membrane but have impaired conduction.
- Class V mutations lead to abnormal splicing of CFTR without alteration of the genomic coding sequence, leading to partial reduction of the normal CFTR protein but normal functional channels.

PANCREATIC DISEASE

In terms of exocrine pancreatic dysfunction in CF, patients are classified as having either PI or PS. PI patients have fat maldigestion and malabsorption as defined by a fecal fat > 7% of fat intake in 3- to 5-day fat balance studies.[35] In contrast, PS patients have normal fat digestion and absorp-

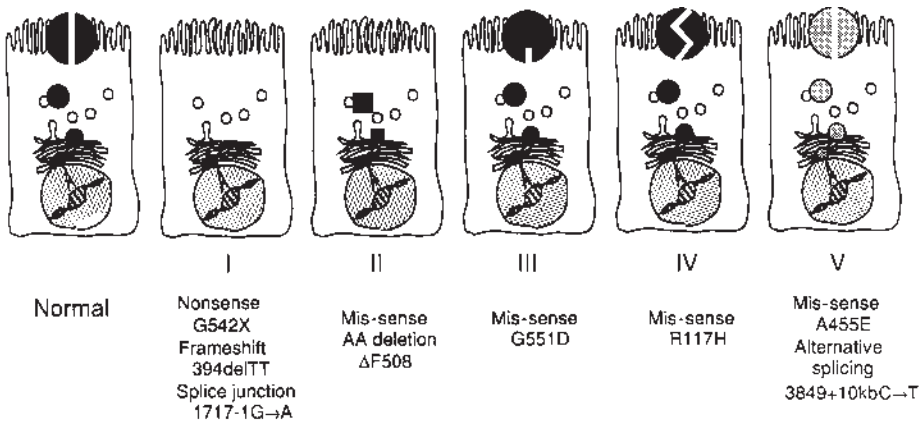

FIGURE 65.1-4 Classification of cystic fibrosis transmembrane conductance regulator (CFTR) mutations in relation to properties of CFTR protein. Class I: defective CFTR protein production: nonsense, frameshift, or aberrant splicing of messenger ribonucleic acid (mRNA); class II: defective CFTR processing: CFTR mRNA is formed, but protein fails to traffic to the cell membrane; class III: defective regulation: CFTR reaches membrane but is not stimulated by cyclic adenosine monophosphate; class IV: defective conduction: CFTR functions, but have altered properties; class V: synthesis defect: less synthesis of CFTR, but channel properties are normal.

tion, with fecal fat ≤ 7 percent of fat intake. Previously, PS patients were defined as having partial PI, partial pancreatic deficiency, or partial or normal exocrine pancreatic function.[36,37] The PS terminology reflects the fact that PS patients have sufficient endogenous pancreatic function to provide normal absorption and is based on pancreatic stimulation test studies in mainly CF patients, comparing pancreatic lipase/colipase secretion with fecal fat excretion,[38,39] as shown in Figure 65.1-5. Colipase secretion rates best delineated normal fat absorbers from those with fat malabsorption, and this is not surprising considering that the degree of lipolytic activity is dependent on the degree of colipase activity.[38] Patients with fat malabsorption had < 1% of average normal colipase activity, but those with normal absorption had a range of colipase secretion that varied from just above 1% up to within the normal control range (as depicted by clear circles in Figure 65.1-5). In large CF populations, 85 to 90% of patients are PI.[40] However, it is readily apparent in populations without newborn screening that patients may present beyond the first year of life with symptoms of malabsorption suggesting that they were PS initially and have lost pancreatic function with time. Studies of infants diagnosed by screening programs have confirmed this occurrence. At the time of neonatal diagnosis, nearly 40% were PS, but within 3 to 5 years, nearly half of these patients had developed PI.[41–43]

The occurrence of either pancreatic phenotype appears to be directly linked to the patient's genotype. In one of the first genotype–phenotype correlation studies, Kerem and colleagues demonstrated that in older CF populations, virtually all ΔF508 homozygotes and 70% of ΔF508 compound heterozygotes were PI, but over 60% of non-ΔF508 compound heterozygotes (who represented 8% of the total population) were PS, as per Table 65.1-1.[44] Subsequently, a number of non-ΔF508 mutations, including R117H and A455E, were demonstrated to be associated with the PS phenotype even if associated with a "severe" mutation (eg, ΔF508), suggesting that the mild PS mutation was dominant.[45] These findings were generally confirmed in a newborn screening population, noting that those who were initially PS and then developed PI had two "severe" mutations, but those with persistent PS had at least one "mild" mutation.[42] In regard to the genotype classification and degree of CFTR dysfunction, as shown in Figure 65.1-4, the vast majority of patients with class I to III mutations are PI, whereas those with class IV and V mutations are PS.

Among PS patients, the phenotype can vary markedly. Some will have obvious lung disease, but others will have minimal or no lung disease. Sweat chlorides may be elevated, borderline (40–60 mmol/L), or even normal, and the latter patients may have only a single mode of presentation (eg, absence of the vas deferens in males or recurrent acute pancreatitis in previously asymptomatic adults who have been subsequently identified with double mutations).[46]

Some of this phenotype variation may be explained by gene modifiers. The R117H mutation is of interest because the polythymidine tract in intron 8 (containing 5, 7, or 9 thymidines) can alter the splicing on exon 9, such that introns with fewer thymidines lead to inefficient splicing and more severe disease.[47]

Pancreatic Insufficiency

In postmortem studies of CF infants dying in the first 4 months of life, there is a marked lack of development of pancreatic acinar tissue.[48,49] Duct luminal volume as a proportion of the total volume exceeds that found in normal subjects, and the ratio of acinar to connective tissue diminishes with age. In premature infants dying from CF, secretory material obstructing pancreatic ducts is an early pathologic feature leading to duct dilatation and progressive atrophy of acinar tissue. Fibrosis can occur early, but in later childhood, patients with PI demonstrate cyst formation, calcification, and, on occasions, a grossly shrunken pancreas. These pathologic changes, which vary with age, have not been correlated with pancreatic function.

Clinical Features. CF infants with PI present with oily stools, and some parents will describe them graphically as looking like melted cheese, butter, or bacon fat. Undigested triglyceride is easily confirmed by stool microscopy

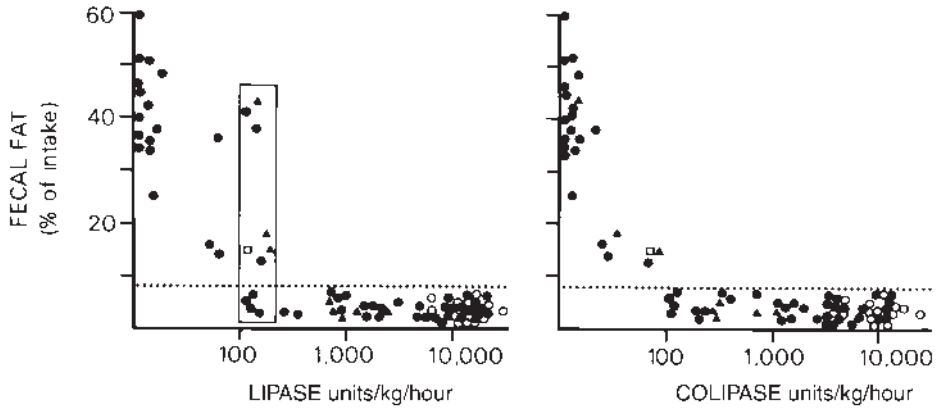

FIGURE 65.1-5 Lipase and colipase secretion rates during pancreatic stimulation with intravenous cholecystokinin and secretin in comparison with fecal fat expressed as a percentage of oral fat intake in 3- to 5-day fat balance studies. Dotted line represents 7% fat excretion. All patients with colipase < 100 U/kg/h have steatorrhea and are pancreatic insufficient, and those with colipase > 100 U/kg/h and normal fat absorption are pancreatic sufficient.

*Percentage of patients with pancreatic insufficiency (PI) or pancreatic sufficiency (PS) in specific genotype groups.

following staining of the specimen with oil red O or Sudan red. Up to 50% of PI patients are hypoalbuminemic with or without peripheral edema at presentation; some may have hemolysis associated with vitamin E deficiency, rectal prolapse, coagulopathy owing to vitamin K deficiency, or even raised intracranial pressure owing to vitamin A deficiency.[50,51] Macronutrient deficiency owing to severe maldigestion and malabsorption, poor feeding, or anorexia with intercurrent illness can be associated with severe failure to thrive, wasting, and even stunting. In nonscreened populations, malnutrition and hypoalbuminemia have been attributed to the lower protein content of breast milk, leading many centers to the recommendation of cessation of breastfeeding following the diagnosis of CF in infancy.

Later presentations during childhood have included patients who develop PI with oily stools and associated vitamin deficiencies, including night blindness associated with vitamin A deficiency. These older patients may have obvious chest symptoms or signs, including clubbing, and some have presented with liver disease. In a sizable proportion of patients, chest symptoms and signs predominate and are responsible for early recognition of the disease.

Diagnosis. In the context of an infant or child with a positive sweat chloride presenting with oily stools, there is little doubt that the patient is PI. However, particularly among infants from newborn screening programs, a history of oily stools may not be forthcoming. Historically, documentation of exocrine pancreatic function status has best been achieved with formal fat balance studies, with PI patients demonstrating, on average, a fecal fat excretion near 40% of fat intake, with variation from 10 to 80%.[35] Formula-fed PI infants will have fat excretions > 10% of fat intake and breastfed PI infants a fecal fat > 2 g/d.[41] In many units, fat balance studies are not undertaken owing to the natural reluctance of collectors and laboratory staff handling fecal material and the risks of contamination and cross-infection. More recently, spot stool analysis for fecal elastase 1 (FE1) has been suggested as a possible alternative, noting that FE1 was very successful in predicting the occurrence of PI.[52] However, some caution is still required with the interpretation of this test because in non-CF adults with chronic pancreatitis with moderate to severe pancreatic dysfunction but with normal fat excretion, approximately 50% registered a near-zero FE1 level, suggesting that they were PI. Moreover, with relevance to units with screening programs, FE1 has not been adequately tested in CF infants.

Treatment. Once PI is diagnosed in a CF infant, treatment should commence with oral enzyme replacement therapy (OERT). Most clinics now use the enteric-coated microspheric OERT preparations that were first marketed in the early 1980s. Prior to that time, OERT preparations consisted of dried pancreatic extract, either in powder, tablet, or capsule form. When ingested, these products were exposed to acid pepsin digestion and thus were mainly ineffective, reducing fecal fat outputs by less than 10%. The microspheric preparations were developed so that the enzyme powder was enclosed in a small bead with a pH-sensitive enteric coating, resistant to acid dissolution but readily dissolved in a pH > 6. In theory, therefore, the microspheres would dissolve only when reaching the upper small intestine. Fat balance studies on CF patients treated with these preparations have consistently shown a marked improvement in average fecal fats in older children and adolescents. Using the standard 5,000 IU capsule, patients receiving 6 to 9 capsules per day had an average fecal fat of 22%,[53] and incremental increases to 25 to 30 capsules per day produced a plateau effect, with average fecal fats between 10 and 15% per day.[54,55] In up to 50% of treated patients, fat excretion decreased to below 10% of fat intake, whereas 5 to 10% treated maintained fecal fats over 20%.[56]

Despite these improvements, during the late 1980s, additional microspheric OERT preparations were marketed containing 10,000 to 25,000 IU of lipase to aid those patients who had persistently high steatorrhea on standard-dose OERT and to reduce the number of capsules consumed by older patients in an effort to improve compliance.[57] These aims were laudable, but many patients were able to self-determine their dose of enzymes; consequently, they were consuming very large doses of lipase, often in excess of 50,000 IU/kg/d. Fat balance studies were not performed to justify these large doses, and as subsequently shown epidemiologically, the introduction of such therapy was coincidental with the emergence of a new complication of CF, namely, fibrosing colonopathy (FC).[58] This complication was a noninflammatory, colonic obstruction associated with marked intramural fibrosis, usually in the ascending or transverse colon.[59] Many patients who developed FC experienced considerable morbidity and required surgical intervention to relieve the obstruction. With doses of lipase in excess of 50,000 IU/kg/d, there is a marked risk of FC; this lessens with decreasing doses, although there is still considerable risk above 20,000 IU/kg/d.[58] Most would recommend keeping the dose below 10,000 IU/kg/d and optimally around 5,000 units/kg/d.

In patients who remain symptomatic on the standard-dose regimen, one should document the degree of steatorrhea. If it exceeds 20%, and the patient is compliant with the dose prescribed, he should be assessed for liver or biliary tract disease, giardiasis, and celiac disease. If such studies are negative, adjunctive therapy using gastric acid suppressants (eg, H_2 receptor antagonists or proton pump inhibitors) should be considered.[54] There are few patients who do not respond to such maneuvers; they may respond better to some of the acid-resistant acid lipases that are under development.

Pancreatic Sufficiency

PS patients comprise 10 to 20% of large CF clinic populations,[40] although, as indicated above, this occurrence is much higher in neonates.[41] In nonscreened populations, they usually present at a later age than PI patients[40] and may have unimodal presentations as adults, with congenital bilateral absence of the vas deferens in males at infertility clinics or recurrent acute pancreatitis. In newborn screening programs using the two-tiered immunoreactive trypsin (IRT) screening strategy, PS infants had IRT values similar to their PI counterparts.[41] However, the more recent strategy using a single IRT test and a ΔF508 mutation analysis will miss non-ΔF508 compound heterozygotes and a proportion of PS patients.[60]

Characteristically, PS patients have a mild disease with minimal pulmonary involvement and encounter nutritional, gut, or liver problems infrequently.[40] *Pseudomonas* lung colonization is reduced compared with PI patients, and the overall prognosis is vastly improved; in the United States, CF median survival of PS patients is 53 years and of PI patients 28 years. It is apparent that persistently PS patients have one or more so-called "mild" mutations, including R117H, A455E, and R347P. They demonstrate impaired Cl^- transport in their sweat, but it is less severe than that of PI patients because they have an average sweat chloride of 86 mmol/L compared with 104 mmol/L in the PI group; they consistently have higher pancreatic HCO_3^- secretion than their PI counterparts.[22] Mild chest disease occurs in 75% of PS patients, 39% have digital clubbing, and 30% have nasal polyps.[40] Interestingly, 4% had rectal prolapse, thus underscoring the validity of obtaining a sweat chloride in every child who presents with rectal prolapse even in the absence of gastrointestinal symptoms. Of equal importance, PS patients develop pancreatitis,[40,46,61] an entity that does not occur in PI patients who have lost their functioning acinar tissue. PS patients do not require enzyme therapy because, by definition, they have sufficient endogenous enzyme production to prevent malabsorption. Equally, they do not require fat-soluble vitamin supplementation. It is imperative for clinics to assess their patients for PS because treating a patient unnecessarily for years is a considerable burden to the child and an unnecessary financial burden to the health care system.

HEPATOBILIARY COMPLICATIONS

A variety of biliary tract and hepatic complications of CF have been described in CF patients, as summarized in Table 65.1-2. They include specific gallbladder diseases, including microgallbladder with or without atretic ducts, dilated or distended gallbladders and cholelithiasis, bile duct diseases with common duct or intrahepatic duct lithiasis, a disease resembling sclerosing cholangitis, and distal common bile duct stenosis. Liver complications include hepatosteatosis and the two forms of fibrotic liver disease considered pathognomonic of CF, namely, focal and multilobular biliary cirrhosis (FBC and MBC, respectively).

Pathologically, gallbladder hypoplasia with or without atretic cystic ducts has been recognized in early childhood.[48] The gallbladder wall contains small epithelial cysts, often distended with eosinophilic material; there is often mucous gland metaplasia and occasionally marked mucosal hyperplasia, but no inflammatory changes. One autopsy study of older patients demonstrated that 14% had calculi.[62] Common bile duct stenosis owing to extrinsic compression of the bile duct has been identified in postmortem specimens of infants, and in one case, the patient was mistakenly diagnosed as having biliary atresia.[63] Liver disease in CF was first recognized by Anderson and was later confirmed by Farber and Bodian.[2,64,65] Farber recognized inspissated material obstructing small bile ductules,[64] and Bodian described the entity of FBC.[65] Later, di Sant'Agnese and Blanc described the severe form of liver disease, MBC.[66] Because patients with MBC also had evidence of FBC, the authors suggested that there was a progression of the focal disease with coalescence and generation of the large nodules characteristic of MBC, as seen in Figure 65.1-6. The focal scarring histologically, as shown in 65.1-7, is associated with fibrosis of portal triads with accompanying inflammatory infiltration, bile ductular hyperplasia, and eosinophilic secretions expanding bile ductules.

Postmortem studies suggest that there is a rising incidence of liver disease with age; FBC is present in 10.6 to 15.6% of infants less than 12 months of age,[48] in 19 to 50% during childhood,[65–67] and in up to 72% of adult CF patients.[68] Similarly, MBC increased from < 1% in early childhood to up to 24% in the above adult postmortem study.[68] In addition to the fibrotic changes, almost 60% of liver specimens showed hepatosteatosis, a finding hitherto unexplained.[69] Currently, the etiology of fibrotic liver disease is also enigmatic. It is likely that the underlying CFTR transport defect impairs fluid secretion from the cholangiolar epithelium,[70] contributing to inspissation of material and obstruction in bile ductules, but it is not clear why some patients develop liver disease and others do not. A distinct possibility is that a gene modifier may influence the operation of CFTR. To date, the presence of liver disease has not correlated with the severity of lung or intestinal disease; it has been described in three patients with PS and no detectable abnormalities in pulmonary function.[71]

It may well be that other entities, including common bile duct disease, distal stenosis, and sclerosing cholangitis, contribute to biliary tract stasis to explain the variable occurrence of liver disease.[69]

Diagnosis

The diagnosis of CF liver disease can be difficult.[72] There is little debate regarding patients with multilobular cirrhosis who have peripheral signs of chronic liver disease, spider nevi, and an obvious multilobulated firm liver, with abdominal distention and signs of portal hypertension, including splenomegaly. Such patients can be recognized clinically and confirmation provided by ultrasonographic examination of the liver. The difficulty comes when attempting to diagnose milder cases who are devoid of physical signs, except perhaps hepatomegaly. Liver function tests may be completely normal, even in subjects with MBC and portal hypertension,[72–74] and ultrasound examinations may demonstrate increased echogenicity of the liver not related to fibrosis but attributable to impacted secretions or the presence of parenchymal steatosis. In addition, although liver biopsy has been touted as being necessary to determine the presence or absence of liver disease, there is considerable sampling error, and biopsies can be normal even in those with MBC.[69] Tests of liver function, including serum bile acids[75] and hepatobiliary scintigraphy,[69] also fail to distinguish between patients with and without liver disease. Ultimately, a combination of findings (clinical, imaging, and biochemical) is used to determine the onset and progression of this complication.

Clinical Presentation

Patients with hepatosteatosis and focal biliary disease are relatively asymptomatic, although in one series, FBC patients had a higher incidence of abdominal pain.[69] Those with multilobular disease may have signs of chronic liver disease, spider nevi, liver palms, abdominal distention, and signs of portal hypertension or ascites. Some may present with esophageal variceal bleeding even prior to diagnosis of CF in late childhood and may have minimal signs of lung disease. The course of those with portal hypertension and splenomegaly is variable, but in my own unpublished series of 28 patients with portal hypertension, 10 experienced variceal bleeding over a 10-year period.

Treatment

Medical management of CF liver disease has centered around supportive measures to provide adequate nutrition, fat-soluble vitamin supplementation, and diuretic therapy for edema and ascites. Ursodeoxycholate therapy was introduced based on the theoretical possibility that it would enhance fluid secretion from the biliary tree. Initial studies were promising, reporting improvements in liver function tests and hepatobiliary scintigraphy,[76,77] but many of the studies contained small numbers of subjects with considerable heterogenicity in their underlying liver disease.[78,79] A recent Cochrane analysis concluded that there was insufficient evidence to justify the routine use of ursodeoxycholate therapy for CF patients and noted the urgent need for a prolonged multicentered collaborative trial with clinically relevant end points.[80]

The management of liver disease with portal hypertension is similar to that for non-CF populations. Patients with variceal bleeding should undergo variceal injection therapy or banding, and in many instances, their bleeding will be well controlled. If sclerotherapy fails, an alternative intervention has to be considered; possibly the best to date has been the use of reversed lienorenal shunts.[81] However, the latter procedure has to be considered in the context of the severity of the lung disease in individual patients. Often the decision is made to proceed based on the urgency of the situation.

Liver transplant is now a viable option for the unusual CF patient with synthetic liver failure or uncontrolled portal hypertension and recurrent variceal hemorrhaging. Data show survivals at least consistent with non-CF liver transplant patients, that is, 70 to 80% survival for the first 5 years post-transplant.[82] Of interest, the decline in pulmonary function was less than expected, a fact possibly related to the anti-inflammatory effects of the antirejection therapy used. Direct contraindication to transplant includes severe pulmonary disease (ie, forced expiratory volume in 1 second [FEV_1] < 50% predicted) and fungal or *Burkholderia cepacia* lung colonization.

NEONATAL LIVER DISEASE

Prolonged neonatal cholestasis occurs in CF infants, but most have considered it to be a rare phenomenon.[83,84] However, in one postmortem study, 10% of infants less than 3 months of age had FBC and 38% demonstrated histologic evidence of cholestasis[48] consistent with a clinical audit in which 35% manifested hepatomegaly/cholestasis in infancy.[72] At first glance, these disparate results are difficult to explain, but, certainly, the postmortem study included very ill septic infants from an era in which neonatal, postsurgical management would be regarded as suboptimal. Moreover, the patients were collected from a wide geographic area for which the true total incidence of CF was unknown. In preliminary results from a newborn screening program over a 14-year interval, 12 of 224 (5%) CF infants developed cholestasis, and 9 of these infants had meconium ileus (MI).[85] Prior to the diagnosis of CF, those presenting with cholestasis and acholia are often considered to have extrahepatic biliary atresia. It is thus imperative that the cholestatic infant has a sweat chloride

FIGURE 65.1-7 Histologic examination of a liver with focal biliary cirrhosis demonstrating fibrosis of portal triad, acute inflammatory cell infiltration, bile ductular hyperplasia, and eosinophilic secretions plugging bile ductules.

test as part of the diagnostic workup because most patients with CF do not have extrahepatic biliary atresia, although they may have prolonged jaundice for periods up to 6 months. Neonatal cholestasis in CF has been linked to MI,[85,86] but others have not found this association.[83]

GALLBLADDER OR BILIARY TRACT DISEASE

Previously, cholelithiasis was a prominent biliary tract complication of CF. With the introduction of microspheric OERT, gallstones have become virtually nonexistent, and at the Sydney clinic we have seen only 3 cases in nearly 700 patients over the last 15 years.

A few patients do experience right-sided abdominal pain unrelated to distal intestinal obstruction syndrome (DIOS); some will be tender in the right upper quadrant. Such patients may have biliary tract disease and require an ultrasound examination to exclude cholelithiasis and hepatobiliary scintigraphy to exclude distal common bile duct stenosis. Cholangiography is required to confirm the latter and may warrant surgical intervention if cholestasis ensues or the pain persists and is interfering with appetite and normal daily activity.[69]

INTESTINAL DISEASE

The gut manifestations of CF as outlined in Table 65.1-3 include esophageal, small intestinal, colonic, and rectal diseases.

Esophageal Disease

There have now been several reports of esophageal disease, particularly gastroesophageal reflux (GER) and esophagitis. One unit reported that up to 25% of patients have GER[87] and another that at least 50% of those with GER will develop esophagitis.[88] Reflux is probably a multifactorial problem contributed to by the severity and treatment of lung disease, drugs that relax the lower esophageal sphincter, and physiotherapy. Delayed gastric emptying may contribute, but the most significant feature to date is intermittent and inappropriate lower esophageal sphincter relaxation.[89]

Patients with GER may complain of heartburn, waterbrash, dysphagia, and regurgitation. Equally common are those patients whose sole symptom is anorexia; thus, patients experiencing weight loss or poor weight gain may have esophageal disease. Investigations should include a barium contrast examination and esophagogastroscopy of the esophagus and stomach, specifically looking for esophagitis, strictures, or a hiatal hernia.

Patients with esophagitis should first be treated with either H_2 receptor antagonists or proton blocking agents. Medical treatment should be prolonged for at least 6 months, and surgery should be considered only as a last resort for those unresponsive to medical therapy.

Gastroduodenal Disease

Peptic ulcer disease was considered a potentially common occurrence in CF, particularly because patients had gastric acid hypersecretion[90] and low pancreatic HCO_3^- secretion.[22] Although ulcers have been anecdotally recorded in the pre-endoscopy era, following the advent of fiberoptic endoscopy, their occurrence has been uncommon. Similarly, *Helicobacter pylori* gastritis is an unusual finding.

Small Intestinal Disease

CFTR has been localized to crypt[91] and villous cells[92,93] in the small intestinal mucosa, and small bowel biopsy specimens from CF patients demonstrate poor Cl^- transport in

response to a number of known CFTR secretagogues.[94,95] Rectal suction biopsy specimens from CF patients demonstrate similarly impaired Cl^- transport,[96,97] which correlates with pancreatic phenotype, that is, samples from PI patients show undetectable transport, but those from PS patients show higher residual Cl^- transport. These findings have led to the proposal that the common small intestinal complications of CF, namely, neonatal MI and DIOS, result directly from impaired electrolyte and fluid secretion and subsequent inspissation of intestinal contents. This scenario is analogous to the genesis of exocrine pancreatic disease, in which poor fluid output leads to hyperconcentration of luminal contents, protein precipitation or aggregation, and subsequent ductular obstruction.[26,98] This hypothesis is supported by findings in the CF mouse model, in which intestinal complications at 12 to 40 days, including obstruction, perforation, fecal peritonitis, and the finding of large intraluminal "putty-like" masses, occur in animals in the absence of significant pancreatic pathology.[99]

In human CF patients, MI and DIOS are virtually exclusive to PI patients and are very rare in PS patients.[100] The CF consortium data furthermore demonstrated that MI occurred in patients with "severe" genotypes associated with PI but did not occur in patients with "mild" mutations associated with PS (eg, R117H).[101] These findings could argue that PI is a critical factor in the genesis of MI and DIOS, but they could equally reflect the severity of the underlying transport disorder in the pancreas and small intestine, as indicated by the correlation of rectal Cl^- transport with pancreatic phenotype. If so, the findings in the mouse model, which appears to have only mild exocrine pancreatic disease, could be reconciled only by the different degrees of expression of CFTR in the wild-type mouse (ie, low in the pancreas but high in the small intestine). However, to date in the small group of CF patients who are PS but have a severe genotype (eg, ΔF508/ΔF508) and poor or undetectable intestinal chloride transport, MI or DIOS has not occurred; thus, the degree of pancreatic function impairment may well contribute to the genesis of these complications.

The lack of alkalinization of intestinal contents as a result of poor pancreatic HCO_3^- secretion in PI patients can lead to protein and phospholipid precipitation in the intestinal lumen. PI patients have poor pancreatic phospholipase secretion; therefore, lecithin will accumulate in the gut lumen.[102] Although hydrolyzed by OERT to lysolecithin, OERT lacks lysolecithinase (carboxyl ester hydrolase)[103]; thus, high concentrations of lysolecithin could accumulate, which is a known hydrophobic compound capable of disrupting epithelial cells. Also, CFTR has intracellular functions that modify the production of mucus glycoproteins.[104,105] The above phenomena, including the Cl^- transport problems, PI and abnormal mucus production, in combination with the known impaired intestinal motility, could all contribute to the production of either MI or DIOS.

Meconium Ileus

Between 10 and 20% of CF neonates will present with small intestinal obstruction owing to inspissation of meconium in the terminal ileum. This phenomenon occurs in utero, and it remains enigmatic as to why only a small proportion of patients develop this complication. Approximately 10% of these cases will suffer perforation in utero and develop meconium peritonitis, an entity recognized by intra-abdominal calcification on abdominal radiographs. Most cases will present with signs of obstruction, including abdominal distention, bilious vomiting, and failure to pass meconium within the first 2 to 48 hours of life. The diagnosis may be suspected if there is a family history of CF but can be distinguished from other forms of neonatal gut obstruction by the lack of air fluid levels in erect or lateral decubitus plain abdominal radiographs (Figure 65.1-8) and a ground-glass appearance to the inspissated meconium. Nearly 50% of cases have complicated MI, in which, in addition to MI, they have malrotation with volvulus or intestinal atresia. Most will have an associated microcolon.

MI is almost invariably associated with CF. Of interest, in neonatally screened populations, the serum immunoreactive trypsin in MI patients can be within the normal range. It is thus important that the screening laboratory is informed of the diagnosis of MI to ensure that they proceed further to the mutational analysis, which would usually be performed only on infants with an initially high IRT value. Only rarely has MI been associated with non-CF conditions, and, to date, it has not been described with the pancreatic hypoplasia in Shwachman syndrome or other forms of childhood pancreatic diseases.

Diagnosis of MI is best achieved with nonionic contrast radiography. In uncomplicated MI, Gastrografin enemas

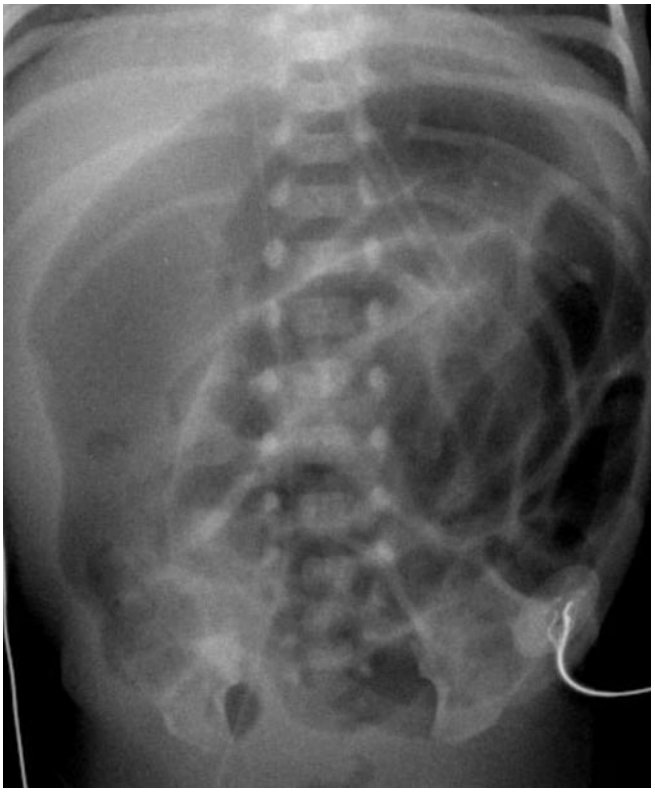

FIGURE 65.1-8 Abdominal radiograph of an infant with meconium ileus. There is marked distention of loops of small intestine without air-fluid levels. The ground-glass appearance of inspissated meconium is evident in the right iliac fossa.

can help elucidate the diagnosis, but because they are hypertonic, it may also be therapeutic in washing out the inspissated meconium. Great care is needed to avoid the perforation, dehydration, and shock associated with the use of the hypertonic enemata. Contrast radiography should be avoided in those with perforation or intra-abdominal calcification. Failure to resolve the obstruction with Gastrografin necessitates surgical intervention. The standard procedure is to milk out the inspissated material following division of the gut and to wash out the residue with saline or solutions containing *N*-acetylcysteine (Mucomyst). Some surgeons prefer the standard Bishop-Koop ileostomy, whereas others prefer a double-barreled ileostomy, and still others use the appendix stump.

Distal Intestinal Obstruction Syndrome

Beyond the neonatal period, a small number of patients present with inspissation of intestinal contents in the terminal ileum, cecum, and proximal colon, a condition hitherto referred to as MI equivalent but now renamed as DIOS. Originally, this syndrome was considered to be more common in adolescents and adults, with an incidence varying from 17 to 24% in two different studies.[106,107] However, these reports were published before microspheric OERT was available, and subsequent studies have suggested a much lower overall incidence of 5%,[108] with some 7.5 cases per 1,000 patient-years occurring in the 15- to 20-year-old age group, increasing to 35.5 cases per 1,000 in the 20 to 25 year olds.

The etiology is unclear, but DIOS rarely occurs in PS patients.[100] Patients present with palpable fecal masses in the right lower quadrant, with or without abdominal pain, or with intestinal obstruction and bilious vomiting. These symptoms and signs are nonspecific and occur also in CF patients presenting with appendiceal or periappendiceal abscesses, purulent mucoceles of the appendix, intussusception, Crohn disease, or colonic strictures. A high degree of suspicion is required when dealing with DIOS, and although fevers and localized peritonism may suggest inflammatory disease, their absence does not exclude these possibilities. Indeed, DIOS can occur simultaneously with appendiceal disease and intussusception, thus adding to the complexity of the diagnosis. The diagnosis of DIOS is initially achieved with plain erect and supine abdominal radiographs. A fecal mass should be evident in the right iliac fossa, and the erect film will help to determine the presence of obstruction. If obstruction is present, one should suspect concomitant pathology such as intussusception or appendiceal disease with an acute history; one should suspect FC, or Crohn disease with a prolonged history. Ultrasound examination is useful in these circumstances and can readily identify intussusception (Figure 65.1-9), as can a computed tomographic (CT) examination (Figure 65.1-10).

In cases of intestinal obstruction or in which washout therapy has failed, Gastrografin enemas may be useful in defining colonic pathology (ie, strictures or intussusception) and relieving impaction in uncomplicated DIOS. Colonoscopy and biopsy will be required for cases in which Crohn disease is suspected radiologically.

Treatment for DIOS has been largely empiric. In simple cases of fecal impaction without obstruction, most respond to a high-dose mineral (paraffin) oil regimen, 30 to 50 mL twice daily over a 7-day period. If the patient does not evacuate, ultrasonography and a diagnostic or therapeutic examination should be performed to exclude intussusception. Thereafter, one should consider using washout therapy with the iso-osmotic colonoscopy preparation fluid Golytely, which contains polyethylene glycol for these oil-resistant cases. Patients may require up to 5 L per 2 to 4 hours to evacuate the mass, and the procedure may need repeating daily if the mass is not completely evacuated.

In DIOS cases with obstruction (ie, with distention and bilious vomiting), it is mandatory to exclude other complications. Once eliminated, washouts per rectum should be attempted, and once the obstruction is relieved, depending on nasogastric tube output, then washout therapy from above can be considered. Persistent obstruction may necessitate diagnostic laparotomy, but this situation is unusual in the absence of intussusception or appendiceal disease.

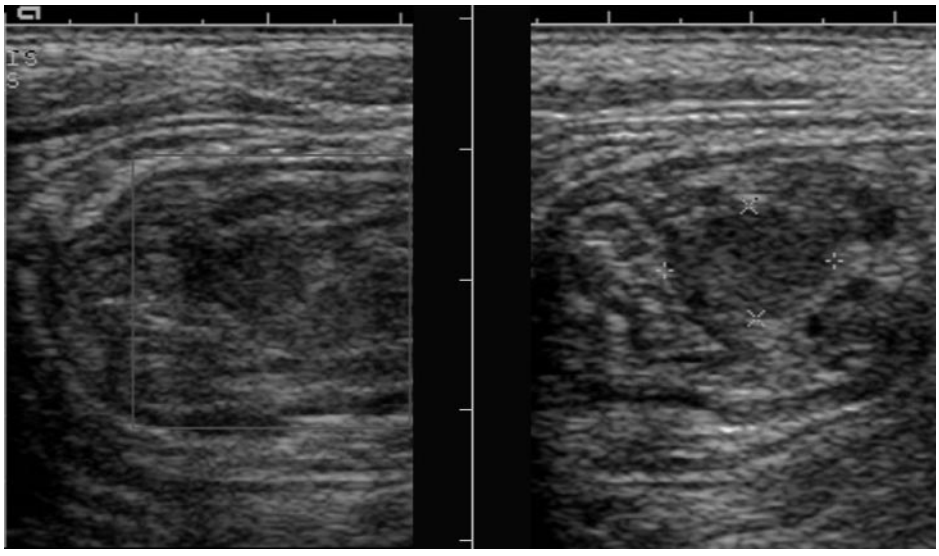

FIGURE 65.1-9 Ultrasound examination of the right lower abdomen in a patient with cystic fibrosis presenting with abdominal distention and a tender abdominal mass. The sonogram demonstrates a multilayered appearance of the intestine, representing the wall of intestine and the wall of the intussusception.

FIGURE 65.1-10 A computed tomographic examination of the abdomen of the patient in Figure 65.1-9, demonstrating the intussusception in the proximal colon.

Recurrent DIOS can be disabling for the CF patient. In such cases, novel therapies, including button placement in the appendix to allow more vigorous washouts, may be required.[109]

Appendiceal Disease

Appendiceal disease, including acute appendicitis,[110] appendiceal abscess,[111] perforation,[111] purulent mucoceles of the appendix, and intussusception of the appendix with rectal bleeding, has been described in CF patients.[112] Although less common than in the non-CF community (1 versus 7%, respectively), the diagnostic delays are of considerable concern in CF, with a high risk of perforation or abscess formation.[111] The cause for delay is unclear but may relate to the presence of a mass lesion that is mistaken for the more common DIOS or to concomitant antibiotic therapy disguising the inflammation. Fever, signs of obstruction, and localized tenderness or peritonism, with or without a tender mass in the right lower quadrant, should alert the physician to this entity, and imaging via ultrasonography or CT is essential to define such a lesion. The physical and radiologic signs may determine whether an operation is required, but the physician's suspicion will ultimately determine such action.

Miscellaneous Small Intestinal Diseases

Giardia infestation,[113] celiac disease, and Crohn disease have all been described in CF populations. Reports of giardiasis in CF are infrequent, but a recent study suggested that *Giardia* infested 28% of CF children and an even higher proportion (44%) of CF adults. These findings require confirmation but are potentially important because ongoing problems with chronic diarrhea are often misinterpreted as a failure to respond to OERT. Similarly, Crohn disease in 1 in 404 CF cases represented a prevalence approximately 11 times that observed in the non-CF control population.[114] Crohn disease should be suspected in cases presenting with abdominal pain, anemia, hypoproteinemia, and extragastrointestinal manifestations (eg, arthritis). Barium contrast imaging may demonstrate the typical segmental cobblestoned appearance, and histologic examination will establish the presence of granulomatous colitis or ileitis. Treatment should be as for non-CF patients.

The coexistence of celiac disease and CF appears to be a rare occurrence.[115] However, given that in some white communities, the incidence is as high as 1 in 75, this entity may be more common than is suspected in the CF population. It should be considered in a CF patient with ongoing symptoms of malabsorption despite compliance with optimal doses of OERT. The need for small bowel biopsy should be governed by positive serum antibody screening, specifically antiendomyseal antibodies or antibodies to tissue transglutaminase. Cases with a positive diagnosis should be managed with a gluten-free diet.

LARGE INTESTINAL DISEASE

Rectal Prolapse

Rectal prolapse (Figure 65.1-11) occurs in 10 to 20% of patients, usually prior to 5 years of age,[116] and may be the presenting feature of the disease.[117] It is far more common in PI patients; its occurrence has been attributed to large bulky stools in wasted patients prior to diagnosis or to ongoing malabsorption in patients following diagnosis. The entity has been described in PS patients[40]; thus, its occurrence cannot be entirely attributed to the presence of malabsorption or malnutrition, although the latter may contribute to the problem. All children presenting with isolated rectal prolapse should have a sweat chloride determination. In most cases, rectal prolapse is a self-resolving problem and requires no specific therapy other than ensuring compliance with OERT and providing laxatives if the patient is constipated. Persistent or recurrent prolapse can be disturbing to patients and their parents. Such patients respond well to pararectal triple saline injection therapy under anesthesia, with complete amelioration of their problems.

Fibrosing Colonopathy

This complication is a relatively new entity described in the early 1990s.[59,118] It is an intramural noninflammatory fibrosing process that affects mainly the proximal colon in CF patients up to early adolescence.[59] Pathologically and clinically, it can be associated with intestinal obstruction and may be preceded by prolonged abdominal pain with or without diarrhea and rectal bleeding. Some may also present with abdominal chylous ascites.[59,119,120]

FC may be diagnosed by imaging with contrast enemas to identify a stricture and proximal obstruction. In some, the diagnosis can be confirmed by colonoscopy and biopsy of the affected area. Surgery is required to relieve the colonic obstruction, and histologic examination of resected specimens will identify the typical elongated fibrotic stricture, which shows minimal inflammation.

Epidemiologically, the entity occurred after the introduction of high-dose lipase OERT and the consumption of large doses of enzyme in excess of 6,000 lipase units per kilogram per meal for periods exceeding 6 months.[59,119,120] Some patients were consuming greater than 50,000 lipase U/kg/d, and it is now recommended that intake does not exceed

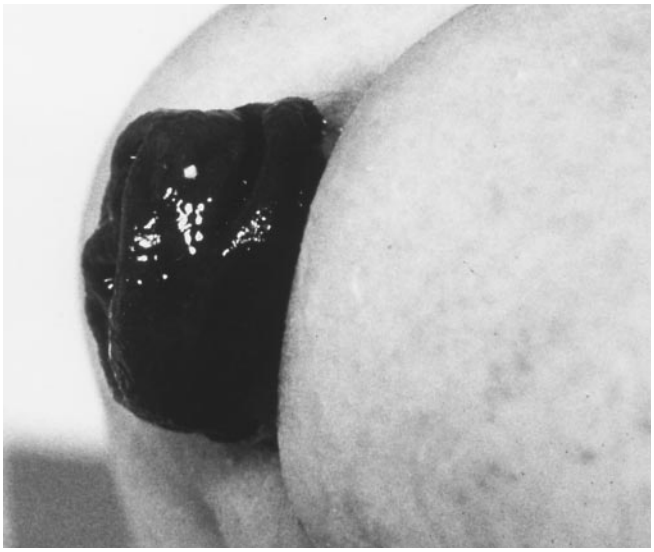

FIGURE 65.1-11 Rectal prolapse.

10,000 lipase U/kg/d or 2,500 U/kg per meal.[59,119] Since the establishment of these guidelines, the incidence of FC has substantially declined. It is important to note that although some have suggested that the entity is related to the differing copolymer content of the microspheric capsule,[121] evidence for this is tenuous because the US survey found a high odds ratio for the occurrence of FC irrespective of the capsule or microtablet used.[58]

Gastrointestinal Malignancy

Gastrointestinal malignancy has been described in adult patients with CF, with 24 cases reported from US and European CF clinic surveys.[122] The majority of cases were large or small intestinal adenocarcinomas, but esophageal, gastric, biliary, and pancreatic malignancies were described. In older CF patients, if confronted with unusual gut symptoms such as anemia, rectal bleeding, or non-DIOS intestinal obstruction, malignant neoplasms need consideration.

NUTRITIONAL PROBLEMS AND THEIR MANAGEMENT

Over the last two decades, nutritional problems have assumed a high priority in the management of CF. At least in part, the nutritional focus arose out of epidemiologic work at the CF Clinic, the Hospital for Sick Children, Toronto, which demonstrated that median survival of near 30 years was considerably better than the median survival of less than 20 years in other Canadian or US clinics.[123] This major difference was a surprising finding because the management of CF pulmonary disease was similar in the major clinics throughout North America. The same study emphasized the near-normal growth of the Toronto patients, except for a decline in weight of adolescent females, and, again, these results appeared superior to those previously published. Later data from Toronto demonstrated normal growth and lung function of their PS patients, and their PI males also had near-normal growth and superior lung function to their PI females, whose weight fell off during adolescence.[40] Apparently, within this one clinic, prognosis and pulmonary function were influenced by nutritional status. Further confirmation of these findings was made following a comparative cohort study between the Boston and Toronto clinics, which demonstrated a 10-year advantage in median survival in the Toronto clinic, despite the fact that comparisons of pulmonary function tests did not demonstrate major differences at the end of adolescence.[124]

Roy and colleagues were the first to allude to a major difference in nutritional management between the Toronto and other clinics, noting that the Toronto patients had been encouraged to consume a high-fat, high-energy diet to replace fecal losses, whereas other clinics had adhered to the universally accepted low-fat diet to avoid the social inconvenience associated with ongoing malabsorption.[125] Dietary analysis demonstrated that whereas, on average, the Toronto patients consumed over 110% of the Recommended Dietary Allowance (RDA) for energy, patients at other clinics were averaging 80 to 90% of the RDA.[126] Later, CF clinics that were changing from a low- to a high-fat diet policy observed that patients consumed over 20% more of the RDA for energy and achieved normal growth, whereas those still adhering to a low-fat, low-energy diet achieved suboptimal weight gain.[127]

Because growth failure with wasting and stunting was common in most clinics, caregivers had adhered to the concept that growth failure was somehow inherent in the underlying disorder in CF. However, the Toronto data disputed this association. Moreover, if inherent in the disease, one would not expect that nutritional rehabilitation would reverse growth failure. To date, a large number of studies have shown that nutritional rehabilitation given by a variety of methods (orally, nasogastric tube, gastrostomy) not only improves weight gain and weight percentiles but also can reverse linear growth failure with achievement of previous or better growth percentiles.[55,128–130]

Pathogenesis of Malnutrition

Protein intakes in CF children are most often very comparable to the high intakes achieved by non-CF children on Western diets of around 200% of RDA, even if a low-fat diet is used.[127] As indicated above, the major adverse effect of a low-fat diet is suboptimal energy intake and subsequent growth impairment. The patient's overall energy deficit can be influenced by other factors, including malabsorption, increased energy needs related to the underlying cellular defect, and to the occurrence of inflammatory lung disease.

Inadequate Energy Intake. Low-fat diets have been one of the main contributing factors to impaired energy intake in CF patients. Fortunately, nowadays most clinics advocate a high-energy normal fat-containing diet, with fat making up nearly 40% of the energy intake. Although, previously, patients on low-fat diets were advised to consume high-energy intakes, this was difficult on the bland high-carbohydrate diets provided. In patients on normal fat-containing diets unable to achieve required intakes for growth, the impaired intake is related to a series of interac-

tive factors, namely, lung disease, drugs given for pulmonary disease, gastrointestinal problems (especially esophagitis), liver or biliary tract disease, long-standing DIOS, and psychoemotional problems. Many of these problems can be managed with medical therapy, but if unsuccessful, invasive nutritional intervention will be required.

Energy Losses. Energy loss occurs via the gastrointestinal tract owing to maldigestion and malabsorption of nutrients. Although 40 to 50% of patients can normalize their fat absorption on optimal regimens of microspheric OERT,[54–56,131] 60% do not, and up to 10% will continue to have fat excretions of over 20% of their fat intake. Again, after investigating such patients for the presence of other complications of CF (eg, gut or liver disease), one may have to empirically treat them with adjunctive gastric acid suppression therapy, attempting to improve the alkalinity of the small intestinal milieu and thereby improve fat digestion and absorption.[54] However, such therapy may not be successful, and larger intakes will be required to avert growth failure.

Energy Expenditure. Several studies of CF patients have demonstrated increased total and/or resting energy expenditure (TEE and REE, respectively).[132–134] In one of the first studies performed, TEE, as measured by the unique doubly labeled water technique, suggested that CF infants had an average TEE that was 25% above age-matched controls.[132] Because they were infants, they were assumed to have minimal lung disease; thus, the increased energy expenditure was attributed to the underlying disease process, in keeping with in vitro studies of CF fibroblasts demonstrating increased oxygen consumption.[135] However, the degree of lung disease in an infant population is difficult to assess; thus, the authors could not conclude that the raised TEE was not in part contributed to by suppurative lung disease. A later study of older patients suggested that REE was negatively correlated with lung function in a quadratic fashion, but this study was in part retrospective.[134] In preliminary results from another center of a large group of patients between 5 and 15 years of age with normal FEV_1 (greater than 80% predicted), PI patients averaged 107% and PS patients 100% of predicted values.[136] At the completion of that study, the latter finding was confirmed, with PI patients maintaining an 11% increase in their average REE ($p < .001$) compared with their PS counterparts, thus indicating that there is an increase in REE related to the underlying severity of the genetic mutation and it occurs independently of the effect of lung dysfunction because these patients had virtually normal lung function.[137] It is of interest that the same study detected a gender difference, with CF females maintaining an average REE of 111% versus 104% for males of their respective control values. This could well explain the noted gender differences in nutritional status and growth and the differences in survival as reported by others.[123]

Malnutrition. In light of the above discussion, it is not surprising that the CF child on a low-fat, low-energy diet consuming only 80% RDA falls well short of the near 110% required for normal growth for a PI child. Furthermore, if the child has had a series of lung infections and ongoing problems with malabsorption, the energy cost of suppuration and lung disease combined with energy losses owing to malabsorption will severely impair the chance of the child even maintaining his/her present growth let alone catching up to previous growth channels.

The consequences of malnutrition in terms of macro- and micronutrients are summarized in Table 65.1-4. Inadequate protein-energy balance is associated with wasting, stunting of linear growth, and, in older children, delayed puberty. Secondary problems occur with abdominal distention, peripheral edema, and ascites with hypoalbuminemia. Fat-soluble vitamin deficiencies can occur at any age and may vary from one age to another. Whereas vitamin A deficiency commonly presents in older children as night blindness, in young infants, it can present as benign intracranial hypertension with a distended fontanel. Vitamin E deficiency often presents as a hemolytic anemia during infancy but later as a severely debilitating neuropathy with ataxia and/or external ophthalmoplegia. Vitamin D deficiency rickets rarely occurs in the hotter subtropical climates but can certainly occur in colder temperate climates, where children are not exposed to sunlight for prolonged periods annually. Overt essential fatty deficiency, which is now seen only in infants at the time of diagnosis, is usually associated with a seborrheic skin rash. A patient on a normal diet supplemented appropriately with OERT should not develop essential fatty acid deficiency.

Malnutrition in CF infants is common where neonatal screening is not operational. Infants present with failure to thrive, wasting, short stature, and/or edema. In the presence of hypoproteinemia, the infants may have a distended fontanel and hemolysis. It is significant that such findings are rare in infants from neonatal screening programs and, if present, are usually subclinical.[41,50] Both controlled and cohort studies of neonatal screening programs demonstrate nutritional and growth advantages in screened infants, although there are limited data supporting an advantage of screening on pulmonary disease and survival.[138,139]

Clinical Evaluation and Management. A summary of a nutritional assessment program is provided in Table 65.1-5. Several other research procedures, including measurement of body cell mass, body protein, and energy expenditure, are undertaken by some units, but they do not have a routine role in the day to day management of CF patients. The major routine assessments, both initially and in follow-up, are measurement of height and weight parameters. In general, maintenance of growth at a specific percentile indicates the well-being of the subject and the adequacy of nutritional intake. Equally, a falling off from a previously held percentile may indicate the inadequacy of oral intake and/or intercurrent problems, particularly chest infection and pulmonary deterioration.

At diagnosis, the other mandatory assessment is an evaluation of pancreatic function, best achieved by a 3- to 5-day fat balance study. Fecal fat values in excess of 10% of fat intake in infants (2 g/d in breastfed infants) or in excess of

TABLE 65.1-4 MALNUTRITION IN PATIENTS WITH CYSTIC FIBROSIS

MACRONUTRIENT DEFICIENCY	
Protein deficiency with hypoalbuminemia	
Edema	
Linear growth failure	
Loss of bone matrix (osteopenia with associated low calcium intake)	
Energy deficiency withweight loss	
Wasting of fat and lean mass	
Wasting of shoulder girdle and buttocks	
Stunting of growth	
Delayed puberty	
MICRONUTRIENT DEFICIENCY	
Fat-soluble vitamin deficiency	
Vitamin A	Benign intracranial hypertension (distention of fontanel in infants)
	Night blindness
	Xerophthalmia: Bitôt spots
Vitamin D	Rickets (rare in sunny climates)
Vitamin E	Hemolytic anemia (infants)
	Peripheral neuropathy
	Ataxia with spinocerebellar tract degeneration
	External ophthalmoplegia
Vitamin K	Coagulopathy
Water-soluble vitamins	Vitamin B_{12} deficiency (rare)
Essential fatty acid deficiency	Seborrheic dermatitis
Salt depletion (hot climates)	Hyponatremia
	If severe, associated with hypochloremia, hypokalemia, and metabolic alkalosis

7% of fat intake in children over 12 months indicate PI and the necessity for OERT. Serum fat-soluble vitamin levels and albumin should be measured at diagnosis and annually thereafter. The normal range of vitamin levels for infants and young children is now available, and, in general, the CF patient should be maintained within that range.[140]

Anthropometric measurements can be repeated at 2- to 3-month clinic visits, and intermittent evaluations of fat absorption may be required in the infant or child with problematic symptoms of steatorrhea. PS patients should have their absorption evaluated at least prior to school entry if asymptomatic and maintaining normal growth or as dictated by the occurrence of symptoms of malabsorption, including failure to maintain their growth percentiles. Given that there are now reports of osteopenia with low bone mineral density in undernourished CF subjects, bone mineral density should be assessed annually in subjects with suboptimal growth.[141] It is also apparent that a large proportion of CF patients (up to 30%) over 10 years of age are glucose intolerant. Although a much smaller percentage is frankly diabetic, some clinics now recommend that a fasting blood glucose be included in the annual evaluation. It remains unclear as to how to approach patients with fasting sugars above 6 mmol/L and whether a 2-hour postprandial serum glucose would be more appropriate. Currently, patients with high fasting or 2-hour postprandial glucose should be referred for evaluation by a diabetologist.

Nutritional recommendations for CF patients are as outlined in Table 65.1-6. Energy intakes should approximate 120% of the RDA but may, of necessity, be increased in patients growing suboptimally. Fat-soluble vitamins should be given on the basis of serum results because a large proportion of subjects can maintain normal levels without supplementation. Vitamin D supplementation is rarely required in sunny climates, where the patient is exposed to ultraviolet light on a daily basis out of doors. Of note, however, those patients from hotter climates require regular salt supplementation during summer months and, to avoid salt depletion and dehydration, at least a doubling of this intake when exercise is undertaken.

Specific Areas of Nutritional Concern

Infants. Recommendations for feeding CF infants have varied over the last 30 years. Prior to microspheric OERT, enzyme replacement was given to infants in the form of enzyme powder. The latter was readily activated in the higher pH of salivary secretions, and, as a consequence, oral inflammation and ulceration were frequent problems. Moreover, the breastfeeding mother experienced excoriated nipples. Both situations, either in isolation or in combination, impaired satisfactory feeding. Consequently, semielemental formula feeds were introduced with the belief that they could be used without enzyme supplementation.[142] Fecal fat analyses purportedly showed normal fat absorption, but, at least in some instances, the analysis technique did not measure medium-chain triglycerides (MCT), and given that many of the diets had high MCT content (up to 80% of fat in the formula), fecal fats were grossly underestimated. The need of OERT to hydrolyze MCT was subsequently demonstrated using the appropriate fecal analytical techniques.[143] Subsequent to the finding that OERT was required for MCT digestion, there appeared little advantage to using semielemental formulas.

TABLE 65.1-5 NUTRITIONAL ASSESSMENT OF PATIENTS WITH CYSTIC FIBROSIS AT DIAGNOSIS

CLINICAL
Height, weight, head circumference
Skinfolds for body fat
Percentile or SD scores thereof
BIOCHEMICAL
Pancreatic function: fecal fat
Serum albumin
Serum fat-soluble vitamin levels
Coagulation screen
FOLLOW-UP
Anthropometric indices (each clinic visit)
Skinfolds (annually)
Bone mineral density (at start of puberty and thereafter as indicated)
BIOCHEMICAL
Fecal fat:
In PS patients suspected of becoming PI
In PI patients for adjustment of OERT
Serum albumin (annually)
Serum fat-soluble vitamins and coagulation screen (annually)
Fasting 2-hour postprandial glucose

OERT = oral enzyme replacement therapy; PI = pancreatic insufficient; PS = pancreatic sufficient.

TABLE 65.1-6 NUTRITIONAL RECOMMENDATIONS IN CYSTIC FIBROSIS PATIENTS

ENERGY	
120% RDA, with 40% as long-chain triglyceride	
PROTEIN	
100% RDA	
FAT-SOLUBLE VITAMINS*	
Vitamin A	5,000 IU/d1–3 yr of age
	10,000 IU/d > 3 yr of age
Vitamin D	500 IU/d
Vitamin E	25 IU/kg/d infants
	100–200 IU/d older children
Vitamin K	5–10 mg, once per week
SALT SUPPLEMENTATION† (hot climates)	
0–6 mo: 0.5 g/d	
6–12 mo: 1 g/d	
1–5 yr: 2 g/d	
> 5 yr: 3–5 g/d	

*Fat-soluble vitamin therapy should be guided by vitamin A and E laboratory results and vitamin K by coagulation screen. Vitamin D is not required in sunny climates.
†Salt intakes should be doubled in hot summer months or during prolonged exercise.

In a subsequent feeding study of infants diagnosed by neonatal screening, a large group of infants achieved and maintained near-normal growth in the first 2 years of life whether breast- or standard milk formula fed.[144] Mothers provided their own choice of feeding at the time of diagnosis, and the subjects were not truly randomized to either regimen. However, in a later randomized study of nonscreened infants, those on standard milk formula achieved near-normal growth parameters.[145] There seems to be no advantage to using expensive semielemental diets in preference to breast milk or standard formula feeding in CF infants provided that the PI patient receives OERT as appropriate.

Adolescents and Adults with Growth Failure and Severe Pulmonary Disease. As respiratory disease advances in CF patients, a vicious circle occurs whereby the chest disease and its management are associated with increasing nutrient requirements in the face of severe anorexia. Weight loss, with loss of lean and muscle tissue, further impairs the likelihood of the subject responding satisfactorily to respiratory therapy, and the cycle continues. Some subjects with less severe pulmonary disease respond readily to high-energy oral supplements, including milk shakes and high-density desserts.[146] However, others with more severe disease are sufficiently anorexic to be unable to comply with these regimens. Consideration should be given in such patients to a more aggressive approach to nutritional intervention, including continuous nocturnal nasogastric tube or gastrostomy button feeds. The severity of the pulmonary disease will often preclude nightly nasogastric intubations, and permanently placed gastrostomy buttons have gained favor over the last decade. These regimens can halt weight loss and, in many instances, can be used to induce catch-up growth. However, the specific advantages of so doing have yet to be realized in terms of overall prognosis. Although initial studies indicated a slowing of the decline in lung function, they were performed on small numbers with mostly reasonably preserved lung function at the start of the studies.[128–130] In patients with advanced lung disease, the benefits are even less obvious; in fact, they may encumber a patient unduly, interfering with the quality of life in the terminal stages of the disease. These issues need to be addressed in patients with severe disease prior to commencement of such therapy, thus preventing discomfort and the emotional challenge in a patient needing palliative therapy only. Some of these patients may be suitable candidates for receiving anabolic agents. Growth hormone can increase height and weight velocity,[147] but as they increase proportionately, patients can remain significantly wasted even after 12 months of therapy. It is also uncertain as to whether the growth changes will be sustained after cessation of the therapy. Similarly, megestrol acetate produces significant improvements in appetite and weight gain, but these are not sustained after cessation of therapy. Although further treatment could be considered, adverse events, including adrenal suppression, insulin resistance, insomnia, hyperactivity, and hypertension, have been described.[148–150]

With the advent of lung transplant, the importance of nutrition needs to be re-evaluated in pre- and post-transplant subjects. Specifically, the physicians involved need to determine whether malnutrition adversely affects transplant outcome and whether the adverse effects can be overcome with nutritional supplementation.

2. *Shwachman-Diamond Syndrome*

Peter R. Durie, MD, FRCPC
Johanna M. Rommens, PhD

In 1964, Shwachman and colleagues and Bodian and colleagues independently described a syndrome predominantly affecting the exocrine pancreas and bone marrow.[1,2] Subsequent reports of larger patient cohorts have demonstrated that the clinical phenotype of Shwachman-Diamond syndrome (SDS) affects additional organ systems, such as the skeleton and liver, and revealed that short stature is also a characteristic feature of the disease.[3–5] Furthermore, the SDS phenotype is extremely heterogeneous, and specific features of the disease change with advancing age.[3,5] After cystic fibrosis (CF), SDS is the most common inherited cause of exocrine pancreatic dysfunction. The disease has an estimated prevalence that is 20 times lower than that of CF, with an approximate incidence of 1 in 50,000 in the North American population. It is known to occur in diverse populations, including those with European, Indian, Chinese, Japanese, North American aboriginal, and African ancestry.

GENETICS

An autosomal mode of inheritance for SDS was initially suggested by the pedigree structure of several family reports[3,6,7] and has been confirmed in formal segregation analysis of a collection of 70 families with corrections for ascertainment considerations.[8] The same collection was then used to initiate investigation into the molecular basis of disease. A genome-wide scan and linkage analysis revealed significant association to disease with markers on chromosome 7 that spanned the centromere.[9] Data from all of the 15 families, each of whom had two or three patients, supported the linkage and confined the location of the affected gene to a 2.7 cM interval. Shared disease haplotypes, consistent with founder disease chromosomes, were identified in additional and unrelated families of common ethnic origins, permitting further refinement of the gene locus to a 1.9 cM interval at 7q11.[10]

Subsequently, an uncharacterized gene containing disease-associated mutations was identified within the 1.9 cM interval.[11] The *SBDS* gene (Shwachman-Bodian-Diamond syndrome) has a 1.6 kb transcript composed of 5 exons, encoding a predicted protein of 250 amino acids (Figure 65.2-1). A pseudogene (*SBDSP*) was identified in a locally duplicated 305 kb genomic segment with 97% nucleotide identity to the disease-causing gene. Gene conversion owing to recombination between *SBDS* and its pseudogene was noted to be a common event in disease alleles. Three common recurring mutations, resulting from conversion of exon 2 segments, introduce changes leading to premature protein truncation. These conversions account for 74% of alleles associated with SDS. Of the unrelated SDS individu-

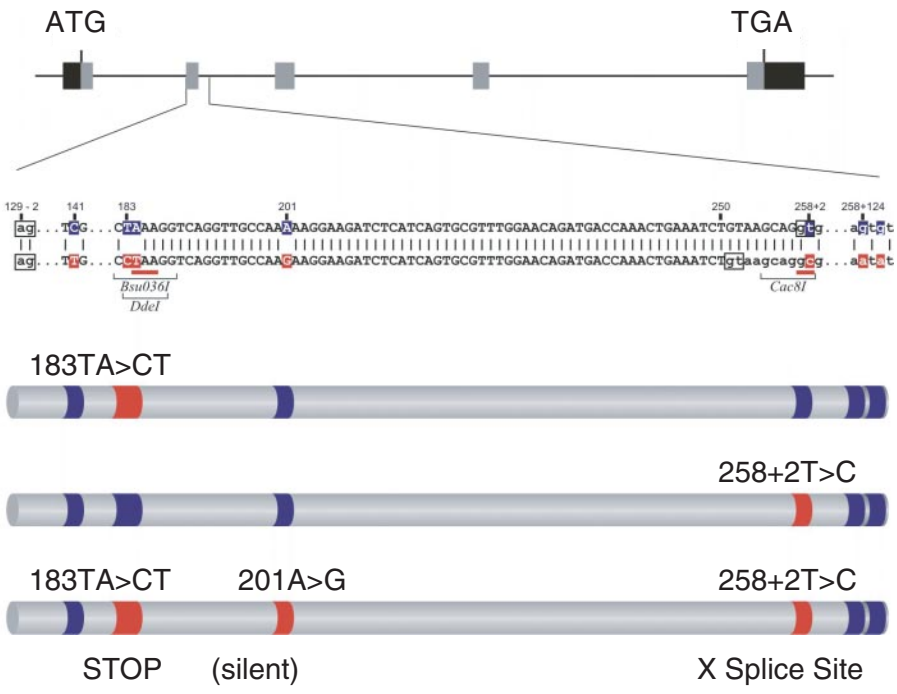

FIGURE 65.2-1 The *SBDS* gene is composed of five exons spanning 7.9 kb. A pseudogene resides in an adjoining duplicated segment. Sequence alignment of exon 2 of *SBDS* and its pseudogene *SBDPS* shows two sequence changes as well as a polymorphic change (201A→G). The most common *SBDS* mutations are derived from gene conversion events between *SBDS* and *SBDPS*. Three converted alleles are shown. These include (1) in-frame stop codon at position 184 (183 TA→CT), (2) splice site change (258+2T→C), and (3) an extended conversion mutation containing both mutant alleles and the polymorphic change.

als, 141 of 158 (89%) carried a gene conversion mutation on one allele and 60% carried conversion mutations on both alleles. Other *SBDS* mutations were identified in patients not involving gene conversion, including nucleotide substitutions leading to splicing interruption, missense changes or nonsense changes, and small deletions or insertions leading to in-frame changes or frame shifting and truncation (Table 65.2-1). These rare mutations were consistent with founder chromosome occurrence; for example, the 119delG mutation was found in two families of French Canadian descent with common haplotypes.[11]

Although the function of *SBDS* is unknown, it appears to be a member of a highly conserved family of proteins. Orthologs of *SBDS* exist in a wide variety of species, including archea, plants, and vertebrates. Ribonucleic acid (RNA) hybridization studies reveal broad but variable levels of expression in all tissues examined to date.[11] The predicted 28.8 kD protein product shows no homology to any known protein, but several lines of indirect evidence suggest that *SBDS* may be important in RNA metabolism.

CLINICAL MANIFESTATIONS

General Features

Based on retrospective analysis of small patient cohorts, affected patients have lower than average weight and height at birth.[12] Although most patients have few signs and symptoms of disease in the early neonatal period, uncommon presentations include asphyxiating thoracic dystrophy, complete bone marrow failure, or severe life-threatening infections. On occasion, poor growth in infancy has raised suspicions and even accusations of parental neglect. We are aware of a tragic example of a 2-year-old girl in whom the diagnosis of SDS was established at postmortem (P. R. Durie, personal observation, 2002). This patient died of bacterial sepsis while in foster care after being removed from her biologic parents' care owing to a presumed diagnosis of "child neglect."

More commonly, patients come to medical attention in infancy or early childhood, with one or more symptoms, which include malabsorption, malnutrition, growth failure, and recurrent infections (Table 65.2-2). Uncommonly, patients present de novo with aplastic anemia or acute myelogenous leukemia. On occasion, patients elude diagnosis until later childhood, and, rarely, the diagnosis is first established in adulthood.[13,14] As is discussed in greater detail below, a large percentage of older patients do not have severe pancreatic disease. Therefore, the absence of signs and symptoms of maldigestion does not exclude a diagnosis of SDS.

The nonspecific nature of the presenting symptoms, as well as poor awareness of the nature of the disease phenotype, can result in a delayed or even an incorrect diagnosis. The median age of diagnosis among 88 internationally ascertained patients was 1 year, with a range of 0.1 to 13 years.[5] In most case series, significantly more males than females have been diagnosed with SDS.[4,5] However, no gender differences were observed among families with more than one affected patient.[5] Given the small size of patient cohorts, the suggestion of a gender difference among isolated cases could be spurious. Alternatively, the contrasting gender differences, among singleton cases but not among multiplex patients, raises the possibility of a societal gender bias favoring clinical evaluation of males with short stature.

Although the clinical manifestations of disease are extremely heterogeneous and may change with age, all patients with SDS appear to have consistent evidence of both hematologic and exocrine pancreatic dysfunction. Other features, such as short stature, hepatic dysfunction, clinical or radiologic evidence of skeletal chondrodysplasia, and dental abnormalities, are sufficiently common to be considered primary features of the disease phenotype. Predilection to recurrent common bacterial infections, such as otitis media, as well as life-threatening deep tissue infections and sepsis, is considered to be a direct consequence of neutropenia and defective neutrophil chemotaxis. More convincing evidence is now emerging that neurologic abnormalities, learning difficulties, and psychological disorders are quite common among individuals with SDS. With further insight into disease pathobiology and evalua-

TABLE 65.2-2 SPECTRUM OF CLINICAL FEATURES OF SHWACHMAN-DIAMOND SYNDROME

EXOCRINE PANCREAS	HEMATOLOGIC	SKELETAL/ DENTAL	GROWTH/ NUTRITION	LIVER	PSYCHOLOGICAL/ NEUROLOGIC
Acinar cell: dysfunction, pancreatic insufficiency, pancreatic sufficiency	Cytopenias: neutropenia, anemia, thrombocytopenia, pancytopenia ↑ Hemoglobin F Marrow aplasia Myelodysplasia Acute myelogenous leukemia	Long bones: delayed maturation, metaphyseal, dysplasia, tubulation Thorax: thoracic, dystrophy, short flared rib, costochondral thickening, clinodactyly, osteopenia Teeth: caries, dysplasia, mouth ulcer	Malnutrition (at diagnosis) Short stature	Hepatomegaly ↑ Aminotransferases Histology: portal inflammation, portal fibrosis	Low intelligence Learning difficulties Pontine leukoencephalopathy

Other: dermatologic; eczema, ichthyosis; renal: anatomic anomalies, tubular dysfunction; cardiac: endocardial fibrosis.

tion of much larger populations, it is likely that other, less common phenotypic features of SDS will be shown to be directly attributable to mutations in the *SBDS* gene.

Exocrine Pancreas

Exocrine pancreatic dysfunction of varying severity appears to be a universal manifestation of SDS. Unlike CF, which is a disorder of pancreatic ductal obstruction,[15] the pancreatic defect in SDS appears to arise from a failure of pancreatic acini to develop. Histologically, the SDS exocrine pancreas shows normal ductular architecture and islets, absent or sparse acinar cells, and extensive fatty replacement (Figure 65.2-2).[2] Cross-sectional imaging may reveal a small shrunken pancreas or pancreatic enlargement owing to lipomatosis (Figure 65.2-3).[16] The suggestion that SDS is a syndrome primarily affecting acinar cells is bolstered by analysis of the results of hormonally stimulated pancreatic function studies, which reveal absent or deficient acinar function (reduced enzyme output) but preserved ductal function.[4,17] The latter is reflected by normal output of anions (chloride and bicarbonate), cations (sodium and potassium), and fluid.

Most infants with SDS have signs and symptoms of fat maldigestion owing to pancreatic failure. Stimulated pancreatic secretions of lipolytic (lipase and colipase) and proteolytic (trypsin) enzymes fall more than 98% below the mean reference values for healthy controls.[17,18] These patients show clinical evidence of steatorrhea owing to pancreatic insufficiency based on correlative evaluation with 72-hour fecal fat balance studies.[4,18] However, cross-sectional and longitudinal evaluation of older SDS patients show that a subset of affected individuals show moderate improvement in pancreatic acinar capacity.[4,5,18] Secretions of lipolytic and proteolytic enzymes are marginally improved in these "pancreatic suffi-

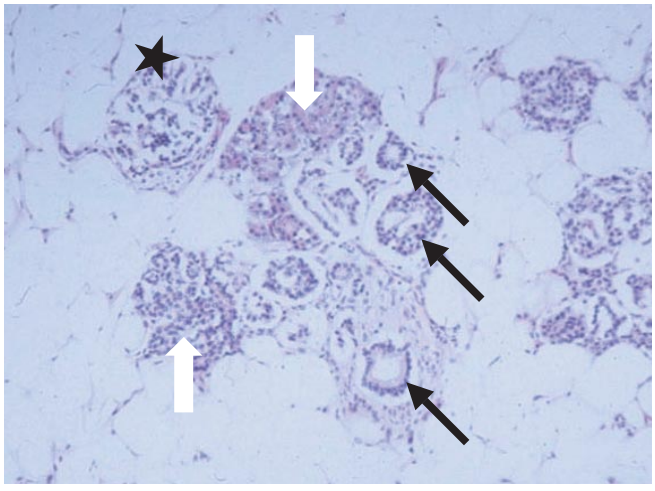

FIGURE 65.2-2 Histologic section of the pancreas from a patient with Shwachman-Diamond syndrome shows few sparse acini (*open arrows* surrounded by extensive areas of fatty replacement). Ductular architecture (*solid arrow*) and islets (*asterisk*) are normal (hematoxylin and eosin, ×50 original magnification).

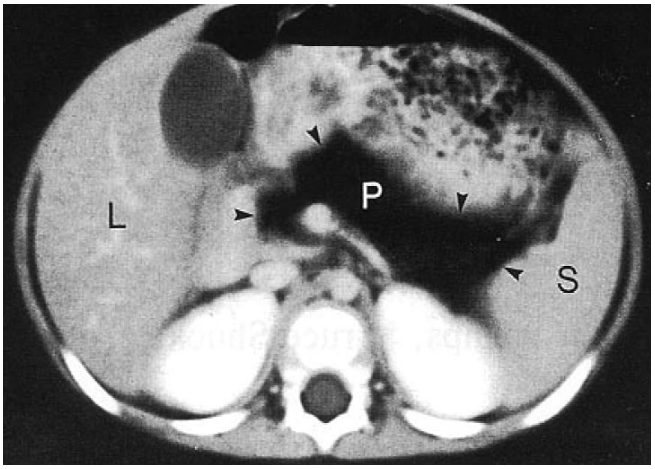

FIGURE 65.2-3 Computed tomographic scan of the abdomen after intravenous contrast injection in a patient with Shwachman-Diamond syndrome. This individual presented clinically with massive hepatomegaly and intermittent neutropenia. Marked fatty infiltration of the exocrine pancreas (P) is outlined with arrowheads. This is in contrast to the soft density of the liver (L) and the spleen (S). Reproduced with permission from Wilschanski M et al.[16]

cient" patients but are sufficient to allow normal endogenous digestion of fat and protein, respectively, without the need for enzyme replacement therapy (Figure 65.2-4). Serial evaluation by 72-hour fecal fat balance studies confirms that stool fat losses, expressed as a percentage of quantified fat intake, normalize with age in this subset of patients.

Similar conclusions have been drawn from cross-sectional and longitudinal analysis of serum cationic trypsinogen concentrations.[4,5] Correlations between serum cationic trypsinogen concentrations and the results of 72-hour fecal fat balance studies (Figure 65.2-5) demonstrate that SDS patients with pancreatic insufficiency have serum enzyme concentrations of less than 6 µg/mL (lower limits of reference range 16.6 µg/mL). In contrast, those with normal fat absorption have serum trypsinogen values exceeding 6 µg/mL. Some of these patients have values within the normal reference range (16.6–45.5 µg/mL).

Taken together, these studies demonstrate that approximately 50% of affected patients will show sufficient improvement in pancreatic acinar capacity with advancing age to no longer require enzyme supplements. However, all of these patients have evidence of pancreatic dysfunction based on quantitative intubation techniques. Therefore, the absence of signs and symptoms of steatorrhea and/or normal serum trypsinogen concentrations does not exclude pancreatic acinar dysfunction or the diagnosis of SDS.

The age-related changes observed for serum trypsinogen do not hold true for other enzymes of pancreatic origin.[19]

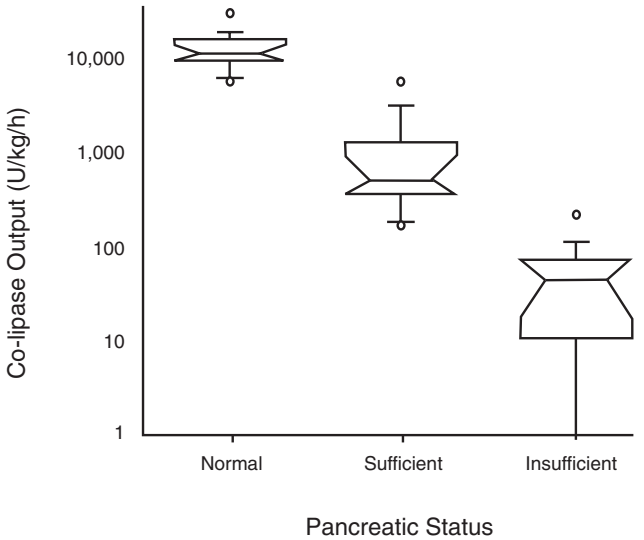

FIGURE 65.2-4 Stimulated exocrine colipase secretion controls, a pancreatic-insufficient patient, and pancreatic-sufficient patients with Shwachman-Diamond syndrome (SDS). The box plots show medians (*middle line*) and 75th (*top line*) and 25th percentiles (*bottom line*). The vertical lines extending above and below each box represent the 90th and 10th percentiles, respectively. Outliers are also shown. SDS patients with pancreatic sufficiency (based on a normal 72-hour fat balance study) have intermediate colipase secretion in comparison with healthy controls and SDS patients with pancreatic insufficiency. Similar results were obtained when total lipase and trypsin output were analyzed (data not shown). Reproduced with permission from Mack DR et al.[4]

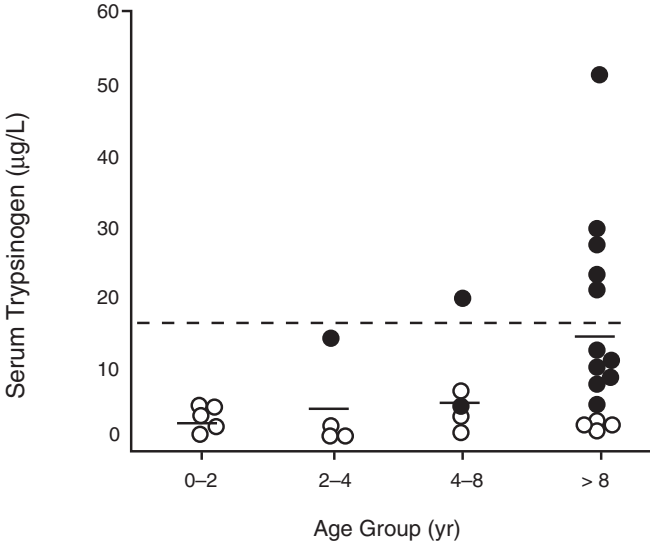

FIGURE 65.2-5 Serum cationic trypsinogen determinations grouped by age, including both pancreatic-insufficient (*open circles*) and pancreatic-sufficient (*closed circles*) patients with Shwachman-Diamond syndrome. The horizontal lines represent the mean value for each subgroup. The horizontal dashed line represents the lower reference limit (16.7 µg/mL for serum trypsinogen). Reproduced with permission from Mack DR et al.[4]

For example, we have observed discordance between serum trypsinogen and pancreatic isoamylase determinations among patients with SDS and similarly aged healthy controls (Figure 65.2-6). In controls, serum trypsinogen concentrations were normal from birth and show no age-related alterations, whereas serum pancreatic isoamylase activities were lower at birth, rising to adult values by 3 years of age. Thereafter, serum pancreatic isoamylase activity remained unchanged with advancing age. We have concluded that the age-related differences of the two pancreatic enzymes mirror their discordant maturation rate postnatally. Pancreatic trypsin synthesis and secretion are mature after birth, whereas pancreatic isoamylase secretion is low at birth and shows gradual maturation over the first 3 years of age. In contrast to the aforementioned observations in controls, all patients with SDS had low pancreatic isoamylase activities irrespective of age, serum trypsinogen level, or their pancreatic status with regard to fat digestion. The independent age-related changes of the two enzymes, which appear to be unique to the pancreas of patients with SDS, have proven to be of great value as a clinical marker of the SDS pancreatic phenotype (see "Establishing a Clinical Diagnosis").

Bone Marrow

All patients with SDS show varying degrees of bone marrow failure. Persistent or intermittent neutropenia is virtually universal among affected patients. Some patients have a variety of other isolated cytopenias involving one or more bone marrow elements,[4,5] which may include pancytopenia and even complete bone marrow failure. The prevalence and range of hematologic abnormalities among singleton cases of SDS are similar to those seen in families with multiply affected children.[5] Furthermore, the fre-

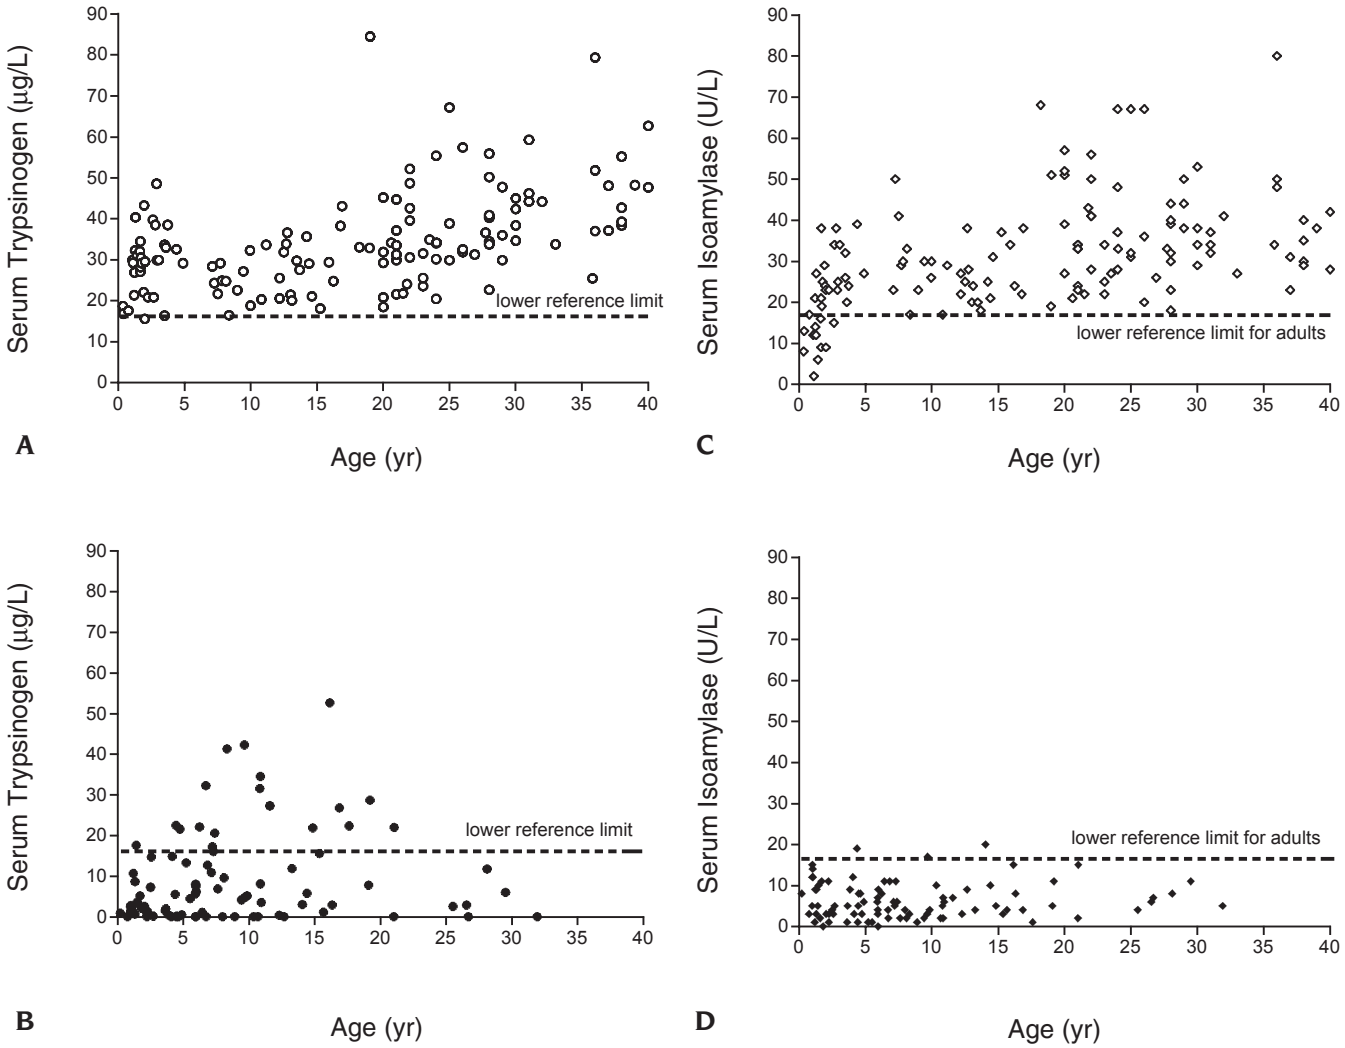

FIGURE 65.2-6 Cross-sectional serum trypsinogen levels in 23 control patients (*open circles*) and 90 patients with Shwachman-Diamond syndrome (SDS) (*closed circles*) plotted as a function of age (*A* and *B*). Twenty-two of 23 patients with SDS who were < 3 years of age showed serum trypsinogen values below the reference range, but values were within the normal range in 20% of older patients. Serum isoamylase values are plotted as a function of age in the same control patients (*open diamonds*) and patients with SDS (*closed diamonds*) (*C* and *D*). Unlike serum trypsinogen, serum isoamylase activities in control patients showed a significant age-dependent rise from birth to 3 years of age. After 3 years, intervals for pancreatic isoamylase (17–80 U/L) were similar to those previously reported for adults. All patients with SDS had low serum isoamylase activities. In 87 of 90 patients, values were below the reference range for adults. However, among patients < 3 years of age with SDS, isoamylase values tended to show overlap with values in similarly aged controls. There was no alteration of serum isoamylase with age in SDS and no association with the corresponding trypsinogen value.

quency and degree of concordance of the various bone marrow–derived cell lines in singleton cases do not differ from those observed in affected siblings.

In the largest patient cohort evaluated to date, 98% of 88 patients had chronic neutropenia, which was intermittent in 61% and persistent in the remaining patients. Iron deficiency anemia (42%) and thrombocytopenia (34%) were the next most common isolated abnormalities.[5] Abnormalities in more than one cell line were common, and pancytopenia was present in 19% of this cohort. The severity of peripheral neutropenia or other cytopenia does not appear to correlate with bone marrow cellularity. Peripheral blood counts do not necessarily predict the onset of myelodysplasia. Persistent elevation of hemoglobin F, which may reflect ineffective erythropoiesis, is present in most patients with SDS.

Neutrophil dysfunction, which is also observed in patients with SDS, almost certainly contributes to the propensity of patients with SDS to suffer from severe life-threatening bacterial infections. Chemotactic migration is significantly impaired, and some reports suggest that neutrophils from SDS patients exhibit defective bactericidal and phagocytic activity.[20–23]

The bone marrow of SDS patients shows reduced numbers of bone marrow precursors, which suggests that the bone marrow disorder is a stem cell defect.[3,24] Using long-term cultures of marrow stromal cells from SDS and unaffected subjects, Dror and Freedman demonstrated that patients with SDS also have dysfunction of the bone marrow stroma.[24] Thus, a dual bone marrow defect, namely a reduced ability of the bone marrow stroma to support and maintain effective hematopoiesis, as well as a stem cell

defect, may explain the severity of the bone marrow defect in patients with SDS.

Bone marrow testing reveals a wide range of abnormalities.[3,5,25] The bone may appear normal in some patients, especially at a young age. The majority of cases show generalized hypocellularity, isolated hypoplasia of single cell lines, or generalized maturation delay or arrest. Complete bone marrow aplasia is known to occur.[26] Myelodysplasia with or without cytogenetic abnormalities is common.[5,27] The most common clonal cytogenetic abnormalities are present in chromosome 7 (eg, monosomy 7, isochromosome 7), but abnormalities are also observed in other chromosomes.[27–29] However, cytogenetic abnormalities, including those involving chromosome 7, may not be directly related to the SDS defect because similar changes are commonly observed in other bone marrow failure syndromes. The prognostic implications of finding myelodysplasia, with or without a clonal abnormality, remain uncertain.

As is the case with most bone marrow failure syndromes, patients with SDS carry a high risk of developing leukemia. The majority of individuals develop acute myelogenous leukemia, but lymphoblastic leukemia has also been reported.[30] The true prevalence of this complication is unknown. Smith and colleagues conducted a retrospective analysis of 21 patients with SDS over a 25-year period.[27] Myelodysplastic syndrome developed in 33% of patients, five of whom developed clonal chromosomal abnormalities. Twenty-five percent of these patients developed acute myeloid leukemia, which was invariably fatal in this series of patients. Males appear to carry a 10-fold greater risk of developing leukemia than affected females.[5,7,28] In general, attempts to induce remission with chemotherapeutic agents have been unsuccessful. Stem cell marrow transplant has been successful in a small number of patients. However, the success rate has been low, with an approximate 50% rate of survival (J. M. Lipton, personal communication, 2003). Also, a high complication rate, including heart and liver failure during induction, remains a concern.

Infections

The presence of neutropenia, abnormal chemotaxis, and possibly neutrophil bactericidal dysfunction function puts patients at risk of severe life-threatening infections.[20–23] The risk of infections may be exacerbated by nonspecific immunologic disorders, including dysgammaglobulinemia and T-cell dysfunction.[31] For poorly understood reasons, infants and young children appear to carry the greatest risk of morbidity and mortality from bacterial infections. Also, younger patients appeared to be particularly susceptible to upper respiratory tract infections and otitis media. In an earlier report, Shmerling and colleagues estimated that patients carried a 25% mortality rate owing to infection.[6] However, a more recent study of 25 patients from our center, who were followed for an average period of 5 years (range 0.5–20 years), showed an 8% mortality rate from infectious complications.[4] However, better survival in this cohort could be due to increased awareness of this complication. Eighty percent of these patients experienced one or more episodes of deep tissue infections, including pneumonia, abscess, osteomyelitis, septic arthritis, or bacterial sepsis. Recurrent fevers of unknown origin are also observed in patients with SDS.[5]

Nutrition and Growth

Short stature, which is common in patients with SDS, is considered to be a primary manifestation of the syndrome. Retrospective analysis of stature at birth shows a moderate deficiency in both height and weight in comparison with healthy newborns.[12] Patients may present with malnutrition at diagnosis.[4] Contributing factors to malnutrition include poor intake owing to recurrent infections and malassimilation of nutrients owing to pancreatic insufficiency. With adequate treatment with an appropriate diet and enzyme replacement therapy, malnutrition is rarely a long-term problem. However, short stature persists, and height and weight remain significantly below the age- and sex-adjusted values for the general population. Approximately 50% of individuals with SDS are below the 3rd percentile for height and weight.[5] Mean z-scores for height and weight are –2.2 and –1.8, below the mean for age and sex, respectively (Table 65.2-3). Cross-sectional studies of growth by age show that height relative to population norms remains the same at all ages. Weight expressed as a percentage of ideal weight for height also remains normal in childhood, but limited data show a tendency for adult patients to become relatively obese. There appear to be no differences in stature or nutritional status between patients with pancreatic sufficiency and those with pancreatic insufficiency.

Skeleton and Dentition

Previous small cohort studies of patients with SDS provide an incomplete picture of the skeletal aspects of the disease.[3–6,32–35] In most studies, only a subset of patients underwent radiologic evaluation, and the lack of longitudinal information failed to provide insight into the natural history of the skeletal abnormalities. Reported abnormalities included abnormal development of growth plates and metaphyses, delayed bone age, progressive deformities, and pathologic fractures. In the perinatal period, severe restrictive respiratory failure can arise as a result of asphyxiating thoracic dystrophy.

More recently, Makitie and colleagues analyzed the radiographs of 15 patients with SDS in whom the diagnosis had been confirmed by identified *SBDS* mutations on both alleles.[36] In 10 of these patients, serial radiographs were avail-

TABLE 65.2-3 GROWTH CHARACTERISTICS OF SHWACHMAN-DIAMOND SYNDROME

AGE (YR)	MEAN HEIGHT (Z-SCORE)	MEAN WEIGHT (Z-SCORE)	MEAN WEIGHT/ IDEAL WEIGHT FOR HEIGHT (%)
0–2	–2.65	–2.62	102
2–4	–2.24	–1.84	107
4–8	–1.84	–1.54	109
8–12	–2.23	–1.45	129
> 12	–2.15	–1.47	119

Adapted from Ginzberg H et al.[5]

able for longitudinal evaluation. The results of this study suggest that skeletal changes are present in all patients with SDS, but there is variable severity and localization changes with age. Typically, infants show delayed appearance of the secondary ossification centers, but epiphyseal maturation tended to improve with age. Varying degrees of widening and irregularities of the metaphyses were common in the ribs and proximal and distal femora in early childhood. With advancing age, a number of patients showed progressive thickening and irregularity of the growth plates (Figure 65.2-7). Most patients with radiologic alterations in the metaphyses showed no clinical symptoms. Some of these irregularities were associated with asymmetric growth and can progress to severe joint deformities, particularly in the proximal and distal femur, as well as the proximal tibia. Slipped femoral epiphyses and coxa vara or coxa valga deformities will require corrective surgery. Abnormal tubulation of the long bones was also observed.

This study also suggested that the right and left limbs were affected similarly, but the legs were more severely affected than the upper limbs. This report also affirmed previous observations that generalized osteopenia may be present at all ages.[3,36] There is no evidence that the osteopenic changes are related to pancreatic insufficiency or to a deficiency of vitamin D. No phenotype-genotype correlations were observed, and patients with identical *SBDS* mutations had a range of skeletal findings.

Several studies have suggested that patients with SDS are prone to oral and dental abnormalities. However, the true prevalence and severity of oral disease await careful prospective evaluation of a larger cohort of patients. Aggett and colleagues identified dental abnormalities in 10 of 21 patients with SDS.[3] Eight of these individuals had extensive caries, and three had dysplastic teeth. Other studies have also identified cases of caries and tooth dysplasia.[4,5] There have been reports of delayed loss of primary dentition and eruption of permanent teeth. Because oral diseases, including oral caries, decay, and periodontal disease, are largely preventable, further insight into the severity and extent of the problem will allow dentists to intervene more appropriately.

Liver

Hepatomegaly is a common observation, especially in infancy.[3,5,16,37] Cross-sectional reports suggest that hepatomegaly resolves in the majority of patients by approximately 5 years of age.[3] Serum aminotransferase values are also elevated in infancy. In a larger cohort series of 88 patients, 60% had abnormal serum aminotransferase levels.[5] In most cases, values were onefold to fourfold above the upper limits of the reference range. Serial data in a subset of these patients showed a tendency for these biochemical hepatic abnormalities to resolve or improve with advancing age. Serum bilirubin levels were consistently normal. Histologic abnormalities are generally quite mild and include micro- and macrovesicular steatosis, periportal and portal inflammation and fibrosis, and, occasionally, bridging fibrosis. Progressive liver disease has not been reported in patients with SDS. There is one case report of chronic liver disease in a patient with SDS.[38] Also, affected patients have reportedly died from hepatocellular failure during induction for bone marrow transplant.

Psychological, Behavioral, and Neurologic Features

Several retrospective case studies,[4,5] clinical observations, and anecdotal expressions of concern from families suggest that individuals with SDS commonly suffer from learning and/or behavioral difficulties. At present, objective testing of patients is limited, and the prevalence and specificity of these deficits require objective prospective evaluation of a larger patient cohort. In the most extensive report to date, Kent and colleagues performed psychometric testing in affected patients, unaffected siblings, and disease controls with CF.[39] They also interviewed the patients' parents to ascertain information regarding developmental milestones, social interactions, and the impact of their child's illness on emotional and social adjustment. Psychometric testing revealed lower intelligence quotients among patients with SDS in comparison with their sibling controls and disease controls suffering from CF. Although group differences with tests of cognition and motor function were not significant, the individuals with SDS

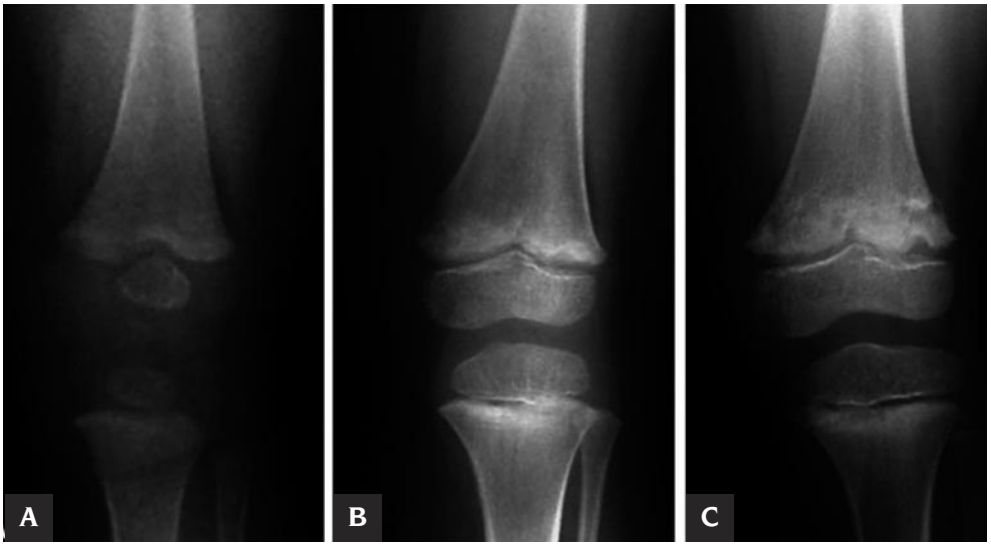

FIGURE 65.2-7 Longitudinal radiologic changes in the knee of a patient with Shwachman-Diamond syndrome. At age 5 months (*A*), secondary ossification centers are small. There is mild metaphyseal widening. At 4 years of age (*B*), secondary ossification centers are normal. The distal femoral and proximal tibial metaphyses are irregular and sclerosed. The metaphyseal changes show more severe irregularity and sclerosis at $5^1/_2$ years of age (*C*). The femoral metaphysis is more severely affected than the tibia. Reproduced with permission from Makitie O et al.[36]

tended to have the lowest scores. In this particular report, the authors found no evidence that individuals with SDS had more behavioral difficulties than the control subjects. Interim analysis of a prospective international study that is being conducted at this center suggests that children with SDS do experience significant cognitive and retention difficulties as well as problems with emotional control.

There have been isolated case reports of specific neurologic abnormalities in both children and adults with SDS.[40,41] In three patients with SDS, focal or multifocal pontine leukoencephalopathy has been identified. Histopathologically, the pons shows lesions within pontocerebellar fibers with central necrosis, calcification, and neuroaxonal spheroids. Frequently, there are extrapontine areas of demyelination. Similar neuropathologic alterations have been recognized in patients with leukemia or lymphoma after radiotherapy or chemotherapy and in immunocompromised patients, including those with human immunodeficiency virus (HIV) or acquired immune deficiency syndrome (AIDS). It is important to note that none of the patients with SDS who developed leukoencephalopathy had evidence of malignancy, nor were they receiving immunosuppressive therapy.

Other Findings

A variety of uncommon abnormalities have been described in patients with SDS. For example, dermatologic abnormalities, including ichthyosis and eczematous lesions, are commonly described in affected patients. There have also been reports of severe endocardial fibrosis, which led to death in a number of patients.[42]

Anatomic abnormalities of the renal system have been reported in individual cases, including double urethra and unilateral nonfunctioning kidney with urethral duplication.[3–5] Nephrocalcinosis and mixed amino acid urea have also been reported.[3–5] Although individual isolated cases of growth hormone deficiency and diabetes mellitus have been described, there is no evidence that these clinical conditions are directly associated with SDS.

ESTABLISHING A CLINICAL DIAGNOSIS

The diagnosis of SDS is established on the basis of characteristic clinical findings. There is no single disease characteristic or a simple biochemical test that is capable of definitively establishing or excluding a diagnosis of SDS. Furthermore, the existence of considerable disease heterogeneity and a lack of medical awareness of SDS make the diagnosis problematic. Other inherited causes of pancreatic exocrine dysfunction, including CF, Pearson bone marrow–pancreas syndrome, and Johansson-Blizzard syndrome, must be excluded. Similarly, transient neutropenia and bone marrow failure syndromes resembling SDS warrant serious consideration as alternative diagnoses. Pearson bone marrow–pancreas syndrome, Fanconi anemia, and Diamond-Blackfan anemia can be excluded by careful clinical assessment, bone marrow analysis, and/or specific laboratory tests.

With appropriate knowledge of the spectrum of the disease phenotype, the clinical diagnosis of SDS can be objectively established or excluded with a high degree of certainty in the vast majority of patients. Two clinical features of the disease, notably exocrine pancreatic and bone marrow dysfunction, appear to be consistently observed in all patients. Therefore, objective confirmation of these two phenotypic manifestation is currently considered to be an absolute requirement for establishing a clinical diagnosis.[5,43]

Pancreatic exocrine dysfunction may be identified by one or more of the following evaluations:

1. Deficit of pancreatic enzyme secretion following quantitative pancreatic stimulation testing with intravenous cholecystokinin and secretin
2. Abnormal 72-hour fat balance study (provided intestinal mucosal disease or cholestatic liver disease is excluded) plus pancreatic imaging demonstrating a small or lipomatous pancreas
3. Low serum trypsinogen in patients under 3 years of age; low serum trypsinogen or pancreatic isoamylase in patients older than 3 years of age[19]

Bone marrow dysfunction may be established by one or more of the following evaluations:

1. Neutropenia (absolute neutrophil count < 1,500 neutrophils/mm^3). Because neutropenia can be persistent, cyclic, or intermittent, it must be documented at multiple time points (at least three times over a period of 3 months or more).
2. Anemia (hemoglobin concentration below the age-related normal range)
3. Persistent thrombocytopenia (platelet count < 150,000 platelets/mm^3)
4. Persistent pancytopenia
5. Myelodysplasia with or without clonal abnormalities

Genetic analysis may be used for diagnostic confirmation. Clinical genotyping for SDS is now available in clinical molecular diagnostic laboratories in the United States, United Kingdom, and Italy, as well as at the Hospital for Sick Children, Toronto.

Other common primary features of SDS are used to provide supportive evidence of the diagnosis of SDS. These include short stature, skeletal abnormalities, and hepatomegaly with or without elevation of serum aminotransferase levels. The absence of these features does not exclude the diagnosis of SDS. Because short stature occurs in a wide variety of other conditions and is not observed in all patients with SDS, it cannot be relied on as a feature of the disease for diagnostic purposes.

BASELINE ASSESSMENT, MONITORING, AND THERAPY

Diagnostic Assessment

The basic diagnostic evaluation of patients suspected of SDS has been outlined above. Additional baseline investigations, which are summarized in Table 65.2-4, include assessment of the status of the patient's pancreas, liver, skeleton, and bone marrow. Careful nutritional evaluation should include height, weight, anthropometry, deter-

mination of serum fat-soluble vitamin levels (A, E, 25-hydroxyvitamin D), prothrombin time, and partial thromboplastin time. Baseline bone marrow biopsy should include evaluation for evidence of cytogenetic abnormalities.

We advocate a multidisciplinary approach to the assessment, education, and treatment of the patient and family. Optimally, this should include ongoing support by a hematologist and gastroenterologist with adequate knowledge of the natural history of SDS. Depending on the family's circumstances and patient's condition, the assistance of a genetic counselor, psychologist, and/or social worker may be required. A dietitian who is familiar with nutritional care and pancreatic enzyme replacement therapy of patients with pancreatic failure should provide ongoing education and monitoring for the patient and family.

Clinical Monitoring and Therapy

The assessment should be performed every 6 to 12 months and should include weight, height, anthropometric measures, bone age, pubertal development, and review of developmental progress. A complete blood count with white cell differential and platelet count should be performed every 6 months or more frequently if indicated. We recommend that serum concentrations of vitamins A, E, and 25-hydroxyvitamin D; prothrombin time; and partial thromboplastin time be performed every 6 to 12 months.

Because a significant percentage of patients suffer from skeletal and dental disorders, anticipatory monitoring is advocated. With respect to the skeleton, we recommend radiographs of the hips and lower limbs every 1 to 2 years and, when indicated, consultation by an orthopedic surgeon with experience in chondrodysplastic disorders. Parents should be advised to seek dental evaluation at an early age, and the patient's dentist should be provided with information concerning the increased risk of oral or dental disorders in patients with SDS.

Steatorrhea may resolve with advancing age, even though pancreatic enzyme secretion remains well below normal levels. In our experience, this usually occurs within the first 4 years of life.[4] Thus, periodic reassessment for evidence of maldigestion is recommended. Monitoring can be conducted by serial measurements of serum trypsinogen concentrations. Fat absorption should be assessed using a quantitative 72-hour fecal fat analysis after the individual has discontinued enzyme supplementation for at least 24 hours. At present, there is inadequate information concerning the specificity and sensitivity of the fecal elastase 2 test for assessing pancreatic function in patients with SDS.[44]

If nutrient maldigestion is identified, pancreatic enzyme replacement therapy is required. The need for fat-soluble vitamin supplements should be determined on an individual basis. Most reports of patient cohorts indicate that patients achieve normal nutritional status with therapy. In our experience, patients with SDS respond well to enzyme therapy. The same dosing range should be used as for patients with CF.[45] There is no recommended therapy for short stature. Growth velocity is usually normal, and, with rare exceptions, growth hormone levels are normal. Pubertal progress may be delayed.

Although there is no objective evidence to support the practice, experts in bone marrow failure syndromes recommend that bone marrow aspirates, biopsies, and cytogenetic studies be performed annually. They recommend more frequent evaluation if myelodysplastic or cytogenetic abnormalities are noted. These recommendations are based on the unproven assumption that anticipatory information concerning early bone marrow changes will yield a beneficial outcome to the patient.

If a patient is experiencing repeated infections in association with severe neutropenia (absolute neutrophil count < 500/mm^3), treatment with prophylactic antibiotics and/or granulocyte colony-stimulating factor (G-CSF) should be considered. There are concerns that long-term administration of G-CSF to patients with severe chronic neutropenia may increase leukemogenic risk. Although this potential risk of long-term G-CSF has not been clearly elucidated, some caregivers recommend limiting G-CSF therapy to short-term administration when a patient develops fever and/or an infection.

TABLE 65.2-4 ASSESSMENT AT DIAGNOSIS

Diagnosis*
Clinical confirmation of SDS by excluding other causes of pancreatic dysfunction and bone marrow failure
PLUS
Objective confirmation of pancreatic dysfunction
AND
Bone marrow failure
Baseline assessment
Imaging
Imaging of liver and pancreas (ultrasonography, CT, or MRI)
Skeletal survey
Bone age (older patients only)
Blood
CBC, differential, platelets; hemoglobin electrophoresis
Total and direct bilirubin, aminotransferases, alkaline phosphatase
Serum vitamins A, E, D (25-hydroxyvitamin D)
Prothrombin time, partial thromboplastin time
Serum trypsinogen and pancreatic isoamylase
Bone marrow
Aspirate
Biopsy
Cytogenetic analysis
Stool
72-Hour fecal fat balance study

CBC = complete blood count; CT = computed tomography; MRI = magnetic resonance imaging; SDS = Shwachman-Diamond syndrome.
*Genotyping may be considered for confirming the diagnosis.

3. Other Hereditary and Acquired Disorders

Michael Wilschanski, MD

A number of rare hereditary and acquired disorders of the exocrine pancreas, apart from cystic fibrosis and Shwachman-Diamond syndrome, are discussed in this chapter.

HEREDITARY DISORDERS

Pearson Marrow-Pancreas Syndrome

This syndrome was originally described in 1979 in four unrelated children with severe macrocytic anemia, variable neutropenia and thrombocytopenia, vacuolization of bone marrow precursors, and ringed sideroblasts in the bone marrow. Pancreatic insufficiency was subsequently diagnosed associated with extensive fibrosis and acinar atrophy.[1] The bone marrow changes, including cell vacuolization and the presence of ringed sideroblasts, distinguished this condition from Shwachman-Diamond syndrome. Other differences include the presence of pancreatic fibrosis rather than lipomatosis and the absence of bone lesions. It has been shown recently that this disease results from defective oxidative phosphorylation and is associated with deletions of mitochondrial deoxyribonucleic acid (DNA).[2,3] Of the respiratory chain enzymes encoded by mitochondrial DNA, complex I is the most severely affected. Genes encompassing two subunits of complex V, one subunit of complex IV, and five transfer ribonucleic acid genes are also deleted. Oxidation of reduced nicotinamide adenine dinucleotide is abnormal in lymphocytes from these patients, but respiratory chain enzyme activities are normal in muscle mitochondria. In severely affected tissues such as bone marrow, neutrophils, lymphocytes, and pancreas, the deletions are found in over 80% of cells, whereas deletions were observed in only 50% of muscle cells. Thus, expression of the phenotype in Pearson marrow-pancreas syndrome in a given tissue may require a minimum threshold number of mutated mitochondrial DNA molecules. However, in the largest series published to date, Rotig and colleagues reported that the size and location of the mitochondrial DNA rearrangements in 21 patients did not correlate with clinical severity.[4] Interestingly, some of these patients may develop visual and muscular symptoms, which are also found in Kearns-Sayre syndrome, a mitochondrial disease characterized by a large mitochondrial DNA deletion.[5]

Johanson-Blizzard Syndrome

Johanson and Blizzard first described this syndrome whose features include pancreatic exocrine deficiency, aplasia or hypoplasia of the alae nasi, congenital deafness, hypothyroidism, developmental delay, short stature, ectodermal scalp defects, absence of permanent teeth, urogenital malformations, and imperforate anus.[6,7] More recently, other associated features were noted, including hypopituitarism,[8] diabetes mellitus,[9] growth hormone deficiency,[10] and congenital heart disease.[11] Prenatal ultrasonographic diagnosis has also recently been described.[12] The genetic defect is unknown, but the pathophysiologic basis of the pancreatic abnormality has been elucidated. Jones and colleagues performed pancreatic stimulation tests on two patients and found that the ductular output of fluid and electrolytes was preserved with decreased secretion of trypsin, colipase, and total lipase and low serum immunoreactive trypsinogen level.[13] These findings are consistent with a primary failure of pancreatic acinar development similar to that observed in patients with Shwachman-Diamond syndrome.[13] The functional exocrine disturbances are in keeping with histopathologic findings, which include absence of pancreatic acini.[14] Unlike Shwachman-Diamond syndrome, bone marrow and skeletal abnormalities are absent in Johanson-Blizzard syndrome.

Jeune Syndrome

This is a rare autosomal recessive disorder characterized by skeletal abnormalities of the thorax and extremities and nephronophthisis and is usually associated with respiratory distress in infancy. Karjoo and colleagues reported two families with asphyxiating thoracic dystrophy with exocrine pancreatic deficiency.[15] There is also one case report of pancreatic fibrosis.[16] Prenatal diagnosis has been reported.[17]

Isolated Enzyme Deficiencies

The deficiencies of the pancreatic enzymes and mucosal enterokinase are very rare but have provided insight into the physiology of digestion and the sequelae resulting from their deficiency.

Lipase Deficiency

Pancreatic lipase is involved in the essential hydrolysis of long-chain dietary triglycerides to fatty acids in the intestinal lumen. The patients present with severe steatorrhea in infancy or early childhood, but despite the maldigestion of dietary fat, failure to thrive is not a feature. It has been suggested that alternative sources of lipolytic activity prevent failure to thrive.[18] Analysis of duodenal juice revealed absent or low lipase activity and, in some cases, low amy-

lase and trypsin as well. Sheldon described this disorder in two unrelated sibships,[19] suggesting an autosomal recessive mode of inheritance. The complementary DNA encoding pancreatic lipase has been cloned[20] and the gene mapped to chromosome 10q24-q26.[21] These children respond well to exogenous pancreatic enzyme supplementation.

Colipase Deficiency

Pancreatic colipase is a cofactor that is involved in overcoming the inhibitory effects of bile salts on pancreatic lipase. Deficiency of this enzyme has been reported in two brothers, aged 5 and 6 years, and is not associated with failure to thrive.[22]

Combined Lipase–Colipase Deficiency

Ghishan and colleagues reported a patient with < 2% of control values for lipase and colipase but normal concentrations of other pancreatic enzymes.[23] Ligumsky and colleagues reported congenital combined lipase and colipase deficiency in two brothers.[24]

Amylase Deficiency

An abnormally low pancreatic amylase concentration below the age of 1 year may be physiologic; thus, the existence of amylase deficiency at this age may be developmentally related. Lowe and May reported a 13-year-old boy with absent amylase, diminished trypsin, and normal lipase concentrations.[25] Brock and Sjolund and their colleagues have reported familial selective deficiency of pancreatic amylase.[26,27] Because low serum pancreatic isoamylase has been observed in patients with Shwachman-Diamond syndrome who have normal fat digestion, this diagnosis should be considered in patients with isolated isoamylase deficiency.[28]

Trypsinogen Deficiency

There have been a few cases reported of this syndrome, which presents as severe malabsorption beginning in the neonatal period. Proteolytic enzyme activity was absent in the duodenal fluid but normalized with the addition of exogenous trypsin.[29] Normally, intestinal enterokinase activates trypsinogen, which, in turn, activates the other proenzymes. Hence, trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase are activated to trypsin, chymotrypsin, carboxypeptidase, and elastase, respectively. Trypsinogen deficiency results in the disruption of the activation casacade because there is a lack of substrate for enterokinase. The trypsinogen gene is found on chromosome 7 and has caused renewed interest because a mutation in this gene causes hereditary pancreatitis, which is discussed elsewhere.[30]

Enterokinase Deficiency

Enterokinase (enteropeptidase) is an intestinal mucosal enzyme responsible for initiating the activation of pancreatic proteolytic proenzymes. It catalyzes the conversion of trypsinogen to trypsin, which, in turn, activates other proenzymes, including chymotrypsinogen, procarboxypeptidases, and proelastase.[31] The first case of congenital enterokinase deficiency was reported in 1969,[32] and several cases have since been documented.[33] These children present in the neonatal period with diarrhea, failure to thrive, edema, and hypoproteinemia. The diagnosis was confirmed by absent trypsin activity in duodenal fluid, which then became active following exogenous addition of enterokinase. Further confirmation of an isolated enterokinase deficiency was the finding of minimal enterokinase activity in the duodenal mucosa in the presence of normal disaccharidase activities. Fat malabsorption was present despite normal amylase and lipase concentrations in unstimulated duodenal fluid because trypsin is required for the activation of colipase and phospholipase. The patients respond well to pancreatic enzyme supplementation, which generates normal duodenal proteolytic activity. This disorder has been reported in siblings, suggesting an autosomal recessive mode of inheritance. Kitamoto and colleagues have cloned the complete complementary DNA that encodes the enterokinase amino acid sequence and mapped the gene to chromosome 21q21.[34]

ACQUIRED DISORDERS

Malnutrition

Protein-calorie malnutrition has a significant effect on pancreatic exocrine function.[35] Studies on children with kwashiorkor have shown a generalized reduction in pancreatic size and histologic evidence of acinar atrophy. Disorganization and loss of acinar pattern were noted with little evidence of inflammation or necrosis. Acinar cells were vacuolated, and the number of zymogen granules was diminished. In more severe cases, varying degrees of fibrosis and fat accumulation were observed.[36] Functional changes in the pancreas closely resemble the structural abnormalities. Barbezat and Hansen performed pancreatic stimulation tests in children with protein-calorie malnutrition.[37] There was a reduction in enzyme output in response to hormonal stimulation, but the volume output and alkalinization of the duodenal fluid were not affected. This is consistent with the histologic observation of ductal preservation, which is the source of water and bicarbonate secretion. Prompt improvement of enzyme secretion was observed with nutritional rehabilitation, although two patients had consistently low enzyme secretion.[37]

Biochemically, acute malnutrition in children has been associated with elevated cationic trypsinogen levels, which are correlated with the severity of the malnutrition.[38] However, persistently low immunoreactive trypsin levels are found in chronically malnourished children.[39] These studies suggest that in acute malnutrition, there is abnormal pancreatic cell membrane function with leakage of zymogen into the circulation, but more chronic malnutrition is associated with extensive pancreatic acinar cell atrophy and diffuse fibrosis, thus producing low trypsinogen levels. Juvenile tropical pancreatitis and its possible association with malnutrition are discussed in Chapter 64.2, "Juvenile Tropical Pancreatitis."

Surgical Resection

Exocrine pancreatic function after surgical resection has rarely been studied in children, but even with 95% pancre-

atic resection for nesidioblastosis, few develop malabsorption. Studies of pancreatic lipase and colipase secretion in children have demonstrated that malabsorption occurs only when values fall below 2% and 1% of mean normal values, respectively[40]; thus, it is not surprising that large pancreatic resections may not induce malabsorption. The necessity for pancreatic enzyme supplementation in these patients can be determined by fat balance studies.

Celiac Disease

Exocrine pancreatic dysfunction has been recognized in both children[41] and adults[42] with celiac disease. The degree of pancreatic impairment is variable, and its etiology is unclear. Some patients have primary pancreatic dysfunction, as evidenced by impaired release of pancreatic bicarbonate and enzymes into the duodenum in response to exogenous stimulation with intravenous cholecystokinin and secretin.[43] However, others have intact pancreatic function in response to exogenous stimulation but an impaired response to stimulation with liquid test meals.[44] This finding is consistent with impaired release of endogenous cholecystokinin and secretin, a concept supported by the demonstration of low serum secretin levels in response to duodenal perfusion of citric acid in untreated patients with celiac disease and normal levels after recovery of the intestinal lesion.[45] Impaired secretagogue release in untreated patients may explain the poor postprandial gallbladder emptying and diminished duodenal bile acid concentrations that, together with the impaired pancreatic enzyme release, contribute to the presence of fat maldigestion.

Carroccio and colleagues evaluated pancreatic function using fecal chymotrypsin levels at diagnosis of celiac disease.[46] They showed a lower weight increase in patients with initial low fecal chymotrypsin levels than in patients with normal chymotrypsin values. They suggested that there is a subset of patients who would benefit from pancreatic enzyme supplementation for a few months until pancreatic function returns to normal.[46] However, it is still unclear if indirect stool tests of pancreatic function can safely distinguish intestinal from pancreatic steatorrhea.

At the other extreme, profound, irreversible pancreatic insufficiency with acinar atrophy and fibrosis rarely occurs in celiac disease, but it has been reported.[47] The lesion may be related to chronic understimulation of the pancreas because of impaired endogenous secretagogue release and subsequent induction of pancreatic cell atrophy, which may be aggravated by malnutrition. In these cases, the coexistence of celiac disease and cystic fibrosis deserves consideration.[48] These patients may even have falsely pathologic sweat chloride concentrations owing to malnutrition, and personal experience suggests that mutation analysis and nasal potential difference measurements[49] may need to be performed.

CHAPTER 66

STUDY DESIGN

1. Outcomes Research on Diagnostic and Therapeutic Procedures

Jenifer R. Lightdale, MD, MPH
Donald Goldmann, MD

Outcomes research is the systematic study of clinical practice with a focus on clinical effectiveness and patient-centered outcomes.[1] It is designed to measure the consequences of providing medical care to determine whether and to what extent such care is beneficial. As broadly defined by the American Gastroenterological Association, outcomes research encompasses studies of (1) clinical and physiologic effects of a given medical product, procedure, or technology; (2) patient-centered end points, such as health-related quality of life (HRQOL), functional status, and patient satisfaction; and (3) medical costs relative to benefits and risks.[2] The purpose of this chapter is to provide an overview of outcomes research, highlighted by examples and pertinent studies in pediatric gastroenterology.

In recent years, outcomes research has received tremendous attention not only within the clinical research world but also from legislators and the general public. In the wake of considerable momentum over the past decade toward advancing the quality of health care, the Institute of Medicine (IOM) released its comprehensive *Crossing the Quality Chasm: A New Health System for the 21st Century* report in 2001.[3] This report highlights the importance of studying health care processes to improve medical outcomes. The IOM defines quality as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[4] Outcomes research provides an important tool for amassing evidence that quality health care is being provided.

Donabedian, an early proponent of using research to advance the quality of medical care, has described a triad of (1) structure, or the characteristics of a health care setting; (2) process, or what is done to patients; and (3) outcomes, or how patients do after health care is provided.[5] His emphasis on understanding and enhancing the process of providing health care to improve outcomes can be somewhat simplistically conceptualized as "doing the right thing right."[1] Donabedian's emphasis was originally on the efficacy, effectiveness, and efficiency of health care.[6] In the past few years, this model has been expanded to incorporate safety, equity, and patient-centeredness as equally essential attributes of quality health care (Table 66.1-1).[3]

This chapter discusses these attributes of quality in the context of an introduction to outcomes research and its methodologies. Specific examples from the pediatric gastroenterology literature are used to highlight aspects of study design and their application to clinical practice. Pediatric gastroenterologists are introduced to the challenges involved in systematically evaluating their own practices with an eye to quality. Like all physicians, pediatric gastroenterologists must understand and use outcomes research to close existing gaps in the quality of care that they provide.

TABLE 66.1-1 DEFINITION OF TERMS USED IN THE EVALUATION OF MEDICAL CARE QUALITY

Efficacy	*Can* it work? (eg, in controlled trials)
Effectiveness	*Does* it work? (eg, in the real world)
Efficiency	Is it *worth* doing?
Safety	Does it *reduce risk* to patients?
Equity	Is it *nonvarying* in quality?
Patient centered	Is it *respectful* of individual patient preferences?

The first section of this chapter briefly reviews the concepts of efficacy and effectiveness, an understanding of which underlies the whole of outcomes research. In the following sections, studies of clinical outcomes, patient-centered outcomes, and health care costs are discussed. Our goal is to provide an introduction to methodology as it relates to outcomes research.

EFFICACY AND EFFECTIVENESS

Quality health care is best ensured by continual formal evaluation of the relationships between processes of providing medical care and the outcomes of those processes. Although many types of clinical research contribute to the evaluation of medical care, it is important to realize that not all clinical studies are outcomes studies. The point of distinction lies mainly in understanding the terms "efficacy" and "effectiveness."[7]

In general, efficacy studies are designed to determine if a given medical intervention can work under tightly controlled conditions. In contrast, effectiveness studies are designed to mirror daily practice and to determine if an intervention is successful in routine clinical practice. To the extent that they measure health outcomes in real-world settings, effectiveness studies are the crux of outcomes research.

Outcomes research focuses on the impact of a given medical practice on health in the real world. The data generated by outcomes research reflect changes in practice and in the natural history of the disease over time. In addition, outcomes study methodology recognizes that unpredictable and uncontrollable changes in patients' lives are important and legitimate factors in determining the ultimate effectiveness of medical care. Effectiveness studies are often less restrictive about inclusion and exclusion criteria than studies of efficacy.

Effectiveness studies, the mainstay of outcomes research, also integrate variations in clinical practice among various practitioners and in different health care settings. These characteristics of effectiveness studies are readily apparent when comparing, for example, the practices of university- or research-based health care groups with those of community-based physicians. Many outcomes studies recognize that there are physician-dependent variables in assessing the effectiveness of medical interventions.

CLINICAL OUTCOMES

In this section, we consider outcomes research that measures physiologic and clinical effects. We discuss some of the strengths and weaknesses of both experimental and observational study designs as they relate to the use of these designs in outcomes research. We also touch on the use of large administrative databases and meta-analysis as increasingly popular methodologies (Table 66.1-2).

Experimental Study Design

Experimental studies are most commonly designed as clinical trials. Clinical trials aim to isolate one factor, generally an intervention, and examine its contribution to patient health by holding all other factors as constant as possible. The gold standard for experimental clinical study design is the randomized controlled trial (RCT). An RCT is a comparative study between an intervention group and a control group. The groups are as similar as possible, except the intervention group is exposed to a health care service (eg, medication, therapy) and the control group is not. Any differences in outcomes between the two groups can then be attributed to the intervention.

Participants in RCTs are randomly assigned to either the intervention or the control group. When performed correctly, the process of randomization removes the potential for bias in the allocation of participants to either group. Randomization also optimizes the chance that the two groups will be evenly matched, on average, in their known baseline characteristics (eg, age, sex, disease status), as well as any unknown factors.

Despite their many strengths, RCTs may have a limited role in clinical outcomes research. For example, if an outcome of interest is rare, an RCT may require an enormous study population to detect any differences between intervention and control groups. If the outcome takes many years to emerge, an RCT may not be feasible. It also may not be possible to randomize certain variables, such as patient preference or physician beliefs. Other limitations of applying findings from RCTs in clinical outcomes research include the fact that RCTs are usually designed to answer specific clinical questions in well-defined patient populations and may use strict exclusion criteria to create a homogeneous study sample. These characteristics of RCTs can limit their generalizability to real-world clinical practice.

However, RCTs can be designed to provide information that is relevant to clinical practice and therefore can play a role in outcomes research. One example of a well-designed prospective, double-blind, placebo-controlled RCT in the pediatric endoscopy literature evaluated the use of oral midazolam as a premedication to conscious sedation for pediatric endoscopy.[8] Although almost all pediatric gastrointestinal procedures are performed with some type of sedation, there is a lack of consensus about the use of premedications to decrease anxiety, which many children experience before the procedure.[9] In this study, Liacouras and colleagues were specifically interested in whether the use of oral midazolam prior to intravenous (IV) line placement led to less apprehension in children before, during, and after an endoscopic procedure.[8] Investigators obtained informed consent for 123 children to be randomized to receive either oral midazolam or placebo approximately 20 minutes before IV placement for endoscopy.

TABLE 66.1-2 TYPES OF OUTCOMES RESEARCH AND RELEVANT STUDY DESIGNS

Experimental studies
Randomized controlled trials
Observational studies
Cohort
Case control
Cross-sectional
Case series
Large administrative database analysis
Meta-analysis

This RCT is a good example of an effectiveness trial that carefully investigated a study question while allowing real-world health care systems to function routinely. Once the oral medication (midazolam or placebo) was given, IV procedural sedation for endoscopy was administered in a routine manner. Importantly, the doses of procedural sedation were not dictated by the study design, and endoscopists were encouraged to use routine means to evaluate patients' levels of sedation. The results of this RCT strongly supported not only the safety but also the effectiveness of oral midazolam premedication for pediatric endoscopy. Such studies have the potential to change clinical practice and therefore can be considered outcomes research.

Observational Study Design

Observational studies often represent the best method for studying rare or remote conditions. In general, observational studies are easier and less expensive to perform in comparison with experimental studies. Observational studies may especially be useful when randomization schemes cannot be feasibly employed. They are also essential tools in outcomes research because they generally measure effectiveness rather than efficacy.

Nevertheless, there are many important disadvantages to observational studies that must be weighed in both critically reviewing the literature or when choosing a study design. In particular, because patients are not randomized, there is an unavoidable risk of both bias and confounding. Bias may be defined as any factor in a study that tends to produce results or conclusions that differ systematically from the truth. This includes errors in analytic methodology and errors of interpretation.[10] A confounder is a third factor in a study that may be associated with both the exposure and the outcome and may, in fact, be responsible for any observed associations between the two.[11]

In the following section, we describe four principal research designs of observational studies: cohort, case control, cross-sectional, and case series.

Cohort Studies. Cohort studies are observational studies that focus on factors related to the development of a disease of interest. They are especially useful for studying the incidence and natural history of disease. In a cohort study, a group of people (the cohort) who do not have the condition of interest at the time of enrolment is selected and observed over time. Suspected risk factors for the outcome are evaluated in all members of the cohort at enrolment and throughout the observational period.

By following all of the members of the cohort for development of the outcome, the relationship between risk factors and outcomes can be assessed. Cohort studies can also measure absolute risks of developing a new disease because rates of exposures and outcomes have been collected. Generally speaking, cohort studies are prospective in nature, meaning that a cohort is followed forward from a set point in time. However, cohort studies can also be retrospective and assemble subjects according to their history of exposure without consideration of outcomes, even though the outcomes may already have taken place.

Cohort studies have many significant advantages over other study designs for outcomes research. First, when a clinical trial cannot be conducted for either ethical or practical reasons, a cohort study may provide the best alternative method to study the question of interest. A cohort study may be useful for studying more than one risk factor and more than one outcome using the same study population. Cohort studies may simultaneously give descriptive information about several diseases or even help to tease out which risk factors are directly linked to which disease. Cohort studies are particularly relevant to outcomes research because they do not occur in tightly controlled research settings.

Cohort studies have some important disadvantages. Members of the cohort may need to be followed for a lengthy period of time before a sufficient number develop the outcome of interest. Furthermore, study resources may be spent following many people in the cohort who will not develop the outcomes of interest or may be lost to follow-up. Another limitation to cohort studies is that they may represent an impractical study design for investigating risk factors for rare diseases. This issue may especially be salient for pediatric gastroenterologists. For example, to study a disease with a known incidence of 1 in 10,000 children, 100,000 children will need to be followed to capture 10 cases of the disease. On the other hand, this issue can be minimized if a cohort is selected that is known to be at high risk of developing the disease.

Recently, several pediatric gastroenterology–oriented cohort studies have been designed that will ultimately improve our understanding of obesity in children.[12,13] For example, the ongoing Growing Up Today Study (GUTS) was established in 1996 to longitudinally follow the activity, dietary intake, and weight changes of children across all 50 United States.[12] GUTS participants were recruited from the offspring of participants from another cohort study, the Nurses Health Study II.

Another example of a recent cohort study in the pediatric endoscopy literature explored the relationship between clinical presentation and primary peptic ulcer disease in children.[14] Primary peptic ulcers are traditionally considered to be unusual in childhood.[15] It is well accepted that the rarity of this diagnosis has limited the ability of investigators to identify risk factors for childhood ulcer disease and to know when to perform endoscopy for diagnosis.[16] To investigate these questions, Roma and colleagues undertook a cohort study from 1990 to 1999, during which time they followed 2,550 children who had dyspeptic symptoms, including epigastric pain, periumbilical pain, bleeding, vomiting, and nocturnal waking.[14] All children then underwent upper gastrointestinal endoscopy with biopsies. Primary peptic ulcers were diagnosed in 2% (52 of 2,550) of the cohort and appropriately treated. Of the 52 patients with peptic ulcer on initial endoscopy, 25 (48%) became symptomatic after treatment and were re-endoscoped. Only 3 (0.12%) of these children were found to have a second ulcer.

In their primary analysis, the investigators found no significant differences between the clinical symptoms of those children with ulcers and those without. Therefore,

Roma and colleagues suggest that all children with dyspeptic symptoms be referred for upper gastrointestinal endoscopy to evaluate for ulcer disease.

This study highlights the types of information available from a cohort design. The results provide an estimate of overall disease prevalence in the population of interest. The clinical follow-up of patients with ulcers at the start of the study allows for an assessment of the effectiveness of treatment. Roma and colleagues' study represents an example of the importance of cohort studies to understanding pediatric gastrointestinal disease and disease management.

Case-Control Studies. A second observational study design method is that of case-control studies. Whereas cohort studies examine people who are initially free of the disease of interest, case-control studies compare people who already have the disease (the cases) with otherwise similar people who do not have the disease (the controls). Case-control studies start by evaluating the outcome (the presence or absence of the disease) and then look back into patients' histories to identify possible risk factors. Both cases and controls must be selected independently of exposure to the risk factors of interest. In this retrospective manner, case-control studies can be used to analyze whether identified risk factors were present more frequently in cases than in controls.

The advantages of performing case-controlled studies include the fact that they can be performed relatively quickly and inexpensively, even for diseases that are rare or that take lengthy periods of time to appear. To epidemiologists, case-control studies represent the basis of outbreak investigations, such as those conducted to determine the etiology of foodborne outbreaks of gastroenteritis. In addition, if the outcome is rare overall, case-control studies may require fewer subjects than cohort studies. They also simultaneously allow multiple risk factors to be investigated within the same study of a particular outcome. Because of these attractive features, case-control studies are often used as hypothesis-generating mechanisms for investigators exploring possible risk factors for rare diseases.

However, case-control studies do have a number of disadvantages, including that they are particularly subject to bias (eg, recall bias). Case-control studies must rely on studying cases that have already been identified. Misdiagnosed or asymptomatic cases or people who have already died either from the disease or other causes are missed by this type of study.

Case-control studies also depend on the identification of an appropriate control group. Controls should be selected from a population of individuals who would have been identified and included as cases had they also developed the disease. Selecting a control group that is comparable to a group of cases can be a surprisingly difficult task for investigators.

Recently, Lazzaroni and colleagues performed a carefully designed case-control study of primary upper gastrointestinal bleeding in infants.[17] Although significant upper gastrointestinal bleeding in otherwise healthy full-term infants has been described in case reports, the available data on the topic are limited owing to the rare occurrence of this disease.[18,19] There were three main aims to this study.[17] The first was to identify types of mucosal lesions in newborn babies with upper gastrointestinal bleeding. The second aim was to examine the safety and necessity of performing upper endoscopy in newborns with gastrointestinal bleeding, and the third was to identify risk factors associated with such bleeding.

Sixty-four of 5,180 infants (1.23%) born at the study center in Italy developed significant upper gastrointestinal bleeding within a mean of 26.5 hours of life. In 53 of 64 cases, an endoscopy was performed. Extensive demographic, prenatal, neonatal, clinical, and hematologic data were collected and analyzed for all cases and their mothers. The same data were collected for a group of 53 controls and their mothers, who were matched for age and sex to the 53 cases who underwent endoscopy. The controls were selected randomly from a population of full-term infants born in the same hospital.

All patients who underwent endoscopy were found to have mucosal lesions of either the esophagus, stomach, or duodenum. A comparison of the 53 patients who underwent endoscopy with the 53 controls revealed no significant differences in demographic or clinical characteristics, except that upper gastrointestinal bleeding was significantly more frequent in those infants whose mothers came from countries outside Europe. Therefore, the investigators concluded that the risk factors for upper gastrointestinal hemorrhages in infants remain obscure.

However, it is important to realize that this study was limited, albeit for ethical reasons, by the lack of endoscopy surveillance of the control group. A second limitation of this study lies in the selection of its control group. The study findings might have been strengthened or even different if a control group had been chosen that was matched by age and sex to all 64 cases of acute gastrointestinal bleeding—not just to those 53 patients who underwent endoscopy. Although case-control studies are important tools for outcomes research, the application of their conclusions for clinical practice may still be affected by limitations in study design.

Cross-Sectional Studies. Cross-sectional studies are based on a single examination of an entire population at a particular point in time. By surveying a whole population, cross-sectional studies assess the proportion of people with a certain disease (eg, the prevalence of the disease) and can be used to examine the relationship between the disease and other characteristics of the population under study. Cross-sectional studies are common in the medical literature and can produce valuable data about a wide range of diseases and types of risk factors. They are important for generating hypotheses for experimental designs.

However, as a descriptive research methodology, cross-sectional studies have several important limitations. In particular, because cross-sectional studies identify existing cases (prevalent cases) of a disease and do not capture the occurrence of new cases (incident cases), they are likely to overrepresent chronic diseases and underrepresent acute diseases. Also, people with certain diseases may either

leave the community or be located in a place where they are not surveyed.

Cross-sectional studies may also be limited by so-called "lead time bias," whereby patients are misclassified by exposures. For example, children with symptoms of peptic disease may choose to stop drinking caffeinated beverages because of their symptoms before inclusion in the study. They would therefore be counted as nonexposed. Finally, the findings of cross-sectional studies must be interpreted cautiously; the mere fact that two variables are associated does not mean that they are causally related.

An example of a recent cross-sectional study in the pediatric endoscopic literature is an investigation into the prevalence of *Helicobacter pylori* in a population of children with chronic abdominal pain, with and without the gross endoscopic finding of nodular gastritis.[20] Endoscopic findings of nodularity are reported frequently in children[21] and have been loosely associated in the past with either acute or chronic *H. pylori* infection.[22] Nevertheless, the relationship of endoscopic nodular gastritis with *H. pylori* infection in children remains ill-defined. The investigators of this study used a cross-sectional design to examine the associations between endoscopic findings and microscopic *H. pylori* infection among children with chronic abdominal pain.[20]

Bahu and colleagues prospectively included 185 children aged 1 to 12 years who presented to two pediatric gastroenterology clinics in Brazil from 1997 to 1999 with chronic abdominal pain. To improve their diagnostic yield, the investigators chose a study population at high risk for *H. pylori*.[20]

The prevalence of endoscopic nodularity in this population was 13% (95% CI 8.5–18.7), and *H. pylori* infection was identified in 27% (95% CI 20.8–34.0) of the study population. Endoscopic nodularity was found in 44% of patients with *H. pylori* infection and in 1.5% who were *H. pylori* negative. In their discussion, the authors state that their results support a significant association between endoscopic nodular gastritis and *H. pylori* infection.[20]

However, as with all cross-sectional studies, an observed association does not prove causality. In fact, because the putative exposure (*H. pylori*) and outcome (nodularity) were assessed simultaneously, it is equally possible that the nodularity in some way predisposed the patient to infection with *H. pylori*. Additionally, it may be difficult to identify confounders in cross-sectional studies. For example, in this case, both *H. pylori* and nodularity were rare in the youngest children; therefore, age may be a confounder, and there may be no true association between *H. pylori* and nodularity.

Another issue with this particular study is that it was conducted in a high-risk study population. Therefore, the generalizability of its prevalence findings to other populations for both endoscopic nodular gastritis and *H. pylori* may be limited. Finally, there was no follow-up of the patient population, as is characteristic of a cross-sectional design. Therefore, it remains a possibility that *H. pylori*–positive children with normal mucosa will go on to develop nodularity.

Case Series. Case series are generally considered the weakest study designs in the so-called "hierarchy of evidence."[23] Nonetheless, they may represent an excellent means of generating hypotheses for more robust studies to examine. A case series simply describes the presentation, and often the clinical management, of a disease in more than one patient. Patients in case series studies are generally not followed prospectively, and they are not compared with a control group. Therefore, case series are not useful for establishing a causal relationship between risk factors and disease or the clinical effectiveness of a management approach.

Case series may also be prone to selective reporting (reporting bias). Owing to small numbers and the anecdotal nature of such a report, the validity of case series findings may be difficult to establish. Similarly, a case report, as a form of case series in which only one patient is described, may suggest an association or a clinical course that is not necessarily generalizable beyond the individual case.

Nevertheless, case series and case reports are both numerous and important to medical literature. They are both used regularly to present information about patients with rare diseases and may be important for stimulating new hypotheses. In addition, a case series that describes an abnormal outcome after routine care has been administered may represent, in and of itself, a reasonable basis for re-examining that care. For example, case reports of sudden death in otherwise healthy infants receiving cisapride as a promotility agent represented sufficient basis for more outcomes studies on the use of cisapride in children with gastroesophageal reflux.[24,25]

In one recent case report, Stiffler described an 11-year-old girl with a 5-year history of persistent obscure gastrointestinal bleeding who underwent capsule endoscopy.[26] The patient described in the case report had undergone several upper gastrointestinal endoscopies, a colonoscopy, push enteroscopy, and enteroclysis prior to undergoing the capsule endoscopy—with all examinations being negative for pathology. The capsule procedure identified a small bowel narrowing with significant erosive and ulcerative changes consistent with Crohn disease.

In the discussion following the case report, Stiffler speculates that capsule endoscopy may prove to be a useful diagnostic modality in pediatric patients with gastrointestinal disease. Stiffler also explains that both pediatric gastroenterologists and their patients may prefer undergoing capsule endoscopy, which does not require sedation.

Indeed, the tactical issue of how to achieve sedation that is both safe and effective for endoscopy and colonoscopy as high-volume pediatric procedures remains a challenge for pediatric gastroenterologists. Although several studies have indicated that general anesthesia allows a safer environment for the performance of more successful traditional endoscopic procedures in children compared with conscious sedation,[27,28] others have postulated that conscious sedation can be just as safe.[29] To date, there have been no outcomes studies that have contributed to resolving this debate.[9] Instead, because most studies in the literature are based on case series at single institutions, it is difficult to compare sedation practices across investigative sites.

The decision to use one regimen over the other is generally left to the clinical judgment of individual physi-

cians, to be made on a case-by-case basis.[9] The lack of an evidence-based approach to the question of sedation for pediatric endoscopy leaves open the real possibility that individual pediatric endoscopists may make inappropriate sedation choices for their patients.

The study of patient safety is an important subset of outcomes research. Patient safety, or the concept that patients should not experience harm from health care that is intended to help them, represents one of the major steps identified by the IOM for improving the quality of health care overall.[3] The question of sedation choice and patient safety for children undergoing endoscopic procedures is a salient example of a quality gap in health care services that will best be addressed by well-designed outcomes studies in the future.

Large Database Review Studies

Outcomes research may employ large administrative databases maintained by health care providers, payers, or government agencies.[30,31] There are many advantages to such databases, which are often (but not always) considered both valid and reliable. First, they are usually electronically maintained and are therefore often computer ready for analysis and inexpensive to acquire. Many databases come packaged together with computer programs for data analysis. Such databases are also often rich in demographic characteristics, as well as diagnoses of patients. Administrative databases often reflect the health care of large populations, and findings may be generalized.

However, there are also drawbacks to using large administrative databases. For instance, they can be limited in the quality and type of clinical information available. Also, because most were developed for billing or administrative purposes, they are often lacking pertinent medical information. Moreover, large institutional databases may include incorrect or incomplete datasets, especially in regard to medical and patient care information. Inconsistencies in diagnostic coding may also limit the usefulness of these databases. As an example, variation in diagnostic codes for abdominal pain in children may make it difficult to characterize the care of or evaluate the outcomes of children with this clinical problem.

Nevertheless, nationally maintained databases are becoming important tools for outcomes researchers in pediatric gastroenterology. For example, the Kids' Inpatient Database (KID) is one of several databases developed and maintained as part of the Healthcare Cost and Utilization Project, which is a federal, state, and industry partnership sponsored by the National Institutes of Health's Agency for Healthcare Research and Quality.[32] The KID pertains to children's health issues and is the only hospital administrative dataset designed specifically to assess use of hospital services by newborns, children, and adolescents.[33] It represents the only large inpatient care database for children in the United States and contains data from approximately 1.9 million hospital discharges for children across 27 states.

Importantly, the KID includes data on all patients, regardless of payer, including children covered by private insurance or Medicaid and the uninsured. This feature of the KID highlights its ability to assess the equity of care provided to children because it includes patients who may vary greatly in personal characteristics, such as gender, ethnicity, geographic location, and socioeconomic status. According to the IOM, ensuring equitable care, or quality care that does not vary along these personal characteristic lines, is a main goal for redesigning the twenty-first century health care system.[3]

Guthery and colleagues were able to perform a population-based outcomes study using the KID to identify the principal gastrointestinal diagnoses associated with hospital use and to describe hospital use patterns associated with pediatric gastrointestinal disorders.[34] In a descriptive analysis using the KID and its associated software program, *Clinical Classification Software*,[33] Guthery and colleagues found that gastrointestinal disorders in children are a significant source of hospital resource consumption, accounting for $2.6 billion in hospital charges annually in the United States and over 1.1 million hospital days. The investigators also found that among children with principal gastrointestinal discharge diagnoses, 67.7% of discharges were from non–children's hospitals, 13.1% were from pediatric facilities, and 19.2% were from pediatric units of a general hospital. In addition, 56.7% of pediatric gastrointestinal disease discharges were from nonteaching hospitals, whereas 43.3% were from academic centers.

Guthery and colleagues concluded that care for children with gastrointestinal diseases is provided at a variety of different types of institutions, which may represent a significant source of variation in care. Further outcomes research may help to explore how this variation in care portends gaps in quality of care for children with gastrointestinal disease across the United States.

Meta-analysis

Meta-analysis has become an especially popular tool for outcomes research and, as a methodology, has been featured prominently in journals dedicated to the field of gastroenterology.[35–38] Meta-analysis employs specific statistical methodologies to retrospectively review and integrate available quantitative data across multiple studies. It is an especially useful method for assimilating data from multiple small studies that have found conflicting answers or statistically insignificant results for the same research question. In meta-analysis, the data of multiple independent studies on the same topic are compiled and analyzed across reports to increase overall statistical power. In essence, a meta-analysis allows the synthesis of the results of numerous tests so that an overall conclusion can be drawn.

There are some fundamental assumptions related to meta-analysis. First, it is important that all studies combined in the analysis have the same research question. Second, the separate studies included in the analysis should be independent of each other. Third, the studies should be of sufficient quality. If any of these assumptions can be challenged, then the use of meta-analysis is not appropriate.

However, there are a few important caveats to interpreting meta-analyses. In particular, there is a tendency in the medical literature to publish positive findings, which, in turn, introduces a bias into the data selection process for meta-analysis. An appropriately conducted meta-analysis

will also incorporate data published only in abstract form and unpublished data collected through communication with investigators.

Additionally, to test for the possibility of publication bias, a meta-analytic study design often will include a sensitivity analysis. For instance, investigators may choose to create a type of scatter plot (a so-called "funnel plot") that allows the sample size of each study to be plotted according to its estimated effect size. In a typical funnel plot, the vertical and horizontal axes represent sample size and estimated effect size, respectively. A vertical line can then be drawn on the graph defining the pooled estimate effect size, and the points from each study included in the meta-analysis will scatter around this line. If there is no publication bias, the results from small studies plotted at the bottom of the graph should have considerable variation, whereas large studies, at the top of the graph, should show less variation in their results. Thus, the graph should look like an inverted funnel. If there is publication bias against small, nonsignificant studies or if the investigator has not included all possible studies, the graph will either not assume a funnel shape (eg, be skewed or asymmetric) or will contain gaps (Figure 66.1-1).

Another possible bias to meta-analysis is that many published studies do not contain sufficient detail that allows investigators to compare the results from one study with those of another. In fact, the main drawback of meta-analysis lies in the inequality of the study designs and end points that it measures. Strict criteria for performing meta-analysis, as well as the application and utility of this outcomes study design, are the subject of many reviews.[39–41]

In one example of meta-analysis in the pediatric gastroenterology literature, Huang and colleagues recently sought to determine whether probiotic therapy improves outcomes in children with acute infectious diarrhea.[42] Although probiotics are considered a promising adjunctive therapy for children with acute diarrhea, studies on the subject have suffered from limited study power and conflicting results.[43]

In compiling data for meta-analysis, Huang and colleagues strictly focused on clinical trials of probiotic therapy in otherwise healthy children less than 5 years old with acute-onset diarrhea in the outpatient setting.[42] The selection criteria for the meta-analysis set a priori were that each trial included must have randomized its patients into intervention and control groups. Also, each trial must have performed a direct comparison between groups and reported duration of diarrhea as an outcome variable. Of a total of 29 studies on probiotic use for diarrhea that were identified and categorized by treatment setting, population characteristics, and patient comorbidities, the investigators identified 18 that met inclusion criteria for their meta-analysis. Nine were excluded either because they lacked a control group or did not report the duration of the diarrhea. An additional two studies were excluded because they used data also published in two of the included trials.

There were two other meta-analyses published in the same year as Huang and colleagues' study that also questioned the usefulness of probiotics in the setting of pediatric diarrhea. Szajewska and Mrukowicz focused on trials in children who were hospitalized and did not include abstracts or unpublished data.[44] Van Niel and colleagues used meta-analysis to look at only randomized double-blind placebo-controlled trials of probiotics in children.[45] All three meta-analyses of probiotics in children defined their outcome as the duration of the diarrhea.

As part of classic meta-analytic methodology, Huang and colleagues provided a summary table of the studies included in their analysis and concluded that probiotic therapy shortened the duration of acute diarrheal illness in children by approximately 1 day.[42] This finding was similar to both Szajewska and Mrukowicz's and Van Niel and colleagues' analyses, which detected shortened duration by 0.6 and 1.2 days, respectively.[44,45] These are three examples of well-designed, rigorously conducted outcomes studies. In their individual discussions, all three investigators appropriately questioned the real-world clinical meaning of their findings. Although probiotics may be efficacious at reducing the duration of diarrheal illness, the clinical effectiveness of this strategy that reduces symptoms by a day or less may not be convincing enough to change clinical mangement.

PATIENT-CENTERED STUDIES

In recent years, the concept that patients' perceptions of their health and satisfaction with their health are important measurable variables has emerged as a fundamental maxim. Furthermore, the more careful allotment of health care dol-

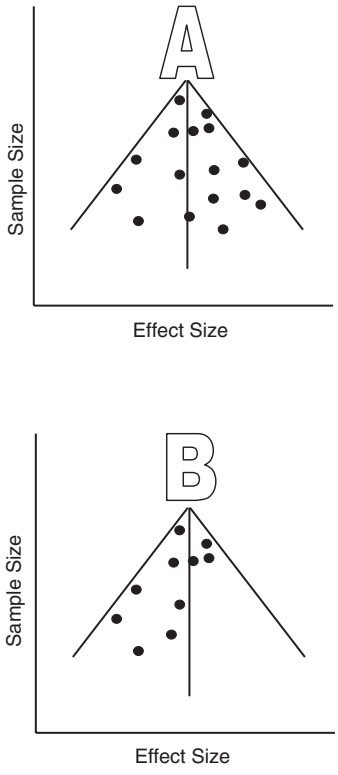

FIGURE 66.1-1 Schematic of two funnel plots for meta-analysis. Plot A shows no association between study size and effect size. Plot B depicts an asymmetric relationship, suggesting a publication bias.

lars has led to increasing demands on physicians to make informed health care decisions that truly benefit patients. In response, outcomes research has begun to focus primarily on the "patient experience"[46] of health care by extending the scope of studies beyond the end points of morbidity and mortality to include quantitative and qualitative measures of patients' perceptions of health and well-being.

Quantitative patient-centered measures may include validated instruments that are often importable across institutions and settings. Qualitative measures often rely on content analysis of open-ended patient-survey questions. The use of either type of measure in patient-centered studies may allow the evaluation of the effects of medical intervention on patients' functional status, their satisfaction, and their HRQOL.

Functional Status

Functional status is defined as a measure of the impact of health or disease condition on the ability of patients to function in various roles in society.[47] As with all patient-centered measures, it is important to recognize that the functional status of children is inherently different from that of adults. Although both may take into account the impact of health on a patient's ability to perform age-appropriate activities of daily living, as well as their moods and abilities to communicate, adult functional status may measure professional productivity, whereas pediatric functional status may be more concerned with play or school attendance.

At any age, functional status, as a measure, can be used to describe a patient at a single point in time or cumulatively over time. The latter use of functional status as a cumulative measure may allow for prediction studies of patients' likely future health gains from given treatments. A number of different pediatric instruments have been validated as measures of functional status in children with many chronic illnesses (eg, Functional Disability Inventory[48] and Functional Status II-Revised[49]). However, these instruments may not be generalizable to all patient populations.

Patient Satisfaction

Patient satisfaction can be measured in terms of patients' satisfaction with health care or with their state of health or disease condition. Although the assessment of patient satisfaction has been emphasized strongly in outcomes research, it may be a difficult measure to interpret. Indeed, the IOM does not consider patient satisfaction a useful type of outcome to measure when evaluating quality of care.[3] According to the IOM, too often "it is difficult to determine what is an acceptable level of satisfaction…[because there] is generally no standard to which to compare the results."[3] Reports of actual experiences with care may provide more clinically relevant information than satisfaction ratings. For example, it may be more appropriate to ask patients whether they were informed about the specific side effects of medications on discharge than to ask whether they were satisfied with nursing care.

When evaluating patient satisfaction in children, there is generally the added complexity of using parents' reports in lieu of their children's.[50] Nevertheless, parental satisfaction continues to be considered a relevant outcome of pediatric care. As such, several instruments have recently been developed for evaluating parents' satisfaction regarding their child's care.[51]

Health-Related Quality of Life

HRQOL is a comprehensive term that refers to the general physical and mental health status of individuals, including their psychosocial well-being, as it is affected by illness or injury and health care interventions or policies.[52] By most definitions, HRQOL is different from functional status in that it measures psychological well-being, whereas functional status is more concerned with physical ability. However, many investigators may choose to measure functional status as a component of HRQOL.[53] In either case, the term HRQOL invokes "the capacity of an individual to perform social and domestic roles so as to meet the challenges of everyday living without emotional distress of physical disability."[54]

Although, currently, there is no gold standard for measuring HRQOL, a general consensus has emerged as to what should be measured.[50] To this end, a general framework is portrayed of a classic core set of disease-related domains that should be measured in any global assessment of HRQOL (Figure 66.1-2). For the purposes of this chapter, we assume that there are at least five domains that comprise the framework for HRQOL: (1) the state of disease, (2) associated physical symptoms, (3) functional status, (4) psychological functioning, and (5) social functioning.

Each domain of HRQOL is independently measurable and can be affected by both the disease and medical intervention. However, the complex interactions between domains must also be appreciated. Also, these domains are not mutually exclusive, and individual patients may react to their diagnosis, symptoms, and treatment in frequently unpredictable ways.

There are many obstacles to measuring pediatric HRQOL, and this area of study has been slower to develop in children, in contrast to the rapid expansion of HRQOL

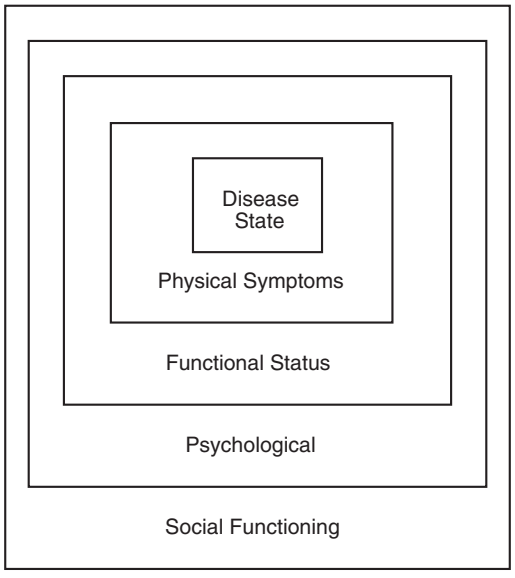

FIGURE 66.1-2 Framework for the essential domains of health-related quality of life.

research in adults.[55] Owing to inherent differences between pediatric and adult patients, most HRQOL instruments used in adult medicine are not readily applicable for use in children.[56] For example, many components of adult functional and social well-being that are measured in adult HRQOL instruments, such as economic status, job performance, and sexual satisfaction, are clearly focused on adult behaviors. Therefore, pediatric instruments, such as the Child Health Questionnaire and the Child Health and Illness Profile, have been developed to capture age-specific and -sensitive issues.[56]

Furthermore, compared with adult questionnaires, greater time and creativity are required to develop nonwritten, nonstandard means to assess HRQOL in infants and young children. Another concern that must be addressed is the incorporation and balancing of parental perceptions, which may not necessarily reflect those of their children and cannot substitute for the perspective of the child.

To date, a limited number of both general and disease-specific instruments to assess HRQOL have been developed for children.[57] Although general instruments allow physicians to assess and contrast various domains across a multiple number of disease states, they often lack the specificity required to understand the impact of a particular disease state. In contrast, disease-specific instruments are highly sensitive for a particular disease but, by definition, cannot be used to compare different disease states. Depending on research aims and feasibility, HRQOL outcomes studies in children that include a battery of both general and disease-specific instruments that measure all or some of the domains of HRQOL may be best.[58]

Patient-Centered Studies

In pediatric gastroenterology, there have been few patient-centered studies regarding interventional practices and procedures. Fortunately, there has been increasing interest in performing such research, and in recent years, there has been a substantial increase in the number of publications in this area.[59–61] In return, we are gaining greater understanding of the broader scope of the experiences that pediatric patients undergo related to their care. Pediatric liver transplant represents a particularly important example of an area of interest in which children with chronic gastrointestinal diseases are increasingly the focus of patient-centered research.

Liver transplant is now widely accepted as the definitive therapeutic procedure for end-stage liver disease in children.[62] Improvements in immunosuppression, surgical techniques, and postoperative management have all contributed to greater than 90% 5-year survival rates at most transplant centers, and morbidity and mortality rates are no longer sufficient indications of success.[63] Instead, increasing efforts are being made to evaluate the broader impact of this procedure on children by focusing on patient-centered measures, including physical and psychosocial functioning, growth and development, and a general perceived sense of well-being.[63,64]

On the other hand, evaluating patient-centered outcomes in children following liver transplant is a complex endeavor. For example, the measurement of HRQOL must factor in both pre- and post-transplant status for both the patient and the family. In many instances, parents are providing living-related grafts for transplant, and their own HRQOL as donors must also be considered. Additionally, the impact of multiple underlying diagnoses and reasons for transplant must be gauged. Post-transplant, certain diseases may recur, increasing the risk of graft failure and poor HRQOL. In other cases, extrahepatic manifestations of disease may persist despite successful liver transplant.

In one study of patient-centered factors after liver transplant, Debolt and colleagues followed 65 children for up to 5 years post-transplant and measured social, behavioral, and emotional adaptation; physical function; and family stress.[65] In this highly comprehensive study, a battery of general psychometric instruments, such as the Mental Scale of the Bailey Scales of Infant Development, the Vineland Social Maturity Scales, and the Wechsler Intelligence Scale for Children-Revised, were administered to children prior to transplant and again at 1 year of follow-up. The children's scores were compared with published data from chronically ill and medically well children. This study supported previous short-term findings showing that transplant recipients had equivalent psychological and functional status compared with both comparison groups.[66]

Debolt and colleagues' findings also indicated that post-transplant, HRQOL in children is highly dependent on immunosuppressive regimens.[65] These findings supported an earlier study by Starzl and colleagues that found that across both pediatric and adult transplant survivors, 1-year post-transplant HRQOL was significantly affected by the degree of steroid dependence.[67] Other outcomes studies more interested in physiologic factors, which may be intermediate steps to HRQOL, have demonstrated the inverse relationship between steroid doses and growth in children following liver transplant.[68] In conjunction with these more clinically oriented studies, Debolt and colleagues' patient-centered results provide tremendous incentive for pediatric hepatologists to aggressively wean post-transplant immunosuppressants.

In the last few years, greater efforts have been made to design a disease-specific HRQOL instrument to assess outcomes of children with liver transplants. In one such undertaking, Andelman and colleagues reported their design and implementation of a pediatric liver transplant–specific HRQOL instrument in children and compared its utility with that of general instruments, such as those employed by Debolt and colleagues,[65] in understanding the impact of clinical management.[69] Again, overall HRQOL in children with liver transplants was found to be similar to that of national norms and control groups of children without liver transplants when assessed by either general or disease-specific instruments.

However, Andelman and colleagues' findings also indicated a greater tendency for the disease-specific instrument to detect differences between the HRQOL of children with liver transplants and that of comparison groups without liver transplants.[69] In fact, only the disease-specific instrument detected the impact of comorbid conditions and the effect of post-transplant morbidities in transplant recipi-

ents.[70] Furthermore, administration of these disease-specific age-appropriate instruments to both children with liver transplants and their parents found different responses among children compared with their parents. These findings support a growing realization that the assessment of HRQOL in children is important and must include the perspective of the child.[71]

STUDIES OF MEDICAL EFFICIENCY

As with the growing emphasis on measuring clinical effectiveness and patient-centered end points, there is increasing focus on determining the clinical efficiency or value of medical intervention to make more informed health care decisions at the individual, institutional, governmental, and societal levels. This emphasis on clinical worth that reconciles economic analyses with clinical practice has had a direct impact on all procedural specialties, including pediatric gastroenterology. In the final section of this chapter, we examine the principles of clinical economics and studies of medical costs as essential tools for evaluating efficiency.

The basic principles of health economics involve three different dimensions of analysis, which are classically represented by three axes of a cube (Figure 66.1-3).[52] In this schematic, three approaches to economic analysis are lined up along the y-axis: cost-identification, cost-benefit, and cost-effectiveness. Along the x-axis, different types of costs and benefits can be portrayed, including those that are direct costs, indirect costs, and intangible costs. Finally, the z-axis is used to display three frequently disparate perspectives: that of the patient, the provider, and the payer. An additional perspective is that of society. The societal perspective has a global impact across all of the three axes.

One important study design for determining economic outcomes is modeling. Economic modeling involves the identification of best practices by theoretically determining the costs and benefits of all possible options for a given medical problem. Similarly to meta-analysis, the methodology of modeling involves following strict a priori guidelines that begin with the performance of a comprehensive and integrative literature review. To characterize best all of the options for medical practice, modeling may also involve conducting structured discussions with recognized medical experts on the question to be studied. Ultimately, a conceptual design model should be developed that captures a majority of differences in care processes and the likely affected health outcomes. This model can be depicted as an algorithm of competing treatment paths, which, in turn, can be comparatively analyzed—often in terms of their relative costs, risks, and benefits.

Types of Cost Analyes

There are several different types of cost analyses. Each can be useful in assessing medical costs, but each is also limited by specific considerations that must be understood prior to developing an analysis.

Cost-identification analysis (CIA) is the simplest means of determining health care costs. In this approach, analysts identify all of the costs involved in applying a certain medical intervention. The CIA is expressed as a ratio of cost per unit of treatment or service provided. This type of analysis is often used to compare the costs of one treatment versus another. For example, CIA can be used to calculate the cost of performing flexible sigmoidoscopy versus colonoscopy. However, it is important to recognize that CIA does not necessarily consider the outcomes or benefits, or which procedure may provide more information, in its calculation. Therefore, CIA is appropriate only if outcomes or benefits, such as information gained about the extent of disease, do not vary according to clinical approach. This approach is also known as a cost-minimization analysis.

The second type of medical cost analysis is cost-benefit analysis (CBA), which involves comparing the cost of a given medical intervention with the cost of its benefit. All other circumstances being equal, CBA determines a medical intervention of worth when economic benefits exceed costs. This type of analysis can express its results as either a ratio of benefit to costs (dollars over dollars) or as a net dollar amount (benefits minus costs). In using a CBA, costs and benefits are implicitly negative and positive, respectively. Another way to think of this is that a cost can be incurred or avoided, whereas a benefit is either gained or lost. These theoretical definitions open CBA to statistical manipulation. A medical cost may initially be classified as such and relegated to the denominator of a calculation. A medical cost can also be reclassified as a lost benefit and moved from the denominator to the numerator. Such reclassification (manipulation) can dramatically affect calculations when using ratios. Accordingly, CBAs that are presented as net costs or savings are preferable.

Regardless of how the results are presented, CBA is limited by its reliance on the ability to express costs and benefits in the same unit of measure. For instance, if both costs and benefits can be calculated in dollars, then CBA is possible. However, it is often difficult to express certain qualitative benefits (outcomes measures), such as HRQOL, in monetary units.

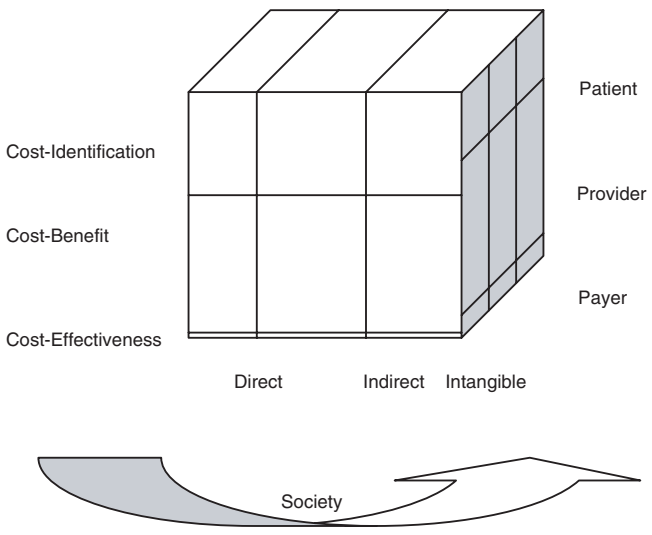

FIGURE 66.1-3 The three dimensions of economic analysis of health care. Adapted from Bombardier C and Eisenberg J.[52]

The third type of analysis is referred to as cost-effectiveness analysis (CEA). In contrast to CBA, all costs in CEA are expressed with the outcome being the denominator (dollars per outcome). This type of analysis allows costs to be expressed in terms of measured clinical or patient-centered outcomes. Accordingly, CEA is most often used to compare two different treatment options with variable or unequal end points. The option that offers less cost with the same or better outcomes is considered to be "dominant."

It is important to note that CEA is complicated by situations in which several important outcomes may result from a single medical intervention. Indeed, a CEA is expressed in terms of a single medical outcome. By definition, it excludes the incorporation of several important medical outcomes simultaneously. For example, if one were to develop a CEA for the treatment of inflammatory bowel disease in children, the results of the study might be expressed as dollars spent per prevention of remission or as dollars spent per symptom-free year of life. However, it would not be possible within the same analysis to compare the costs of remission with the costs of each symptom-free year of life.

To address this problem, analysts can rank the valued importance of the various outcomes to be measured and express the results of their analyses to each. In this weighted ranking system, the comparison of costs for each outcomes measure is called cost-utility analysis (CUA). One common strategy in CUA is to estimate people's personal preferences for different states of health and combine them into a single scale, called a quality-adjusted life-year (QALY). As a unit of "utility" that is impacted by medical intervention, QALYs are useful for measuring health improvement from health care. However, the use of QALYs has not been universally embraced because there are important ethical questions about whose values should be used to derive them.[72]

Another example of a utility-based statistical modeling technique is decision analysis, which involves analyzing decision making under conditions of uncertainty. Classically speaking, to perform a decision analysis, one needs to construct a decision model, also known as a decision tree (Figure 66.1-4). The model must include at least the following four components: (1) all possible choices that can be made in the decision making, (2) all outcomes or potential consequences of these choices, (3) the probabilities or likelihood of the outcomes of each choice, and (4) utilities or values assigned to each outcome. Utilities are often defined as a relative preference for the outcome, with 1 signaling a perfect outcome and 0 the worst possible outcome. A decision tree is then analyzed by summing the product of each probability for each outcome multiplied by its utility. The "best choice" in the decision analysis is that with the highest expected utility.

All decision analyses should include a sensitivity analysis to determine whether the "best choice" remains so if probabilities are different. There are a number of important rules to follow when performing a decision analysis. In particular, it is important to view the problem from a specific perspective (see below). Additionally, the problem must be modeled in the context of the decision and must also include an appropriate level of detail and relevance.

Types of Cost

Three commonly recognized types of cost may be considered in clinical economics: direct, indirect, and intangible. All three types of cost are highly dependent on the perspective of the analysis. The same cost might be classified as a direct cost from one perspective but an indirect or intangible cost when a different perspective is taken.

The most easily understood costs are direct costs, which are usually expressed in terms of actual dollars. Direct costs include all medical and nonmedical financial expenses encountered by both physicians and patients. Such costs include pharmaceutical costs, physician fees, and the costs of diagnostic interventions, among others. Other direct costs incurred include nonmedical costs related to the process of care, such as the cost of transportation to the hospital, the cost of special clothing needed because of an illness, and the cost of housing modifications to meet a patient's needs, among others.

Direct costs may be fixed or variable. Fixed costs of an intervention are not dependent on volume of treatment, whereas variable costs are incurred each time the treatment is provided. For example, when taking the perspective of a director of an endoscopy laboratory, the cost of endoscopy would have both fixed and variable components. Fixed costs might include the equipment used during the procedure, which must only be purchased once and can be used over and over. Variable costs might include costs of staffing and

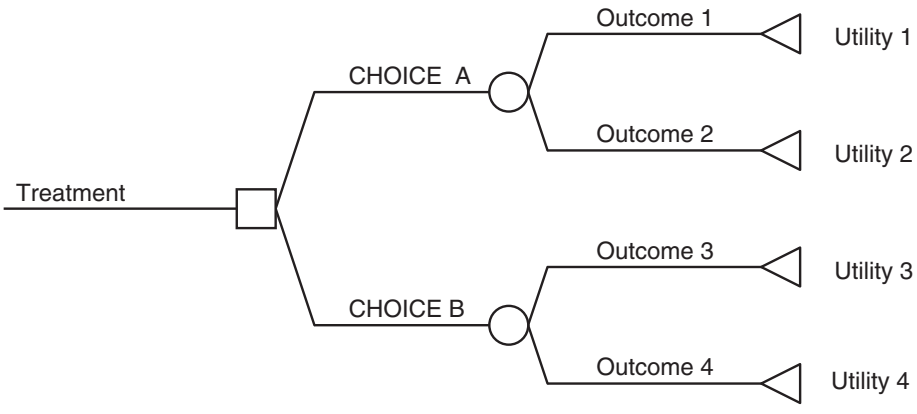

FIGURE 66.1-4 Schematic of a decision tree used in decision analysis.

disposable supplies, which vary from laboratory to laboratory based on the volume of patients undergoing procedures.

Indirect costs of health care are related to all lost opportunities in a patient's life because of illness. In general, they are the financial losses related to morbidity and mortality. For example, because of illness, adult patients may lose household income. In the case of children, indirect costs may be reflected in days away from school, which have projected financial implications for the child and for the parents. These types of costs are often difficult to calculate.

Multiple techniques have been developed for estimating the indirect costs of illness and health care in adults. Assessing the indirect costs of health care or illness in young children is more complex. Whereas the indirect cost of a complication following liver transplant in an adult may be determined by estimating the costs of time lost from the workplace, the equivalent determination in a 6-year-old child requires estimating the costs of missing part of first grade, as well as parental time lost from work.

Finally, intangible costs are those of pain, suffering, and grief. Although these costs may be very difficult to measure, they often figure prominently in decisions made by patients and physicians alike. However, few statistical techniques have been developed to determine intangible costs. Some, such as willingness-to-pay analysis, in which patients are asked to put monetary values on intangible costs, cannot be used to gain the perspective of young children, whose cognitive repertoires do not include an understanding of financial gain or loss. Therefore, although intangible costs may be among the most influential factors in the clinical decision making of pediatric gastroenterologists, they are almost uniformly absent from relevant health care cost analyses.

Perspectives of Cost

Regardless of the type of analysis and which costs are calculated, one must always be cognizant of the perspective used. In general, there are four perspectives that one might take in performing an economic analysis. These perspectives include the patient, the provider, the payer, and society. For example, indirect costs saved by spending more time following a procedure in the hospital might be important to a recuperating patient but less important to the payer, who may be more concerned with the direct costs of prolonged hospitalization. Likewise, direct out-of-pocket expenses for home nursing might be an important factor for a discharged patient recovering from a procedure but of little concern to the payer. This is true not only for adults but also for pediatric populations. Direct costs are generally incurred by parents, whereas the indirect and intangible costs might be incurred by the child and/or the parents. Factoring in all costs from the child's perspective clearly poses a unique difficulty.

Based on these definitions, a study's perspective will determine how costs and benefits are labeled and measured. For instance, early discharge following percutaneous gastrostomy tube placement can be considered at the same time a benefit to third-party payers and an incurred cost by patients and their families; parents may miss work to rehabilitate their children. Clearly, attention must be paid to perspective in interpreting medical cost literature. Although societal costs are generally used as a primary analysis and both CBA and CEA, it is important to keep in mind that the economic impact of an intervention will be reported very differently depending on the perspective of the study.

Cost Analyses

Few cost analyses involving procedures in pediatric gastroenterology have appeared in the medical peer-review literature. Although limited in number, these analyses have tackled pertinent clinical controversies from the provider's perspective of costs and benefits and have contributed important clinical and economic information about current management options.

One example of a recent cost-effectiveness study in pediatric gastroenterology was published by Deutsch and Olson in 1997.[73] In this provocative modeling study, the investigators surveyed both physician practice and associated costs involved in evaluating pediatric patients with colitis-like symptoms. Using a nationwide survey, the investigators were able to demonstrate that significant regional variation in clinical practice was associated with varying costs of care but similar outcomes. At the center of Deutsch and Olson's study was the question of whether the initial evaluation of children with colitis-like symptoms (such as culture-negative diarrhea or rectal bleeding) should consist of flexible sigmoidoscopy or colonoscopy.

By using a clinical survey that identified physician reasoning at each decision-making point, the investigators designed a clinical model for each management approach with estimated costs for each scenario. This emphasis on reasoning allowed the investigators to detect that "physician desire to know the extent of disease" was the most important factor in determining which procedure was employed initially and whether colonoscopy was performed ultimately. The dominant identified strategy in this study, taking the perspective of the providers, was that early colonoscopy was most cost effective.

Deutsch and Olson's study can also be used to illustrate the importance of perspective taken in cost-analysis studies. For example, if the perspective of the payer were taken into account, a different conclusion might have been realized because the cost of colonoscopy far exceeds that of flexible sigmoidoscopy. If the perspective of the patient was used, a CUA reveals that patient-centered outcomes, such as discomfort and preparation, would need to be factored into this analysis and possibly lead to a different relative or absolute result.

In another cost-effectiveness study, Olson and colleagues compared the clinical and economic implications of several treatment strategies in children with recurrent abdominal pain.[74] In this study, the authors investigated the cost-effectiveness of five different approaches: (1) empiric symptomatic treatment for abdominal complaints in children using antisecretory therapy; (2) empiric treatment of all patients for *H. pylori* with antisecretory and antibiotic therapy; and (3) immediate referral for diagnostic endoscopy, as well as two test-and-treat strategies using

(4) noninvasive and (5) invasive (endoscopy) methods, in which treatment with antibiotics was given only for those with documented infection. In their comprehensive assessment, Olson and colleagues created a decision analytic model that incorporated both clinical and economic outcomes of these five strategies. Followed over time, costs incurred related to treatment failures, such as eventual endoscopy, were also included.

In the economic part of the analysis, the investigators assumed the perspective of payer and included only a small portion of the patients' financial burden (the direct pharmaceutical costs). Indirect and intangible costs were not included.

It is interesting to note that when a cost-minimization approach was taken to this model, empiric antisecretory therapy (arm 1) appeared to be the most economical strategy. However, the use of this type of analysis assumed equal effectiveness. Indeed, when the high rate of recurrent pain and the need for endoscopic evaluation in arms 2 to 5 of the study were taken into account, the savings achieved by initially avoiding the invasive tests in many children were lost.

In this study, the authors believed their results to be highly influenced by parents' initial willingness to have their child undergo endoscopy. They postulated that if patients and/or their parents preferred noninvasive workups, then empiric treatment would prove to be more cost-effective. However, if patients and their parents were more willing to undergo early endoscopy, this became the more cost-effective strategy. As such, the authors suggest that evaluating the cost-effectiveness of each procedural and treatment strategy is highly dependent on patient-centered factors.

2. Methodology (Statistical Analysis, Test Interpretation, Basic Principles of Screening with Application for Clinical Study)

Patricia L. Hibberd, MD, PhD
Andrew B. Cooper, PhD

The ever-increasing amount of information on the screening, diagnosis, prevention, treatment, prognosis, and risk factors of pediatric gastrointestinal disease is both exciting and daunting. Fortunately, critical evaluation of the literature and use of information for evidence-based decision-making has evolved into a formal process. For example, the Cochrane Library publishes systematic reviews of studies.[1] Examples of available topics include the following:

- Enteral nutritional therapy for induction of remission in Crohn disease
- Glutamine supplementation for prevention of morbidity in preterm infants
- Feed thickener for newborn infants with gastroesophageal reflux
- Antituberculous therapy for maintenance of remission in Crohn disease
- Budesonide for maintenance of remission in Crohn disease
- Mechanical bowel preparation for elective colorectal surgery
- Interventions for treating collagenous colitis
- Cisapride treatment for gastroesophageal reflux in children

Similarly, the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) Web site provides position papers on various topics.[2] However, systematic reviews are often not available to assist with decision-making about new methods of screening or diagnosing gastrointestinal disease in pediatric patients. Therefore, this chapter focuses on a straightforward way to evaluate reports of tests to screen children for risk of developing gastrointestinal disease in the future or to determine whether disease is already present.

WHAT IS SCREENING?

Screening involves the testing of apparently healthy people to find those who are at increased risk of having a disease, either now or in the future.[3] One of the best examples of a screening program involves the screening of newborns in the United States that has been in place since the 1960s. The overall goal of screening is to reduce morbidity and mortality as a result of early detection of this increased risk, although, as recently reviewed by Khoury and colleagues,[4] concerns are increasingly being raised about population screening for genetic susceptibility to conditions that have their onset in adulthood. The most useful screening tests are for diseases that result in substantial morbidity and mortality, that have a presymptomatic phase during which time the test is positive, and for which treatment or preventive strategies are available and cost effective.

In an ideal world, screening tests would be positive for everyone at risk of developing a disease and negative for everyone who was not at risk of developing the disease. They would be safe, reliable, easy to perform, noninvasive, and inexpensive. Subjects who have a screening positive test need follow-up and may be offered a subsequent diagnostic test and/or ways to prevent disease from occurring at a later stage. One of the best ways to evaluate screening tests is to randomize subjects to receive the test or not receive the test and to compare health over time, although these studies are rarely performed, and the value of screening tests is often inferred from observational studies.

WHAT ARE DIAGNOSTIC TESTS?

Diagnostic tests are usually performed in individuals who have signs or symptoms of disease or who are at risk of having disease based on a positive screening test. Again, in an ideal world, diagnostic tests would be positive for everyone who has the disease and negative for everyone who does not have the disease (ie, the test accurately discriminates between those who do and do not have the disease). Unfortunately, there are few diagnostic tests that meet these criteria. The best way to evaluate diagnostic tests is for subjects in a defined and relevant clinical population to have both the new and a "gold standard" diagnostic test and for the results of the two tests to be read independently and compared.[5,6]

WHAT IS MEANT BY DIAGNOSTIC TEST ACCURACY?

A diagnostic test is evaluated in relationship to the truth, that is, whether or not a disease is present. Four situations are possible:

- The test may be positive, and the subject has the disease (true-positive [TP]).
- The test may be negative, and the subject does not have the disease (true-negative [TN]).
- The test may be positive, and the subject does not have the disease (false-positive [FP]).
- The test may be negative, and the subject does have the disease (false-negative [FN]).

The first step to evaluating a diagnostic test is based on how good it is at correctly identifying subjects who have the disease (sensitivity) and subjects who do not have the disease (specificity). Sensitivity is calculated as the number of TPs as a percentage of all of those with the disease [TP/(TP + FN)]. Specificity is calculated as the number of TNs as a percentage of all of those without disease [TN/(TN + FP)]. The question now is what is an acceptable level of sensitivity and specificity? This varies from test to test. For example, if the test was to diagnose a highly treatable form of cancer providing that it was caught at an early stage, then a diagnostic test that missed the diagnosis in 10% or had a sensitivity of less than 90% would likely be totally unacceptable. Similarly, to expose 5% of children to toxic chemotherapy when they did not have cancer owing to a test specificity of 95% would likely be equally unacceptable. However, sensitivity and specificity alone do not tell the whole story about the diagnostic accuracy of a test.

The next step is to take into account the population that is being tested because the sensitivity and specificity of a test depend on how common the disease is in the population being tested. To understand how this impacts on the clinical usefulness of a diagnostic test, we have made up two hypothetical populations in which the results of a serologic test for immunoglobulin G to *Helicobacter pylori* (diagnostic test) were compared with the results of a gold standard test (endoscopy, biopsy, and positive histology) (Table 66.2-1). In both situations, we assumed that the sensitivity of the test is 80% and the specificity is 90%. One hypothetical population includes consecutive asymptomatic children attending a primary care clinic, 1% of whom truly have *H. pylori*, and a second hypothetical population includes consecutive children with dyspepsia presenting to a pediatric gastrointestinal specialty clinic in a hospital, 50% of whom truly have *H. pylori*. We recognize that it would be unacceptable to perform endoscopy on healthy children, as suggested in the first example. In this example, we are drawing attention to the predictive value of a positive test (PVP) and the predictive value of a negative test (PVN). Although the relationship between test sensitivity and specificity and the prevalence of the disease is typically expressed using Bayes theorem, for practical purposes, PVP can be calculated as the odds of having the disease if the test is positive [TP/(TP + FP)], and PVN can be calculated as the odds of not having the disease if the test is negative [TN/(TN + FN)]. In this example, an asymptomatic child in population 1 has a 7% chance of having *H. pylori* based on the serologic test (very unimpressive), whereas a child with dyspepsia has an 89% chance of having *H. pylori* based on the serologic test.

WHO DECIDES WHETHER A TEST IS NEGATIVE OR POSITIVE?

Many diagnostic tests produce continuous results (eg, serum albumin). In an ideal world, patients with disease would all have test results above a certain point, and healthy subjects without disease would all have test results below a certain point. In reality, test results for those with and without disease overlap, sometimes extensively. Although it is attractive to report a diagnostic test as either positive or negative, some risks are taken when

TABLE 66.2-1 COMPARISON OF THE PERFORMANCE OF A HYPOTHETICAL SEROLOGIC TEST FOR *HELICOBACTER PYLORI* IN TWO PATIENT POPULATIONS

	H. PYLORI ON ENDOSCOPY		
***H. PYLORI* SERUM IGG**	**PRESENT**	**ABSENT**	**TOTAL**
POPULATION 1*			
Positive	8 (TP)	99 (FP)	107 (TP + FP)
Negative	2 (FN)	891 (TN)	893 (FN + TN)
Total	10 (TP + FN)	990 (FP + TN)	1,000
POPULATION 2†			
Positive	400 (TP)	50 (FP)	450 (TP + FP)
Negative	100 (FN)	450 (TN)	550 (FN + TN)
Total	500 (TP + FN)	500 (FP + TN)	1,000

FN = false-negative; FP = false-positive; IGG = immunoglobulin G; TN = true-negative; TP = true-positive.

*1,000 asymptomatic children in a primary care clinic, *H. pylori* prevalence 1%: sensitivity = TP/(TP + FN) = 8/10 = 80%; specificity = TN/(TN + FP) = 891/990 = 90%; positive predictive value = TP/(TP + FP) = 8/107 = 7%; negative predictive value = TN/(TN + FN) = 891/893= 100%.

†1,000 children with dyspepsia in a pediatric gastroenterology clinic, *H. pylori* prevalence 50%: sensitivity = TP/(TP + FN) = 400/500 = 80%; specificity = TN/(TN + FP) = 450/500 = 90%; positive predictive value = TP/(TP + FP) = 400/450 = 89%; negative predictive value = TN/(TN + FN) = 450/550 = 82%.

a cutpoint is chosen to separate normal from abnormal. Figure 66.2-1 shows a hypothetical distribution of serum albumin levels in children with and without liver disease. Let us assume that 200 children were studied, 100 with liver disease and 100 without liver disease. If the cutpoint to separate normal from abnormal is placed at 4 g/dL (see Figure 66.2-1A), in this example, 15% of subjects without liver disease will be incorrectly classified as having liver disease. In addition, 15% with liver disease will be incorrectly classified as being normal. Thus, with a cutpoint of 4 g/dL, the test specificity is 85% and the test sensitivity is also 85%. If the cutpoint is moved to 3.5 g/dL (see Figure 66.2-1B), now only 2% of subjects without liver disease will be incorrectly classified as having liver disease, but 50% with liver disease will be incorrectly classified as being normal. This time, the test specificity is improved to 98%, at the expense of loss of sensitivity, which drops to 0%. Fortunately, there is an efficient way to show the relationship between sensitivity and specificity: using receiver operating characteristic (ROC) curves. ROC curves compare the TP rate with the FP rate (see Figure 66.2-1C). The goal of the diagnostic test is to have a cutoff that has the highest TP rate and the lowest FP rate (ie, is as close to the top left as possible) and as far away as possible from the line of equality (when the TP rate is the same as the FP rate). From above, in Figure 66.2-1A, using a cutpoint of 4.0 mg/dL, the TP rate [TP/(TP + FN) – sensitivity] is 85% and the FP rate [1 – (TN/(TN + FP) or 1 – specificity] is 15%. In Figure 66.2-1B, using a cutpoint of 3.5 mg/dL, the TP rate is 50% and the FP rate is 2%. Clearly, neither cutpoint is perfect, and this raises an important question: Should a cutpoint be chosen at all and, if so, based on what?

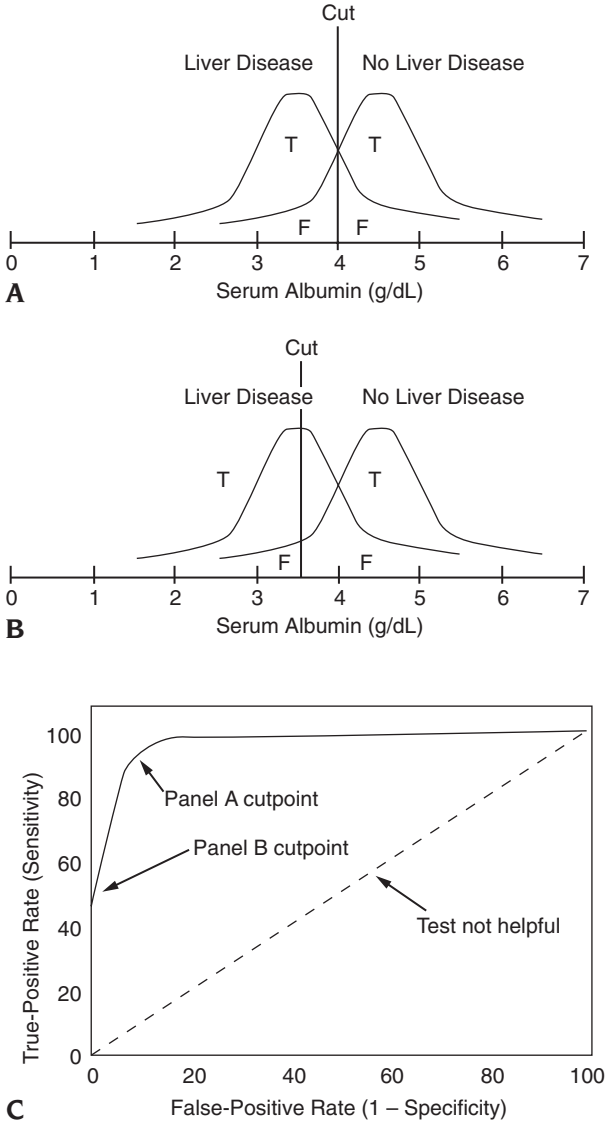

FIGURE 66.2-1 Hypothetical distribution of serum albumin levels in normal children and those with end-stage liver disease. F = false; T = true.

Along with exploring the range of cutpoints, the ROC curve provides another estimate of the overall accuracy of the diagnostic test. The estimate of the area under the ROC curve (AUC), which will be between 0 and 1, is also the probability (or chance) that a random person with the disease will have a higher test value than a random person without the disease. A diagnostic test that has an AUC of 0.5 has the same accuracy as a diagnosis that is made at random (eg, by a coin toss), meaning that the test does not help sort out who does and who does not have the disease. However, just because one diagnostic test has a higher AUC (or accuracy), it does not necessarily make it a preferred test. Cost and invasiveness must also be considered in decisions about which test is preferred.

HOW DOES ONE ASSESS THE VALUE OF A DIAGNOSTIC TEST?

Authors of studies that assess the accuracy of a diagnostic test need to convince the reader that they have done everything that they can to ensure that the test results truly represent the way in which the test will work in the population studied (ie, how useful the test will be). If the test was studied in a patient population for whom the test is not relevant (eg, a new saliva enzyme-linked immunosorbent assay–based assay to detect the presence of *H. pylori* being studied in children presenting with coughs and colds), it is very difficult to make conclusions about the way in which the test will work in children presenting with dyspepsia in whom the test is likely to be relevant. Table 66.2-2 provides a checklist of points to consider while reviewing a study of a new diagnostic test and how these points affect whether the study results are likely to be valid.

Based on this checklist, a description of the study population is critically important and should include the following:

- Demographic characteristics (at least age and gender)
- Presence of comorbid conditions
- Previous tests that have been conducted (likely nondiagnostic)
- Setting of the study (eg, primary care, tertiary care, outpatient, inpatient)
- Duration of symptoms or illness prior to testing
- Spectrum of disease and nondisease in the study population

TABLE 66.2-2 EVALUATING STUDIES OF DIAGNOSTIC TESTS

POTENTIAL THREATS TO STUDY VALIDITY IF ANY OF THE FOLLOWING ARE PRESENT	EFFECT OF THE THREAT	BEST PRACTICES APPROACH TO MINIMIZE THE THREAT OF INVALID RESULTS
POPULATION STUDIED		
Selection of only those patients who are known to have the disease	Cannot estimate diagnostic accuracy of the test	Study population is subjects for whom the test is relevant in clinical practice (eg, all patients presenting with a symptom). Population needs to be described.
Selection of patients known to have the disease and selection of another group known to be healthy normal subjects (case-control study)	Overestimates diagnostic accuracy of the test	
Systematic or unknown reasons for excluding subjects who are part of a relevant clinical population	Over- or underestimates the diagnostic accuracy of the test depending on the reasons for excluding subjects	Consecutive patients in the relevant population are studied
Some patients studied more than once	Over- or underestimates the diagnostic accuracy of the test depending on whether overrepresented subjects have or do not have the disease being studied	Each subject is studied the same number of times (usually once or at first encounter)
COMPARISON WITH A STANDARD		
Gold standard (reference) test is not done in everyone (eg, only those with positive tests have the reference test)	Cannot estimate diagnostic accuracy of the test	Gold standard test is performed on everyone (best practices) or at least a random subset of all subjects
Gold standard test is done for only those patients with positive test and a different test is done for those with negative tests	Cannot estimate diagnostic accuracy of the test	
Gold standard test is read with knowledge of the result of the diagnostic test (or the diagnostic test is read with knowledge of the result of the gold standard test)	Overestimate the accuracy of the test, particularly if either test requires subjective interpretation	The gold standard and diagnostic tests are read independently (blinded) and, if any test requires subjective interpretation, ideally should be read by more than one independent person. Results of agreement of independent reading should be reported.
TESTING		
Way in which the gold standard and diagnostic test were performed is unclear	Cannot interpret diagnostic accuracy	Way in which the gold standard and diagnostic test were performed should be described in sufficient detail to allow reader to replicate the measurements
REPORTING OF RESULTS		
No information on whether indeterminate test results occurred and/or were included or excluded in the analysis	Potential for distortion of diagnostic accuracy	All study results should be reported (positive, negative, indeterminate), and tests of diagnostic accuracy should indicate how indeterminate values were treated and effects on measures of test accuracy

Similarly, a description of the diagnostic test should include the following:

- Precise way (adequate details) in which the test was performed to enable others to reproduce the test conditions
- Cutpoint used to categorize the test as positive or negative and explanation of why that cutpoint was chosen
- The proportion of subjects who could not have the test performed or in whom the test result was indeterminate
- Test reproducibility
- Tables summarizing the sensitivity, specificity, PVP, and PVN compared with an acceptable gold standard

THE NEXT LEVEL: STATISTICAL CONSIDERATIONS

Estimates of sensitivity, specificity, PVP, PVN, and AUC will all have uncertainty associated with them. As such, researchers should also report the 95% confidence intervals associated with these values. The size of the confidence intervals and one's ability to compare the accuracy of a diagnostic test with either a null value or a "gold standard" test will depend on the study's sample size and design. In general, the fewer the patients studied in a study, the wider the 95% confidence intervals associated with the estimates of sensitivity, specificity, PVP, PVN, and AUC. However, most equations relating sample size to a desired power or confidence interval width rely on asymptomatic theory despite the fact that most studies rely on fewer than 50 patients.[7]

CONCLUSION

Improved, noninvasive diagnostic tests for pediatric gastrointestinal disease are urgently needed for a wide range of conditions, but despite the promise of exciting new

technologies (such as genetic testing and videocapsule endoscopy), there is an even more urgent need for improved quality of diagnostic studies to evaluate these new innovations. The ethical and regulatory issues relating to diagnostic testing are discussed in the next chapter (Chapter 66.3, "Ethics and Regulatory Issues").

3. Ethics and Regulatory Issues

P. Pearl O'Rourke, MD
Jennifer P. Stevens, MS

Effective and safe medical care for children requires that care be appropriate to the patient's developmental and/or chronologic age.[1] Advances through research with adult subjects are not always relevant to children. Children and adults can have different manifestations of the same disease process, and age-specific differences in renal and hepatic function make it impossible to directly translate adult pharmacokinetics and pharmacodynamics to the child. In addition, children suffer unique diseases such as sudden infant death syndrome, Reye syndrome, and infantile spasms.[2]

But should children be allowed to be research subjects? Is any risk appropriate for a child? Can children truly volunteer? Can their parents "volunteer" for them? In response to such concerns, a regulatory framework that governs pediatric research has evolved.[3] Investigators working with pediatric populations must negotiate a range of federal, state, local, and institutional protections for vulnerable research participants and must also accommodate a number of methodologic challenges that are unique to pediatric research. This review summarizes the importance of pediatric research, the history of pediatric research ethics, and the fundamental regulatory requirements and provides several recommendations for pediatric research investigators.

IMPORTANCE OF PEDIATRIC RESEARCH

An often-repeated adage is that children are not small adults. Data learned from research conducted with adults may not be scalable to the child. As noted above, children have unique diseases, unique manifestations of "adult" diseases, and renal and hepatic functions that vary with developmental age. Although the focus of this chapter is children in research, it is relevant to at least note that many of the same concerns and issues are also relevant to the developing fetus. The thalidomide tragedy in the 1960s reminded the public of the importance of understanding the effects of diseases and drugs on intrauterine fetal development. Revelations about the teratogenicity of this drug generated support for a rigorous premarket drug safety screening process in the United States and continue to serve as a brutal reminder of the specific vulnerability of the developing fetus.[4]

Too often, even today, pediatric clinicians must provide clinical care without the benefit of age-appropriate, validated data.[5–7] In 2000, Conroy and colleagues demonstrated that as many as 67% of children (421/624) admitted to five general pediatric wards in Europe received drugs that were unlicensed for use in children or were being used off-label.[8] In this study, dosing issues (either amounts or frequency of doses) and use of the drug in an untested age group were the most common reasons for unlicensed or off-label uses. In 1998, McKinzie and colleagues reported a lower but still large rate of off-label drug use for children in a US emergency department: 179 of 521 children (34%) received off-label drug prescriptions, with the highest rate found in patients 3 to 11 years of age.[9] Turner and colleagues reported a significant association between the percentage of off-label drugs prescribed per child and the incidence of adverse events in five pediatric wards in the United Kingdom.[10]

Conducting pediatric research presents a number of unique challenges. Among these are (1) the need for multiple age cohorts to study different developmental stages, (2) small study populations owing to the limited incidence of many pediatric illnesses,[11,12] and (3) the resultant limited industry interest and financial support. There are also a number of pediatric-specific ethical issues to consider: (1) the acceptable risk to which one may expose a child, (2) under what circumstances a child may be a healthy control,[13] (3) at what age a researcher should discuss study participation with a child subject,[14,15] and (4) when and how a child participant should be remunerated.[16]

The US government created a number of initiatives to support pediatric research in the late 1990s. Briefly, these included the following: The Food and Drug Administration (FDA) Modernization Act of 1997 (FDAMA) required that the FDA extend drug testing to children.[17] The National Institutes of Health (NIH), in 1998, specified that children be included in all research barring a scientific or ethical reason for their exclusion.[18] The Children's Act of 2000 codified previous congressional decisions to increase money dedicated to pediatric research.[19]

Of interest, this support for pediatric research came at a time of growing concerns about the adequacy of protections of human research subjects in general and protections for children specifically.[3,20–25] The 1999 death of Jesse Gelsinger, an 18-year-old volunteer in a phase I gene transfer trial conducted at the University of Pennsylvania, and the 2001 death of Ellen Roche, a healthy volunteer in a lung physiology study at Johns Hopkins University, focused much of this concern. Federal assessments of these two tragedies raised issues about informed consent, coercion, reporting of adverse events, and financial conflict of interest, among others. These high-profile cases served as watershed events for

many in the research safety community and prompted a number of changes in the oversight of human research.[26–29]

HISTORY OF HUMAN SUBJECT PROTECTIONS

The Nuremberg Code, which provides the foundation of the current system of human subject protections, was developed following the Nuremberg Military Tribunal convened after World War II. The Code defined 10 ethical principles for research, including, among others, the voluntariness of consent and the need to minimize risk. In the years following, other complementary guidelines and principles for the protection of human research subjects were developed at the World Medical Association Declaration of Helsinki and by the Council for International Organizations of Medical Sciences (best known as CIOMS).

In the United States, federal regulations for the protection of human subjects advanced during the 1960s and 1970s in response to several sentinel events. One of these events was Beecher's review article in 1966, which focused attention on several historic but ethically controversial published peer-reviewed studies.[30] One cited study was Krugman and colleagues' work with infectious hepatitis. The investigators intentionally exposed mentally impaired children between the ages of 3 and 10 years to hepatitis virus, arguing that the children would have been exposed to the virus at some time during their institutionalization.[31] Although parental consent was obtained at admission to the institution, there were many concerns regarding coercion, inadequate consent, and inappropriate risk to this vulnerable population. Following Beecher's article, revelations about the Tuskegee Syphilis Study became public in a 1972 *New York Times* exposé.[32] These two reports together generated a public and professional demand for a regulatory framework.

The federal government responded with a series of initiatives and regulations for the protection of human subjects. *The Belmont Report*, proposed by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (the National Commission) in 1979, provided landmark definitions in the ethical domains of respect for persons, beneficence, and justice and created the groundwork for the current Institutional Review Board (IRB) system of local peer review of human research protocols.[33] The National Commission's work ultimately evolved into the Common Rule, a set of federal regulations, which are described below.

The National Commission also identified additional protections for pediatric research participants. Among other recommendations, the Commission concluded that IRBs should consider the scientific significance of the pediatric protocol, that studies be conducted first in animals and adults before children, that the privacy and confidentiality of parents and children be protected, and that research with wards of the state, underage prisoners, or the mentally infirm be further restricted.[34] The National Commission drew distinctions between research of minimal risk and of greater than minimal risk for pediatric subjects and recommended seeking a child subject's assent and parental permission for participation. These recommendations were ultimately codified in additional regulations, which are discussed below.

REQUIREMENTS FOR FEDERALLY FUNDED RESEARCH: THE COMMON RULE AND SUBPARTS OF TITLE 45 OF THE CODE OF FEDERAL REGULATIONS, PART 46

The Common Rule is the regulatory foundation for the current system of human subject protections. This rule, found at Subpart A of Title 45 of the Code of Federal Regulations, Part 46 (45 CFR 46), "Protection of Human Subjects," is called the Common Rule because it is held in "common" by 17 federal departments or agencies, including the NIH in the Department of Health and Human Services (DHHS), the largest funding agency for biomedical research.[35] Not all research is covered by the Common Rule. The Common Rule covers only human subject research that is conducted or funded by any of the 17 agencies that have accepted the rule. Research that is not conducted or supported by 1 of these 17 agencies is not subject to this rule. Despite this legal allowable "gap" in coverage, most academic institutions that receive NIH funding voluntarily extend these protections to all human subject research conducted by the institution. This extension of the Common Rule is done with a formal agreement with the federal government.

The Common Rule (subpart A of 45 CFR 46) outlines the process of required institution-level peer review of the ethics of individual research projects through a committee called an IRB. The Common Rule provides the general framework for IRB functions, organization, and operations but allows for limited institution-level interpretation in some areas.[36] Investigators are encouraged to familiarize themselves with their institution's IRB policies and procedures.

The Common Rule includes criteria for the membership of the IRB, mandating the inclusion of both scientists and laypersons with appropriate expertise. It specifies that if an IRB reviews research to be conducted with vulnerable populations (eg, children, prisoners, or pregnant women), then that IRB must have members with knowledge specific to research and ethics in those fields.[36]

The process for reviewing research protocols draws a distinction between research protocols of greater risk to subjects that require full IRB review and those of minimal risk, which can be reviewed by an accelerated review process, termed an expedited review. Per the Common Rule, research protocols can be approved only for a maximum of 1 year, at which time investigators must reapply to the IRB for continuing review and approval. The Common Rule also requires that every approved study be monitored at a level that is commensurate with the risk to subjects involved in the study. All changes to the research protocol or informed consent document must be reported to and approved by the IRB (note that sponsors may also require review and reporting of changes). For more detail regarding the Subpart A requirements for an IRB, see Table 66.3-1.[36]

In addition to the Common Rule (Subpart A), 45 CFR 46 also has three other subparts: B, C, and D. Subparts B, C, and D were codified after Subpart A and outline additional regulations for specific vulnerable subpopulations. Subpart B, codified in 1975 and revised in 2001, addresses research with pregnant women, human fetuses, and neonates; Subpart C, codified in 1978, addresses prisoners; and Subpart D, codified in 1983, addresses children. Because Subparts B, C, and D are not followed by all of the aforementioned seventeen agencies that follow Subpart A, these subparts are not considered part of the Common Rule. Researchers should note that the NIH does adhere to all subparts.

Additional Protections for Children Involved as Subjects in Research (45 CFR 46 Subpart D)

Subpart D is of particular importance to pediatric investigators as the principal set of regulations that governs pediatric research. This subpart categorizes pediatric research, unlike adult research, into four levels of risk and benefit that trigger different levels of review, consistent with the recommendations of the National Commission (Table 66.3-2).[37] Three of the four categories can be reviewed and approved by the IRB. These include (1) research not involving greater than minimal risk, (2) research involving greater than minimal risk but presenting the potential of direct benefit to the specific child, and (3) research involving greater than minimal risk that, although not presenting the prospect of direct benefit to the specific child, is likely to produce information about the child's disease or condition. The fourth category addresses research that is greater than minimal risk, that has no prospect of direct benefit to the child, and that would not produce information about the child's disease or condition. The IRB cannot approve research in this last category; it can be approved only by the Secretary of Health and Human Services after consultation with a panel of experts.[37]

Minimal Risk in Pediatric Research. Subpart D fails to define the amount of risk that may be considered minimal for children participating in research. Some interpret minimal risk to include only those risks that a healthy child may experience in everyday activities. However, a 2002 federal advisory committee of experts to the DHHS Office of Human Research Protections interpreted minimal risk to be relative to the health condition of each specific minor. This advisory committee suggested that for a healthy child, minimal risk equated to no additional risk above and beyond the risk that a healthy child encountered on a daily basis. In contrast, chronically ill children faced substantial risk as part of their clinical care, and minimal risk for these children meant no additional risk above and beyond the risk inherent in their standard of care.[38,39]

Pediatric Assent and Parental Permission. Subpart D also amplifies the requirements of informed consent. Consistent with the National Commission's original report, subpart D requires investigators to seek parental permission rather than parental consent, drawing a distinction between the two terms to highlight that one may not consent to research conducted on another person. The IRB can require the permission of either one or both parents depending on the level of risk to the child. The permission of only one parent is adequate for research considered of minimal risk to the child participants (Section 46.404) or for research likely to yield direct benefit to the children (Section 46.405). The permission of both parents is required for pediatric research conducted under Section 46.406 or 46.407 (see Table 66.3-2) unless one parent is deceased, unknown, incompetent, or not reasonably available or when only one parent has legal responsibility for the care and custody of the child.[40] In addition, investigators must also seek the age-appropriate assent of children subjects; of note, failure to object cannot be considered an assent.[37]

TABLE 66.3-1 SUMMARY OF THE REQUIREMENTS OF INVESTIGATORS DELINEATED BY THE COMMON RULE (SUBPART A, 45 CFR 46)[36]

Requirements for IRB approval	Risk to subjects are minimized. Risks to subjects are reasonable in relation to anticipated benefits, if any, and the importance of the knowledge that may result. Subject selection is equitable. Vulnerable populations are given additional protections both in the selection of subjects and the research generally. An informed consent form and process are provided, or a waiver of all or part of the informed consent is approved. A waiver of informed consent may be obtained by an investigator from an IRB if the study involves no more than minimal risk to the subjects, if the waiver does not adversely effect the rights and welfare of the subjects, if the research cannot be conducted without the waiver, and, whenever appropriate, the subjects will be provided additional pertinent information after participation. Adequate provisions for data and safety monitoring are in place when appropriate. Adequate privacy of the subjects and confidentiality of the data are maintained.
Required elements to be provided to each subject when obtaining written informed consent	A statement that the study is research, an explanation of the purpose of the study, the length of time the subject is expected to participate, a description of the procedures, and the identification of the experimental procedures. A description of the risks and benefits. Disclosure of appropriate alternatives that might benefit the subject. A statement of how the confidentiality of the data will be maintained. A description of compensation and the procedures and treatments available for potential injury. Investigator contact information. A statement that participation is voluntary and the subject will not be penalized in any way for discontinued participation. Additional requirements must also be included whenever appropriate (eg, withdrawal from the research).

IRB = Institutional Review Board.

TABLE 66.3-2 ALLOWABLE RESEARCH WITH MINOR SUBJECTS UNDER SUBPART D, 45 CFR 46[37]

Research not involving greater than minimal risk (Section 46.404)	These studies may be permitted if the IRB finds Adequate provisions are made for soliciting the assent of the children and the permission of their parents or guardians.
Research involving greater than minimal risk but presenting the prospect of direct benefit to the individual subjects (Section 46.405)	These studies may be permitted if the IRB finds that The risk is justified by the anticipated benefits to the subjects; The relation of the anticipated benefit to the risk is at least as favorable to the subjects as that presented by available alternative approaches.
Research involving greater than minimal risk and no prospect of direct benefit to individual subjects but likely to yield generalizable knowledge about the subject's disorder or condition (Section 46.406)	These studies may be permitted if the IRB finds that The risk represents a minor increase over minimal risk; The intervention or procedure presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social, or educational situations; The intervention or procedure is likely to yield generalizable knowledge about the subjects' disorder or condition, which is of vital importance for the understanding or amelioration of the subjects' disorder or condition; Adequate provisions are made for soliciting assent of the children and permission of their parents or guardians.
Research not otherwise approvable that presents an opportunity to understand, prevent, or alleviate a serious problem affecting the health or welfare of children (Section 46.407)	Allowable only if the IRB finds that the research study meets this requirement and the Secretary of Health and Human Services, after consultation with a panel of experts, determines that The research presents a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem affecting the health or welfare of children; The research will be conducted in accordance with sound ethical principles; Adequate provisions are made for soliciting the assent of children and the permission of their parents or guardians.

IRB = Institutional Review Board.

Issues of child assent and parental permission are complex. The ethical and legal controversies surrounding parents' ability to provide permission for pediatric subjects were the focus of the 2002 *Grimes v. Kennedy Krieger Institute* case.[41] This case involved the Johns Hopkins–affiliated Kennedy Krieger Institute and its 2-year-old lead abatement study in low-income housing. The judgment of the Maryland Court of Appeals discussed issues of parental consent for the participation of children subjects and attempted to define minimal risk. The court was concerned that the parents had an inaccurate assessment of their children's risks (dust lead level reporting was delayed) and benefits (the offer of a lead-reduced household may have been coercive) in this research. Regarding minimal risk, the court initially determined so-called nontherapeutic research to have a zero-risk standard but relented to define minimal risk as "the minimal kind of risk that is inherent in any endeavor."[41] Given the judgment in the *Grimes v. Kennedy Krieger Institute* case, researchers should be aware of the fluid nature of parental permission in pediatric research.[42,43]

The issue of assent is also controversial. The American Academy of Pediatrics (AAP) recommends seeking assent from children with an intellectual age of 7 or greater.[44] Researchers working with adolescents in studies in which parental consent may be inappropriate should consider state-level laws that designate some adolescents to be "mature minors" or "emancipated minors" under specific circumstances.[15] The AAP recommends several specific elements of assent, which include (1) helping the child achieve a developmentally appropriate awareness of his or her condition, (2) explaining tests and treatment, (3) making an appropriate assessment of the child's level of understanding, and (4) soliciting the child's willingness to participate.[15] Little research has been done in this area of pediatric consent. Tarnowski and colleagues examined forms that parents were asked to sign to grant their permission for their children to participate in research. The language in these consent documents was at the college graduate level rather than the required eighth grade reading level.[45] Susman and colleagues examined the comprehension level of children ages 7 to 20 years participating in cancer or obesity research. Several days following consent or assent, the subjects were found to be less likely to understand the purpose of the relevant research study, the procedures, and the risks involved than they were to understand other, more concrete elements of the study, such as the duration of their participation. When stratified into two age groups, 7 to 13 years and 14 to 20 years, there was no statistical difference in mean scores; age did not appear to affect the children's understanding of some elements of the research study in which they were participating.[46] These findings are similar to assessments of the readability of informed consent forms for adult subjects.[47] Issues of consent, permission, and assent require specific attention to comprehension if this process is to be meaningful.

Remuneration of Pediatric Subjects. Another concern, as in any research, is the issue of coercion or inappropriate influence to elicit a subject's assent or consent. The regulations speak to coercion broadly, but there are no specific recommendations on the issues of remuneration of pediatric or adult research subjects. Dickert and colleagues studied 32 IRBs and found that 37.5% had written guidelines for

investigators about adult research subject compensation. All but one institution had "rules of thumb," suggesting that institutional approaches to adult subject remuneration varied widely.[48] In terms of remuneration of pediatric subjects, Weise and colleagues found that two-thirds of 128 participating institutions permitted payment to pediatric research subjects. Only 7% (6/84) of those who permitted remuneration had written policies. The most common method of payment was money, with gift certificates and savings bonds named as other permitted and common options.[16] Although there is little formal guidance, the AAP recommends that the families of research subjects be reimbursed for direct and indirect costs of study participation. Similarly, remuneration to child subjects should be limited to a token and should be discussed with the child only at the completion of the study.[44]

Additional Protections for Pregnant Women, Human Fetuses, and Neonates Involved in Research (45 CFR 46 Subpart B)

Subpart B of 45 CFR 46 addresses research with pregnant women, human fetuses, and neonates. The specific requirements of Subpart B, revised on November 13, 2001, are described in Table 66.3-3. This revision defined permissible research with fetuses, neonates of uncertain viability, and nonviable neonates, as well as requirements for paternal consent. Note that research with viable neonates, defined as newborns until 28 days of age, falls within the scope of Subpart D.[49]

Subpart B generally requires that research involving pregnant women or fetuses must be of no greater than minimal risk or should hold the possibility of direct benefit to the pregnant woman and/or fetus. Consent is required of only the mother if the research is of minimal risk or if the research is likely to yield direct benefit to either the pregnant woman alone or both the woman and the fetus. Research likely to yield direct benefit only to the fetus requires the consent of both parents.[49]

Although viable neonates are covered in Subpart D, research on neonates of uncertain viability is covered by Subpart B. Research on neonates of uncertain viability is allowed only if there is the prospect of enhancing the likelihood of survival or if the purpose of the research is important and adds no additional risk to the neonate and the information cannot be obtained in any other way. Consent is required from only one parent.[49]

Research with nonviable neonates can be approved by the IRB only if the research will not stop the respiration or heartbeat of the neonate and, similar to research with neonates of uncertain viability, the research is important and adds no additional risk to the neonate, and the information can be obtained in no other way. For research with nonviable neonates, consent must be obtained from both parents except under limited circumstances.[49]

FEDERAL REQUIREMENTS SPECIFIC TO THE FDA

The FDA has its own set of regulations that cover any research conducted on a product that is regulated by the FDA. These regulations present special considerations for human studies that involve drugs, biologics, and devices. These regulations are similar but not identical to those of the Common Rule.

Typically, a sponsor, such as a pharmaceutical, biotechnology, or medical device company, initiates the application but does not function as the investigator. Investigators are required to assume the responsibilities of conducting the research, which include (1) abiding by the investigational plan and statement, (2) protecting the rights and safety of the human subjects, and (3) controlling any drugs under investigation.[50] In some limited cases, an individual or group of individuals may serve as the sponsor-investigator.

Although the FDA requirements for informed consent and IRB review are similar to those of the Common Rule, they are not identical. Some of the differences are listed below. Note that research studies conducted under both the DHHS and FDA are subject to both sets of requirements:

- The FDA permits the use of an investigational drug, device, or biologic for a limited number of emergency uses without prior IRB approval. The emergencies qualifying for this exemption are listed in Table 66.3-4. Each of these uses must be reported in writing to the governing IRB within 5 days, and subsequent use is subject to IRB review.[51]
- The informed consent requirements may not be waived if the risk to subjects is a breach of confidentiality.[52] This is a more stringent standard for waiver criteria than that provided by the Common Rule.
- Potential subjects are required by the FDA to be informed that the agency may review the records of the study. In addition, informed consent forms must be dated and signed by the subjects.[53]

In October 2000, the Children's Health Act of 2000 (Public Law [PL] 106-310) extended Subpart D of 45 CFR 46 (pediatric research) to all health and human services agencies, including the FDA.[19] Prior to this legislation, the FDA was one of several agencies that had agreed to abide by the Common Rule (Subpart A 45 CFR 46), but as the FDA regulated rather than funded research, it did not require the same protections for children as were required by the NIH.

Pediatric drug research was a focus of the 1997 FDAMA and the FDA Pediatric Rule. The FDAMA gave pharmaceutical companies an additional 6 months of patent exclusivity for all uses of the entire active moiety if pediatric-specific trials for on- or off-label uses of those drugs were supported.[17] In 2002, the Best Pharmaceuticals for Children Act (PL 107-109) reauthorized the pediatric provisions of FDAMA.[54] Although the FDAMA produced a regulatory pathway by which sponsors could voluntarily provide these data on drugs, it did not require sponsors to generate pediatric-specific data. Concerned that many drugs would not be evaluated in the voluntary program under the FDAMA, the FDA developed the Pediatric Rule. The Pediatric Rule served as the "stick" to the FDAMA "carrot," mandating that drug companies conduct trials in children if the on-label indication was for a substantial number of children (defined as greater than 50,000 children) or if the drug or

TABLE 66.3-3 SPECIFIC RESTRICTIONS, SUBPART B 45 CFR 46[49]

Research involving pregnant women or fetuses (Section 46.204)	All of the following must be met: Preclinical animal and nonpregnant women studies have been conducted; The risk to the fetus is caused solely by the interventions or procedures that hold out the prospect of direct benefit for either woman or fetus, or the risk is no greater than minimal risk with the prospect of important biomedical knowledge; The risk is minimized for achieving the objectives of the research; The research holds the prospect of direct benefit to the woman, the fetus, or both, or the risk is no greater than minimal risk with the prospect of important biomedical knowledge; If the prospect of direct benefit is solely to the fetus, consent is required of both the mother and father, except under limited circumstances; Both mother and father are aware of potential risks to the fetus or neonate; Children who are pregnant must adhere to the restrictions under Subpart D of 45 CFR 46; No inducements will be offered to terminate the pregnancy; Individuals engaged in the research will have no part in any decision to terminate the pregnancy; Individuals engaged in the research will have no part in determining the viability of the neonate.
Research involving neonates of uncertain viability (Section 46.205(c))	All of the following must be met: Preclinical and clinical trials have been conducted to assess potential risks to the neonates; Individuals providing consent are fully informed of the risks to the neonate; Individuals involved in the research will have no part in determining the viability of the neonate; The IRB determines that (1) the research holds out the prospect of enhancing the probability of survival of the neonate or (2) the purpose of the research is the development of important biomedical knowledge that cannot be obtained any other way and there will be no additional risk to the neonate; Informed consent will be gathered from either parent.
Research involving nonviable neonates (Section 46.205(d))	All of the following must be met: Preclinical and clinical trials have been conducted to assess potential risks to the neonates; Individuals providing consent are fully informed of the risks to the neonate; Individuals involved in the research will have no part in determining the viability of the neonate; Vital functions of the neonate will not be artificially maintained; Research will not terminate the heartbeat or respiration of the neonate; There will be no added risk to the neonate resulting from the research; The purpose of the research is the development of important biomedical knowledge that cannot be obtained by other means; The informed consent of both parents must be sought, except under limited circumstances.
Research involving, after delivery, the placenta, the dead fetus, or fetal material (Section 46.206)	Research with these materials is subject to all state, federal, and local laws and regulations. If identifiable health information of living individuals is used, those individuals are considered human subjects, and all relevant regulations apply.
Research not otherwise approvable that presents an opportunity to understand, prevent, or alleviate a serious problem affecting the health or welfare of pregnant women, fetuses, or neonates (Section 46.207)	The Secretary of Health and Human Services must consult with a panel of experts to determine if the proposed research Presents a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem affecting the health or welfare of pregnant women, fetuses, or neonates; Will be conducted in accord with sound ethical principles; Will require informed consent.

IRB = Institutional Review Board.

biologic would provide "meaningful therapeutic benefit" over existing treatment.[55] In combination, the FDAMA and the Pediatric Rule resulted in an increase in the number of pediatric trials. The Pharmaceutical Research and Manufacturers of America estimated that in 2002, 194 drugs were being studied in children.[56] In 2002, however, the Pediatric Rule was struck down when the US District Court ruled that the FDA had exceeded its regulatory authority.[57] As a result, pharmaceutical companies need only comply with the voluntary provisions of the FDAMA.

TABLE 66.3-4 ALLOWABLE EMERGENCIES BY THE FDA FOR USE OF AN INVESTIGATIONAL DRUG OR BIOLOGIC WITHOUT PRIOR IRB APPROVAL[62]

Life-threatening situations necessitating use of the test article
If the subject is unable to provide consent
Insufficient time in which to obtain consent from the subject's legal representative
No available alternative method of approved or generally recognized therapy of equal or greater likelihood of saving the subject's life

ADDITIONAL REGULATORY AREAS

NIH Policy Guidance on the Inclusion of Children in Research

On March 6, 1998, the NIH published guidance for research conducted with children.[18] This guidance, which defines children as individuals under 21 years of age, requires that children be included in all NIH-supported research unless there are scientific or ethical reasons to exclude them. Hence, the inclusion of children in research is the rule rather than the exception. The justifications for exclusion of children in research are described in Table 66.3-5.[18]

Children's Health Act of 2000 (PL 106-310)

As noted above, this law extended Subpart D of 45 CFR 46 to all agencies of the DHHS. In addition, this broad piece of legislation provided several other pediatric research provisions. One of these provisions is the Pediatric Research Initiative, which authorizes $50 million in funding to support pediatric research by the NIH and to require the FDA to promote the use of clinical trials in pediatric populations. The legislation also creates a pediatric loan repayment program to be administered by the Secretary of Health and Human Services and the director of the NIH for professionals performing pediatric research.[19]

Institutional Requirements and State or Case Law

Although federal law provides the general framework by which human subjects in research are protected, investigators should consider local requirements. State and case laws may provide specific requirements for researchers, particularly those working with vulnerable populations or working in politically charged fields. Similarly, research institutions may have more strict internal policies in place. For example, many institutions extend the requirements of the Common Rule to include all research that is conducted by its researchers rather than restrict the Common Rule to federally supported research. Institutional recruitment and remuneration policies are specific areas that vary widely across institutions.

CHALLENGES TO RESEARCHERS

There are several areas of new and innovative research in which more regulatory guidance is needed. Such research includes broad fetus to adult longitudinal studies, tissue banking, and genetic research, among others. With broad implications for the future of pediatric research and care, it remains unclear how investigators and regulators are likely to proceed in these areas.

Other challenges result from extending human subject protections to fetuses. As discussed above, fetuses are defined as a vulnerable population protected by Subpart B of 45 CFR 46.[49] In addition, in 2002, embryos and fetuses were categorized as human subjects in the charter of the recommissioned Secretary's Advisory Committee on Human Research Protections.[58] The repercussions of these determinations remain unclear.

Another area of concern is the documentation of compliance with existing protections for pediatric populations in research. Similar to studies with adult subjects, two reviews of the pediatric research literature report that in only 52 to 61% of pediatric publications was there proper documentation of appropriate ethical review in the resulting article.[59,60] Sifers and colleagues found that parental permission was documented 41.5% of the time.[61]

Current and future guidance on human subject protections is primarily provided by the DHHS Office of Human Research Protections. Investigators should familiarize themselves with changes in federal, state, and local research policy. By working with vulnerable populations, investigators have a dual responsibility: to protect minor subjects from inappropriate risk in research and to provide pediatric populations with age-specific treatment and care.

RECOMMENDATIONS TO RESEARCHERS

1. Despite difficulties in designing pediatric research, scientifically and statistically sound studies in children can and should be conducted.
2. Consider study designs that maximize benefit to the individual child subject. Minimize risk as much as possible to risk experienced in the subject's daily life.
3. When allowable by the institution, consider remuneration strategies that are age and study appropriate.
4. Consider the most appropriate way to seek a child subject's assent if possible.
5. Review institutional, case, study, and federal policies and restrictions for pediatric research.

TABLE 66.3-5 ALLOWABLE JUSTIFICATIONS FOR EXCLUSION OF CHILDREN IN NIH-FUNDED RESEARCH[18]

The research is considered to be irrelevant to children.
There are laws or regulations barring the inclusion of children to the research.
Data are already available for children elsewhere in this research area.
A separate child-specific study in this field would be more appropriate.
Insufficient data are available in adults to perform the study ethically in children.
The study is designed to collect additional data on an existing adult cohort or
Other special cases, justified by the investigator and acceptable to the review group.

CHAPTER 67

GASTROINTESTINAL ENDOSCOPY

1. *Patient Preparation and General Considerations*

Victor L. Fox, MD

PATIENT AND PARENT PREPARATION

Anticipation and fear of potentially painful procedures provoke intense anxiety in children. These feelings may be compounded by a child's ability to sense parental anxiety. A detailed description of a procedure to the parents and to the patient in terms that are suitable to the child's stage of emotional and intellectual development may relieve some of this anxiety. The preoperative evaluation might also include a brief tour of the procedure facility. Adequate preoperative preparation may reduce anticipatory anxiety and increase patient and family satisfaction with the child's care. It may even have a positive impact on the amount of medication required for adequate sedation.[1] A child should be encouraged to bring attachment objects such as a favorite stuffed animal or blanket to provide comfort and security as he or she enters the strange environment of a hospital or procedure unit. The endoscopist should inquire about past problems with procedures or sedation, thus identifying medical and emotional risk factors that may guide decisions about the optimal procedure setting, type of sedation, and postprocedure monitoring.

A minor hurdle in providing controlled sedation to a child is the establishment of intravenous (IV) access. Premedication with oral[2] or intranasal midazolam[3] and dermal anesthesia using lidocaine preparations such as EMLA (Astra Pharmaceuticals, Wayne, PA) or Numby (IOMED, Inc., Salt Lake City, UT) can reduce the anxiety and pain of inserting an IV catheter. A topical lidocaine or benzocaine anesthetic applied to the posterior pharynx reduces gagging. Sprays work well with most children. Paste can be applied to the pharynx in infants using the tip of a finger or a soft-tipped applicator. Dimmed lights, soft music, comfortable room temperature, familiar objects, and a steady, soothing voice issuing reassuring comments are other environmental comforts that enhance successful sedation in children.[4] Parents are encouraged to accompany their child into the procedure room and during the initiation of sedation unless their own anxiety is too disruptive or stimulating for the child. They should then be escorted to a waiting area during the procedure. The continued presence of a parent during a procedure under sedation has no proven benefit, and distraction of the endoscopist and staff from their primary task is possible.

INFORMED CONSENT

A thoughtful discussion with the patient or guardian about the potential risks and benefits of a procedure should be the initial step in obtaining informed consent. This discussion should also identify the risks of sedation and include alternatives to the proposed procedure. The important elements of this discussion should then be acknowledged in writing. This process of informed consent enhances a sense of trust between patient and physician and provides legal documentation. Clinical investigators must clearly identify and obtain separate consent for any aspects of a procedure that are being conducted solely for the purposes of research. US federal regulations require that children and adolescents provide their "affirmative agreement" (assent) before they are enrolled in any research protocol.[5] Exceptions to this requirement are (1) children unable to provide assent because of age or cognitive abilities and (2) protocols or interventions that directly benefit the patient and are not otherwise available.

DIETARY RESTRICTIONS

Pre-endoscopy dietary restrictions reduce the potential for aspiration of gastric contents during sedation. Patients with large residual gastric fluid volumes with a low pH are at increased risk for aspiration injury.[6] Dietary guidelines are, therefore, primarily designed to minimize the volume of gastric acid at the time of sedation. High-risk patients undergoing deep sedation or general anesthesia (GA) are sometimes given acid-reducing and promotility medications to further reduce volume and elevate the pH of gastric fluid. Stomach contents may also be emptied through a

nasogastric tube. Conventional recommendations for a prolonged fast prior to sedation have been challenged by two studies demonstrating the adequacy of a brief fast. Ingebo and colleagues demonstrated that the duration of fasting correlates poorly with the volume of retained gastric fluid at the time of endoscopy and that clear fluids empty rapidly from the stomach in children.[7] Schriener and colleagues found no difference in gastric volume or pH in children allowed clear liquids 2 to 3 hours before induction of anesthesia compared with conventional prolonged fasting.[8]

The following presedation dietary guidelines adapted from the American Society of Anesthesiologists[9] (ASA) are recommended by the Sedation Committee at Children's Hospital, Boston:

- Children should be offered clear liquids (this includes breast milk but not other milk or formula) up to 2 to 3 hours prior to sedation to avoid dehydration.
- Infants less than 6 months may receive formula up to 4 to 6 hours and clear liquids up to 2 hours before sedation.
- For patients older than 6 months, solids and nonclear liquids should be held for 6 to 8 hours before sedation.

SEDATION AND MONITORING

Endoscopy with or without Sedation

With the exception of limited flexible sigmoidoscopy, most endoscopic procedures of the upper and lower gastrointestinal tract are associated with periods of mild to moderate discomfort and sometimes intermittent pain. The duration and severity of discomfort and pain vary with the complexity of the procedure, patient anatomy, equipment used, and the skill of the endoscopist. A procedure may be prolonged or aborted if the patient becomes uncooperative or combative owing to discomfort. Although most endoscopists prefer the use of sedation to enhance the technical success of a procedure and minimize unpleasant recall by the patient, some will withhold sedation in selected cases to reduce additional risk, time, and cost.

Gastrointestinal endoscopy has been performed safely in children without sedation.[10,11] This practice is most often advocated for young infants, less than 6 months of age. However, it is difficult to ethically justify withholding analgesic and hypnotic medications from children who undergo potentially painful or frightening procedures regardless of age.[12] The physiologic stress and emotional trauma imposed on an unsedated child during an uncomfortable procedure are difficult to measure accurately, although they may have a negative impact on future medical encounters. Therefore, most pediatricians and parents endorse the use of sedation when it can be administered safely.

Depth of Sedation

Despite more than two decades of experience with pediatric endoscopy, controversy remains regarding the preferred depth of sedation and the level of training required to administer sedative medications.[13–15] Confusion over terminology adds to this controversy.[16,17] Levels of sedation are best viewed as a continuum of states that range from minimal sedation (anxiolysis) to GA. Also, the level of sedation in a given patient may fluctuate over time. Moderate sedation, also called "conscious sedation," and deep sedation are controlled states of depressed consciousness whereby the patient maintains protective reflexes. The former describes a patient who is able to respond appropriately to physical stimulation or verbal commands, a state that is often difficult to ascertain in infants and young children. Patients under deep sedation are less arousable and respond less purposefully to pain. GA is a depressed state of consciousness in which the patient is completely unresponsive to painful stimuli and has lost protective reflexes and safe airway support. Because young children often are more anxious and less cooperative than adults, they generally require a deeper level of sedation, at times bordering on GA, to render them motionless. Some endoscopists prefer to enlist the support of an anesthesiologist or specially trained intensivist to induce the necessary level of sedation for an individual patient, while focusing their attention exclusively on the procedure. Other endoscopists will administer sedatives or supervise nurse-administered sedation.

Sedation Risk Factors

A simple anesthesia risk scale used by the ASA for preoperative assessment classifies patients according to their physical status or the presence and severity of systemic disease (Table 67.1-1). ASA class I and II patients and carefully selected class III patients may be safe for IV sedation without airway intervention. Higher risk category patients require anesthesia with complete airway control.

Among ASA class I and II patients, the endoscopist must also consider other factors when choosing an optimal approach for sedation. A history of noisy breathing, nighttime snoring, or sleep apnea should alert the endoscopist to potential difficulties with airway management. Physical findings that may compromise an airway include obesity, short neck or limited neck extension, small mouth, large tongue, tonsillar hypertrophy, deformed palate, small jaw or limited jaw mobility, and generalized or pharyngeal hypotonia. Other general factors include (1) patient age; (2) the patient's prior experience with sedation; (3) expected duration, complexity, and risks of the procedure; (4) sedation, monitoring, and resuscitation skills of the endoscopist and support staff; (5) efficient use of the endoscopist's time and personnel; and (6) cost containment. Transient nonsystemic or mild systemic conditions that

TABLE 67.1-1 AMERICAN SOCIETY OF ANESTHESIOLOGISTS' PHYSICAL STATUS CLASSIFICATION

CLASS	DEFINITION
I	A normal healthy patient
II	A patient with mild systemic disease
III	A patient with severe systemic disease
IV	A patient with severe systemic disease that is a constant threat to life
V	A moribund patient who is not expected to survive without an operation

affect airway risk must also be considered. Mild upper respiratory tract congestion in an awake patient may result in airway obstruction once sedation has been administered. Therefore, elective procedures in children with mild but unresolved upper respiratory tract infection should be deferred until the congestion has cleared.

The jaw thrust maneuver, an oral airway, or a nasopharyngeal airway may be used to acutely improve a compromised airway. However, children with any airway difficulties should have an anesthesia consultation and probable airway intubation for total control.

Sedation Monitoring

Patients who are sedated require intensive monitoring, additional skilled personnel, and immediately available resuscitation equipment. This requires that one assistant, generally a nurse who is skilled in airway management, devotes exclusive attention to patient monitoring and has no other responsibilities during the procedure.[16] A minimum of two assistants is, therefore, required when sedation is administered for endoscopy in children. One assistant supports the airway, assesses vital signs, and administers medications, whereas the other assists with biopsies or other endoscopic interventions. A third assistant may be needed occasionally to restrain an agitated child.

Essential monitoring equipment includes a transcutaneous pulse oximeter, an electrocardiogram monitor, and a blood pressure monitor, preferably an automated device. Improved technology now permits reliable expired CO_2 or capnography recording in nonintubated patients.[18,19] Although this highly accurate measurement of ventilatory function is now a standard of care for anesthetized patients, its role in monitoring nonanesthetized patients remains to be decided.[9] The endoscopy room must be equipped with a continuous source of pressurized 100% oxygen and additional suction outlets. Resuscitation equipment, including an anesthesia bag with large and small masks, medications, and equipment for airway intubation, and a defibrillator must be immediately available.

Medications

For many years, diazepam, a benzodiazepine, and meperidine, a narcotic, were the principal medications used for endoscopy sedation. Although some centers still rely on these medications, others have converted to newer derivatives, midazolam and fentanyl, respectively. Midazolam, roughly equivalent in potency to diazepam, causes minimal pain during IV infusion and provides excellent amnesia. Midazolam alone causes minor respiratory depression but, similar to other benzodiazepines, significantly potentiates the respiratory depression of narcotics.[20] Fentanyl has 1,000 times the potency of meperidine and offers rapid onset and a short duration of action.[21,22] Less urticaria, less nausea, and fewer dysphoric reactions seem to occur with fentanyl than with meperidine.

Midazolam combined with fentanyl produces in children, as in adults, rapid-onset anxiolysis, hypnosis, amnesia, and analgesia, with a relatively brief duration of action and a comfortable margin of safety against complete loss of consciousness. Following an initial dose, both midazolam and fentanyl are titrated using incremental doses every 3 to 5 minutes until an adequate level of sedation is achieved. Although rarely needed, reversal agents, flumazenil[23] and naloxone, are available for midazolam and fentanyl, respectively. Routine use of flumazenil for children undergoing endoscopy has not shown great benefit.[24] The recommended doses for these medications are listed in Table 67.1-2.

A newer IV sedative-hypnotic agent, propofol, has stimulated considerable interest given its rapid onset and brief duration of action with minimal side effects.[25–29] Propofol is typically used to induce a state of anesthesia. In low intermittent or continuous doses, however, it can be used to achieve deep sedation without GA. Because propofol is associated with a rapid transition to apnea and GA, specialists who are highly skilled in airway management, such as anesthesiologists or intensivists, have generally administered it to children. Yet there is growing interest among adult endoscopists for gastroenterologist-administered or supervised nurse-administered propofol.[30] Although analgesia is less important than sedation for most endoscopic procedures, propofol provides none. Therefore, narcotics or other analgesics should be added to propofol for particularly painful procedures.

The dissociative agent ketamine is another potent sedative that has been administered extensively by nonanesthesiologists to immobilize children. Ketamine possesses a number of properties that are desirable for pediatric endoscopy, including reliable deep sedation, amnesia, and analgesia without cardiopulmonary depression.[31] Enthusiasm for this drug has been tempered by concerns about nightmares and hallucinations, as well as laryngospasm. The former is less of a problem in children than in adults and can be attenuated by premedication with midazolam. The latter problem may result from heightened airway sensitivity and increased secretions.

TABLE 67.1-2 MEDICATIONS FOR SEDATION

MEDICATION	DOSE
Midazolam	Oral, rectal, or nasal presedation: 0.5 mg/kg (maximum dose 20 mg) IV initial dose 0.05 mg/kg (maximum 2.5 mg), then titrate additional doses at 3-min intervals to maximum cumulative dose 0.3 mg/kg or 15 mg, whichever is less.
Fentanyl	IV initial dose 1.0 μg/kg (maximum 50 μg), then titrate additional doses at 5-min intervals to maximum cumulative dose 5 μg/kg or 250 μg, whichever is less
Reversal agents	
Flumazenil	IV 0.01 mg/kg (maximum 0.2 mg); repeat at 1-min intervals to maximum of 0.05 mg/kg or 1.0 mg, whichever is less
Naloxone	IV 1 μg/kg, followed by 2 μg/kg if no response after 90 s, followed by 4 μg/kg if no response after additional 90 s, to a maximum cumulative dose of 400 μg

Clinical Studies

Few studies have prospectively examined the outcomes of sedation protocols for children undergoing endoscopy,[32–35] and comparison between studies is difficult owing to differences in study design. Sedation studies for endoscopy have often relied on potentially biased reporting by participants rather than use blinded observers. Nonstandardized behavioral rating scales have also been used. Sedation study methodology must incorporate blinding, validation, and reliable behavioral measures to provide useful comparative data.[36,37]

Several studies have examined the outcome of IV sedation for children undergoing endoscopy. Balsells and colleagues, at the Cleveland Clinic, reported satisfactory safety and efficacy of IV sedation in a retrospective review of 2,711 total endoscopic procedures (2,026 patients) over a period of 12 years.[38] In this group, only 96 (3.5%) procedures were performed under GA. The combined major and minor complication rate was only 0.3%, with no deaths, cardiorespiratory arrests, or aspiration events. Colonoscopy was completed to the cecum in 80% of cases. Chuang and colleagues, at the Children's Hospital of Philadelphia, reported their experience with IV sedation in 614 children undergoing upper gastrointestinal endoscopy.[35] The study included 150 infants under 1 year of age, and less than 1% of patients had incomplete procedures owing to inadequate sedation. Only 19 (3.1%) patients had prolonged oxygen desaturation that was easily corrected with supplemental oxygen, and there were no major cardiovascular or respiratory complications. Similarly, in a prospectively entered endoscopy database at Children's Hospital, Boston (V. L. Fox, unpublished data, 1994), 22 of 663 (3.3%) children undergoing upper endoscopy with IV sedation developed clinically significant oxygen desaturation sufficient to interrupt the procedure or require supplemental oxygen. Seven patients (1.7%) required supplemental oxygen postendoscopy, and two patients (0.5%) needed transient assistance with oxygen delivered by anesthesia bag and mask. No cardiopulmonary arrests or aspiration events occurred.

Gilger and colleagues detected a high incidence (79%) of cardiac dysrhythmias in a prospective study of 34 children receiving conscious sedation for endoscopy.[39] However, all of the arrhythmias were transient, and none required intervention. Sinus tachycardia was the most common, and most arrhythmias were temporally associated with transient oxygen desaturation. Twenty-two patients (65%) developed transient oxygen desaturation, and three patients (8.8%) required supplemental oxygen to correct desaturation.

Some pediatric endoscopists advocate GA for the majority of their patients. Anesthesia renders the child completely motionless and free of pain, discomfort, or memory of the events. It shifts the burden of responsibility and liability of sedation to the anesthesiologist, freeing the endoscopist to focus exclusively on the procedure. Modern pediatric anesthesia may provide superior sedation with respect to some outcome measures. Lamireau and colleagues performed a limited prospective study comparing cardiovascular and respiratory changes and operator satisfaction in two groups of 18 children (age range 3 months to 6 years) who underwent esophagogastroduodenoscopy under either IV sedation or GA.[40] Patients receiving GA desaturated less frequently, had a more stable heart rate and mean arterial pressure, and had higher operator satisfaction scores than patients receiving IV sedation. Some pediatric endoscopists fear that such deep sedation, however, may allow for serious mechanical trauma from the endoscope in an unresponsive patient, particularly during colonoscopy. Few pediatric data support this fear, although one perforation was reported in a recent study of 136 children undergoing colonoscopy under GA.[41] Stringer and colleagues prospectively evaluated 250 colonoscopies in 215 children, all performed under GA over a 3.5-year period during which they reported no colonoscopy-related complications.[42]

Squires and colleagues, at the Children's Medical Center of Dallas, prospectively evaluated the efficacy, safety, and cost of IV sedation compared with GA in 226 children undergoing endoscopy.[43] IV sedation was used in 103 and GA in 123 patients. No serious complications occurred in either group. Five (4.8%) cases with IV sedation and none with GA were incomplete owing to inadequate sedation. Procedure room time tended to be longer for children undergoing upper gastrointestinal endoscopy with IV sedation compared with GA, and no significant time difference was seen with colonoscopy. The average charge for the GA group was more than double that of the IV group.

INFECTION CONTROL

Patients and staff must be protected against infections that may be transmitted or acquired during an endoscopic procedure.[44] Although the rate of transmitted infection is estimated to be very low (1 in 1.8 million gastrointestinal endoscopic procedures[45]), the risk is always present, and most exposures are preventable by adhering to well-established protocols for equipment reprocessing.[46] Microorganisms may be spread by contact with contaminated equipment, blood, or other body fluids or tissues. Universal precautions should be practiced when handling blood or tissue samples to prevent contact with human immunodeficiency virus (HIV), hepatitis B virus, hepatitis C virus, and other serious bloodborne infections. Use of needleless injection catheters will reduce the risk of needlestick exposure during administration of IV medications. Endoscopy staff should wear protective gloves, moisture-resistant gowns, and eye protection for personal protection and to prevent cross-contamination.[47] Face shields are superior to standard eyeglasses for protection against splash contamination of eyes and other mucous membranes.

Although single-use disposable accessories have become commonplace, concerns about cost containment and the growing burden of medical waste sustain interest in reusable accessories. Once reusable equipment has been cleaned, the level of disinfection is determined by the type of item. Critical use items are devices that enter sterile tissue or vascular spaces, such as needles, biopsy forceps, and electrocautery snares. These items require sterilization,

defined as a process that kills all microbial organisms, including bacterial spores. This is usually accomplished by exposure to heat or ethylene oxide gas. Although endoscope water bottles are not truly critical use items, they are easily resterilized and should be filled with sterile water to prevent waterborne microbial contamination. Semicritical items are devices that contact mucous membranes and nonintact skin, such as endoscopes. These items require high-level disinfection but not sterilization. A variety of chemical germicides are used for high-level disinfection. Glutaraldehyde has been used most commonly for disinfecting gastrointestinal endoscopes, but peracetic acid[48] and hydrogen peroxide have also been used.

There are three important steps in endoscope reprocessing: (1) mechanical cleaning, (2) disinfection, and (3) rinsing and drying. Because biologic debris may be retained inside an endoscope,[49] mechanical cleaning by hand is an essential first step. High-level disinfection may be achieved with immersion in 2% glutaraldehyde solution for a minimum of 20 minutes at a room temperature of 20°C. Then the endoscope must be rinsed free of residual germicide and dried to prevent proliferation of any residual microbes during storage. A final rinse with 70% alcohol facilitates this drying stage. Automated endoscope washers may be used, but they require vigilant surveillance for contamination. Most documented transmitted infections have resulted from a breach in disinfection protocol or a contamination of automated equipment.[50]

ANTIBIOTIC PROPHYLAXIS

Antibiotic prophylaxis (Table 67.1-3) should be used for patients with valvular heart disease, biliary obstruction, or pancreatic pseudocyst. If endoscopy-induced bacteremia or contamination occurred, subsequent infection may be life threatening. Prophylaxis is used to prevent peristomal infection for patients undergoing percutaneous endoscopic gastrostomy.[51] Because there are few data measuring the rates of endoscopy-related bacteremia and infection in children, recommendations for prophylaxis have been extrapolated from adult experience. A low rate of transient bacteremia occurs during most types of endoscopic procedures.[52] Stricture dilation and variceal sclerotherapy may result in higher rates of bacteremia. Bacteremia with colonoscopy in adult patients has been reported in the range of 4 to 5%,[53,54] and infectious sequelae are rarely reported.

There have been two prospective studies in children assessing the rate of bacteremia during endoscopy. Byrne and colleagues studied 75 patients (50 esophagogastroduodenoscopy and 25 colonoscopy).[55] They detected a single episode of bacteremia after esophagogastroduodenoscopy owing to group D *Streptococcus*. El-Baba and colleagues studied 108 patients (68 esophagogastroduodenoscopy, 29 colonoscopy, 11 sigmoidoscopy).[56] Four episodes of bacteremia immediately followed the endoscopy, and all were thought to represent skin contaminants.

Indications for antibiotic prophylaxis must take into account both the rate of bacteremia or bacterial contamination and the vulnerability to severe infectious sequelae for a particular lesion or clinical condition. The American Society for Gastrointestinal Endoscopy (ASGE)[57] and the American Heart Association (AHA)[58] have independently issued updated guidelines for antibiotic prophylaxis. The ASGE guidelines recommend prophylactic antibiotics only for patients with high-risk lesions who undergo procedures with higher rates of bacteremia or contamination. Patients with cardiovascular disease and a history of endocarditis, prosthetic cardiac valve placement, system-pulmonary shunts, complex cyanotic congenital heart disease, and synthetic vascular grafts placed less than 1 year prior, are considered to be at high risk for infectious complications. Procedures associated with a higher rate of bacteremia are esophageal stricture dilation, sclerotherapy for esophageal varices, and endoscopic retrograde cholangiopancreatography with biliary obstruction. In other situations, antibiotic prophylaxis either is not recommended or is left to the endoscopist to choose on a case by case basis. Biliary obstruction and pancreatic pseudocyst are conditions with increased risk for infectious complications following endoscopy and warrant antibiotic prophylaxis independent of endocarditis risk. Infectious sequelae are less likely to occur when adequate drainage has been established. The AHA guidelines tend to be more aggressive than the ASGE guidelines in recommending prophylaxis for moderate-risk cardiac lesions. Major changes in the AHA guidelines include a simplified clinical outcome-based stratification of endocarditis risk categories (Table 67.1-4), elimination of the follow-up dose of antibiotic for oral/dental or low-risk procedures, and elimination of erythromycin as the preferred alternative antibiotic for penicillin-allergic patients.

TABLE 67.1-3 ANTIBIOTIC PROPHYLAXIS

ENDOCARDITIS PROPHYLAXIS
High risk
Ampicillin 50 mg/kg (maximum 2 g) and gentamicin 1.5 mg/kg (maximum 120 mg) IV or IM 30 min before the procedure, followed by ampicillin 25 mg/kg (maximum 1 g) IV or IM or amoxicillin 25 mg/kg (maximum 1 g) PO 6 h afterward
Low risk
Amoxicillin 50 mg/kg (maximum 2 g) PO 1 h before procedure
PENICILLIN ALLERGY
Vancomycin 20 mg/kg (maximum 1 g) IV infused slowly over 1 h beginning 1 h before procedure
Use vancomycin in place of ampicillin or amoxicillin and add gentamicin for high-risk patients
PERCUTANEOUS GASTROSTOMY
Cefazolin 25 mg/kg (maximum 1 g) IV or IM 30 minutes before the procedure
ERCP (for biliary obstruction or pancreatic pseudocyst)
Ampicillin/sulbactam 50 mg/kg (maximum 2 g) IV 30 min before the procedure or cefazolin 25 mg/kg (maximum 1 g) IV or IM 30 min before the procedure

ERCP = endoscopic retrograde cholangiopancreatography.

PROCEDURE COMPETENCE AND TRAINING

Endoscopy in children should be performed by physicians with technical and cognitive skills that are sufficient to complete the task with a high rate of success and minimal

TABLE 67.1-4 CARDIAC CONDITIONS ASSOCIATED WITH ENDOCARDITIS

ENDOCARDITIS PROPHYLAXIS RECOMMENDED
High-risk category
Prosthetic cardiac valves, including bioprosthetic and homograft valves
Previous bacterial endocarditis
Complex cyanotic congenital heart disease (eg, single-ventricle states, transposition of the great arteries, tetralogy of Fallot)
Surgically constructed systemic pulmonary shunts or conduits
Moderate-risk category
Most other congenital cardiac malformations (other than above and below)
Acquired valvular dysfunction (eg, rheumatic heart disease)
Hypertrophic cardiomyopathy
Mitral valve prolapse with valvular regurgitation and/or thickened leaflets
ENDOCARDITIS PROPHYLAXIS NOT RECOMMENDED
Negligible-risk category (no greater risk than the general population)
Isolated secundum atrial septal defect
Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residua beyond 6 mo)
Previous coronary artery bypass graft surgery
Mitral valve prolapse without valvular regurgitation
Physiologic, functional, or innocent heart murmurs
Previous Kawasaki disease without valvular dysfunction
Previous rheumatic fever without valvular dysfunction
Cardiac pacemakers (intravascular and epicardial) and implanted defibrillators

complications. The necessary skills are generally acquired through formal training programs in pediatric gastroenterology. Pediatric endoscopy is also performed by pediatric surgeons who are trained in flexible endoscopy and adult gastroenterologists who offer expertise in advanced diagnostic and therapeutic techniques.

The North American Society for Pediatric Gastroenterology and Nutrition (NASPGN) has issued revised guidelines for training in pediatric endoscopy.[59] These guidelines suggest a two-tiered program of training for basic and advanced skills and include a table of minimum threshold numbers (eg, 100 cases each for diagnostic esophagogastroduodenoscopy and diagnostic colonoscopy) that are recommended before competence can be assessed for various procedures. The threshold numbers were adapted from previous ASGE guidelines. The techniques for hemostasis of variceal and nonvariceal bleeding, dilation of strictures, and placement of enteral feeding catheters are listed under advanced training.

The ASGE has also issued updated guidelines for training in endoscopy.[60] The ASGE guidelines were revised after objective evaluation of trainee skills failed to substantiate the previously recommended threshold numbers for assessing procedure competence. Recent data indicate that much higher threshold numbers are required for the average trainee to attain competence. The current ASGE guidelines distinguish between standard and advanced types of procedures and have abandoned threshold numbers in favor of serial assessment of cognitive and technical skills for individual trainees. In contrast to NASPGN guidelines, ASGE guidelines include endoscopic hemostasis, stricture dilation, and enteral access under standard procedures. Technical competence is defined as achieving 80 to 90% technical success with a specific skill such as intubation of the pylorus during esophagogastroduodenoscopy or intubation of the ileum during colonoscopy. Expert endoscopists are more likely to perform at a level of 95 to 100% technical success. Both the NASPGN and ASGE encourage a formal program of endoscopic training with periodic review of each trainee's progress led by a training director with advanced skills in endoscopy.

QUALITY IMPROVEMENT

Quality assurance is a term used to describe programs that identify and rectify problems leading to unacceptably poor performance or outcomes. In contrast, quality improvement is a term applied to programs that evaluate performance with the goal of continuous improvement beyond minimum standards. Endoscopy units are ideally suited to systematic data collection and multidisciplinary peer review, both core elements of a quality improvement program.[61] The procedure record and pathology reports, combined with clinical outcomes, provide a wealth of data that can be easily monitored and evaluated. Computerized reports may facilitate data collection and analysis. Once important clinical indicators are identified, an individual endoscopist or an endoscopy center can be assessed and compared with internal and external standards of care. Some examples of useful clinical indicators include (1) appropriateness of indications for specific procedures, (2) technical performance or successful procedure completion, (3) adequacy and yield of histopathology samples, (4) sedation- and procedure-related complications, and (5) beneficial clinical outcomes. Data can be used for reporting to hospital officials in charge of renewing clinical staff privileges and to agencies that issue institutional accreditation such as the Joint Commission on Accreditation of Healthcare Organizations.

2. Upper Gastrointestinal Endoscopy

Michela G. Schaeppi, MD
Jean-François Mougenot, MD
Dominique C. Belli, MD

In the late 1960s, endoscopic equipment saw the development of the fully flexible endoscope. This and further improvements, with smaller diameter and videoendoscopes, made it accessible to pediatrics, allowing its use in almost all ages and weights.[1–4] In 1972, a working group of the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) convinced Olympus to develop the first pediatric endoscope. A new dimension was introduced 10 years later with the appearance of therapeutic endoscopy.[5] In the meantime, with advances in sedation and the development of specialized care units, it became increasingly distinct from adult endoscopy.[6–10] At present, endoscopy plays a primary role in the diagnosis and management of pediatric gastrointestinal disorders. As endoscopy has become part of the everyday life of the pediatric gastroenterologist,[11,12] guidelines for training minimums to ensure competence have been issued by the North American Society of Pediatric Gastroenterology and Nutrition,[13,14] the Joint Advisory Group, and, more recently, by the endoscopy steering group of the British Society of Paediatric Gastroenterology, Hepatology and Nutrition.

Before the Procedure

An important part of the procedure actually takes place before the endoscopy itself. The need for an upper examination being established, preoperative assessment will provide information on both sides. The endoscopist will inquire about past problems with procedures or anesthesia, as well as a personal and family history, to adjust any aspect of the procedure in consequence (eg, administration of antibiotics, discontinuation of some medications). Examination of the child will reveal unusual bruises suspicious of a coagulopathy, physical attributes such as retrognathia or micrognathia, a short neck that can make intubation difficult, or a loose tooth needing to be removed. From the patients' point of view, they and their parents can address questions and concerns while benefits and potential risks are explained to them. It is essential that they are taken through all aspects of the procedure, not only for legal reasons but also to reduce their anxiety. When possible, a brief visit to the day-care unit and endoscopy suite should be proposed. The rooms are child friendly, with toys, decorations, and videotapes. In fact, good psychological preparation is known to reduce not only the stress but also the amount of sedation needed.[15] Part of this assessment can be performed by a trained nurse.

Consent

Over the years, informed consent has changed from an ethical notion to a legal requirement. Express consent must be obtained from at least one parent or legal guardian, ideally 24 hours before the procedure. Each unit should develop a code of practice suitable to its mode of operation; nevertheless, written should be preferred to oral consent. In some units, a leaflet is distributed containing the main information. It is the physician's duty to provide information about the nature of the procedure, its reason, and its benefits but also the risks, complications, and alternatives to the procedure. Children should be involved in the discussion, encouraging active participation in their own health care at an age-appropriate level of understanding.[16–24] An increasing number of units let adolescents sign their own consent form, although this has no legal value. The endoscopist should countersign to prove that information was provided. In case of intravenous sedation, some units allow one parent to stay during the procedure. When research biopsies are to be collected, a separate consent should be signed after approval by the institutional review board or local ethical committee.[17,25–30]

Preparation

The patient should fast to minimize the risk of pulmonary aspiration. Recognized as a cornerstone in safe practice, the duration of the fasting itself has not reached worldwide consensus, and every institution follows its own protocol.[31] In an attempt to rectify this, guidelines have been established,[32,33] and we recommend that gastroenterologists read those published in the country of practice. However, some general lines can be drawn: the conventional 8-hour fast applied in adult practice is suitable only for the older child. General consensus allows a last feed 4 hours prior to sedation in those 0 to 5 months old. Some institutions are more flexible and allow clear fluid, including breast milk, to be given up to 2 hours prior to sedation. In older children, feeds will be stopped 6 hours before sedation.

Adequate venous access is important not only for administration of medication but also in case quick rever-

sal is needed. It is good practice to check patency just before the start of the procedure.

DURING THE PROCEDURE

Monitoring

At present, pediatric patients undergoing an endoscopy must have some sort of sedation. The use of the different agents available is discussed below; however, all can cause side effects and, at times, unpredictable reactions. Therefore, cardiopulmonary monitoring is essential to provide optimum safety and conditions for both the patient and the endoscopist.[34] The basic equipment includes a pulse oximeter, to monitor oxygen saturation and heart rate, a pressurized oxygen source, and a suction outlet. A ventilation bag with age-appropriate–sized masks and suction tubes should be ready and checked before the start of each procedure. Most equipment also includes a blood pressure monitoring device. In addition, an immediately accessible resuscitation trolley is an essential element. The last important factor for the comfort and safety of the patient is the room temperature, which should be adjustable and appropriate for the age to avoid hypo- or hyperthermia. The safest practice is that one person, a nurse or a physician, trained in pediatric life support is fully dedicated to the vital signs surveillance throughout the procedure.

Sedation

Potential complications of upper endoscopy among children must not be underestimated and are related to both endoscopy methods and the medications used for sedation. The most frequent complication in endoscopy is slight to profound hypoxemia, which is mainly due to sedation, resulting in a dispute between the advocates and opponents of the need for sedation in adult cooperative patients. Unsedated upper endoscopy in children has also been documented and judged to be safe and feasible in motivated children.[35] However, 80% of these patients would choose to have sedation if upper endoscopy was to be repeated.

From a pediatric point of view, there is no doubt that children are unable to express their pain and fear. Consequently, the rationale and aims of sedation are evident in pediatrics and are shown in Table 67.2-1. At present, this attitude is shared by both American[36] and English[37] adult gastroenterologists because only 2% of physicians perform endoscopy without any medication in these countries. Furthermore, sedation must be administered to all pediatric patients, especially in infants and young children,[38] because pain is a real problem in medically and surgically treated pediatric patients, even neonates.[39]

TABLE 67.2-1 AIMS OF SEDATION IN PEDIATRIC GASTROINTESTINAL ENDOSCOPY

To give maximal comfort to the child during endoscopy
To aim for amnesia of endoscopy
To facilitate quick, precise, and safe endoscopy
To use safe and short half-time agents that provide a rapid onset and effective sedation with minimal side effects

Preparatory information and psychological preparation are mandatory before esophagogastroduodenoscopy (EGD). Indeed, they can reduce anxiety and procedural distress in both adults and children.[40] Furthermore, less sedation seems to be necessary after good psychological preparation.[41] In addition, a calm and relaxed atmosphere in the examination room is recommended. In our experience, hypnosis can also be of great help to patients who need repeated procedures.

Local anesthetic agents are widely used by adult[37] and pediatric gastroenterologists. Local anesthesia can be a good complement to intravenous sedation. Indeed, the amount of medication necessary seems to be reduced owing to the lack of pharyngeal stimulation. In our experience, this positive effect is correlated to the level of sedation depth, being more effective in the "lighter" sedation regimen. When used, local anesthesia with lidocaine, without exceeding a dose of 5 mg/kg body weight, can be recommended.

As regards pharmacologic sedation, the most important goals are maximal comfort, endoscopy amnesia, and a short-term effect drug, leading to short time of onset of sedation, length of procedure, and recovery time. The widespread use of sedation in EGD in children imposes the need for resuscitation and monitoring equipment in the endoscopy room. Standard monitoring must include an electrocardiogram, a blood pressure monitor, and a pulse oximeter. Pediatric anesthesiologists are becoming increasingly involved in this process because the risk of disaster is great when a child is sedated and scoped by the same person.

The types of sedation can be described as follows:

- Intramuscular "lytic or so-called Toronto cocktail"
- Intravenous diazepam or midazolam alone
- Intravenous diazepam or midazolam with meperidine, fentanyl, or alfentanil (± atropine)
- Intravenous propofol
- Miscellaneous drugs
- Endotracheal anesthesia

Half-life time and bolus dose of drugs used for sedation are shown in Table 67.2-2. It is important to note that half-life times are often different between children and adults.

Historically, the combination of intramuscular meperidine, promethazine, and chlorpromazine, the so-called "lytic or Toronto cocktail,"[42] was used for a large variety of pedi-

TABLE 67.2-2 HALF-LIFE TIME AND BOLUS DOSE OF DRUGS USED FOR SEDATION DURING ESOPHAGOGASTRODUODENOSCOPY

DRUG	$T^1/_2$ (H) CHILD 3–10 YR	$T^1/_2$ (H) ADULT	IV BOLUS DOSE
Diazepam	7–18	20–50	0.1–0.2 mg/kg BW
Midazolam	1.2	2–3	0.1 mg/kg BW
Meperidine	1.5–4	2–5	1–2 mg/kg BW
Fentanyl	1.1	2.5–5	1–3 µg/kg BW
Alfentanil	1.0	1.6	7.5–10 µg/kg BW
Ketamine	2.2	2.5–2.8	2 mg/kg BW
Propofol	0.5	4–7	2–3.5 mg/kg BW

BW = body weight; IV = intravenous.

atric procedures. Nevertheless, the efficacy of its sedative effect is limited in EGD, and an intravenous sedation must be favored. Benzodiazepines were the most routinely used method of sedation because of their anxiolytic, sedative, amnesic, and muscle-relaxing properties. Among them, diazepam was the usual choice for many years; however, its half-life time is long, discouraging its use in newborn and young children. Moreover, diazepam has respiratory-depressing effects, especially when combined with narcotics.[43] At present, midazolam replaces diazepam because it has more sedative potency, more anterograde amnesic activity, and fewer local effects at the injection site.[44] In addition, midazolam has a short time of uptake and elimination. The effective bolus dose is of 0.1 to 0.2 mg/kg body weight. It also has a potent respiratory negative effect, which is dose dependent and enhanced by concomitant use of opioids. To shorten the total time of EGD, some adult gastroenterologists recommend reversing the effect of midazolam. However, this would not seem necessary in children because they recover rapidly after correct medication.

Opioids have also been used for many years and are synergistic with benzodiazepines.[45] They are useful in providing analgesia and sedation, as well as in decreasing the need for other drug requirement and allowing smooth recovery. Their disadvantages include nausea, vomiting, respiratory depression, hypotension, dysphoria, hallucinations, and bile duct spasm. Meperidine is a long-acting narcotic analgesic that is commonly used in pediatric EGD even if it does not represent a modern anesthesiologist approach.[46] This is explained by its large safety margin in the inexpert hands of endoscopists. Doses for intravenous sedation are a bolus of 1 to 2 mg/kg body weight and should then be titrated. Meperidine is generally used with benzodiazepine,[44,47] and 80% of patients have total amnesia after the procedure.[48] As a combination of drugs was advocated to improve the quality of sedation, other drugs were tested alone or in combination. Among them, fentanyl (1–3 µg/kg body weight) and alfentanil (7.5–10 µg/kg body weight) were studied because of their quicker effect. In a study, we compared a combination of alfentanil-midazolam with meperidine-midazolam.[38] Alfentanil-midazolam had a shorter sedation time and recovery period, with a lower risk of hypoxemia.

The recent development of propofol, a sedative-hypnotic agent, has led to an improved quality of sedation during pediatric EGD.[49] The main advantages of this drug are rapid recovery, less prolonged sedation, and a lower incidence of nausea. The dose is 1 to 3.5 mg/kg body weight as a bolus, followed by a titrated infusion of 0.1 to 0.3 mg/kg body weight/min. Propofol can be used in association with benzodiazepine.

Other drugs have been proposed: intramuscular ketamine, especially in children older than 7 years,[50] or inhaled anesthetic gas. Chloral hydrate and atropine are frequently used in addition to a standard regimen of sedation.

Finally, endotracheal anesthesia is rarely performed because effective deep intravenous sedation is satisfactory in most cases. It can be used for young children (< 2 years), for patients who undergo upper and lower endoscopy in the same session, or for interventional procedures.

Antibiotic Prophylaxis

A transient bacteremia seldom occurs during a procedure and is usually cleared spontaneously by healthy patients.[51] The reported incidence ranges from 0.5 to 4.2% for diagnostic EGD.[51–55] It is important to distinguish diagnostic endoscopy from therapeutic endoscopy, which carries a higher incidence: 8.9% for variceal ligation, 11% for endoscopic retrograde cholangiopancreatography, 15.4% for variceal sclerotherapy, and 22.8% for esophageal dilation.[53,56]

The incidence might even be lower in the pediatric population as shown by the two prospective studies carried out to determine the incidence of bacteremia that identified 1 episode in 75[54] and 4 probable contaminations in 108 children.[57] Neither mucosal biopsy nor polypectomy seems to be a risk factor.[58,59] These episodes of bacteremia are asymptomatic and short-lived. The most feared complication, endocarditis, is reported in a few patients, [60,61] mainly those with risk factors.[52,54,56,62–65] Antibiotic prophylaxis has been demonstrated to be efficient and to diminish incidence by 49%.[66] Over the years, the number of patients with a cardiac implant has steadily increased, yet no evidence of any increase in the incidence of endocarditis has been reported. To answer the question of which patient should benefit from prophylaxis, guidelines have been established by several organizations.[67–74] On average, about 1 to 3% of patients undergoing endoscopy will need prophylaxis.[75] Despite these publications, inappropriate use of antibiotics reaches up to 90% of cases, with a tendency to overtreat patients, [76,77] although failure to treat is also reported.[78] The institution of a mechanism for continuous quality improvement, as simple as monthly meetings, could significantly reduce overprescription by half.[76]

Most pediatric centers use protocols following the guidelines issued by the American Heart Association (AHA) and the American Society of Gastroenterological Endoscopy (ASGE)[68,79] recommending administration of prophylactic antibiotics only in selective situations.[74] Specific clinical conditions recognized as such are cardiac lesions with high or moderate risk of bacterial endocarditis.[80–83] Durack has established a list of high, moderate, and low risks, which are summarized in Table 67.2-3.[51] Available recommendations are not standardized, with the ASGE proposing prophylaxis only in high-risk patients, whereas, recently, the AHA proposed a simplified regimen for moderate-risk patients. It consists of dropping the gentamicin and the second dose of antibiotics. The latter dose is thought to be unnecessary because prolonged serum levels above the minimal inhibitory concentration are obtained with amoxicillin.[84,85] Whereas the parenteral route is recommended in the first group, oral administration is proposed as a choice in the latter. Mitral valve prolapse is addressed specifically by Dajani, and physicians treating such a patient should refer to his publication.[70]

Other special conditions are immunocompromised, either neutropenic or immunosuppressed, children. Neutropenia, depending on the level of cells, is seen as either a high (neutrophils < 100×10^9/L) or a moderate (neutrophils 100–500×10^9/L) risk in Europe[73,86] but not in America and Canada.[68] An American-Canadian survey of

TABLE 67.2-3 CARDIAC INFECTION RISK LEVEL

HIGH RISK	MODERATE RISK	NEGLIGIBLE RISK
Prosthetic valve	Congenital malformations	Isolated ASD
Surgically constructed pulmonary shunt or conduit	Acquired valvular dysfunction	Surgical repair ASD, ventricular septal defect, patent ductus arteriosus
Previous endocarditis	Hypertrophic cardiomyopathy	Pacemakers
Complex congenital cyanotic heart disease	Mitral valve prolapse with regurgitation and/or thickened leaflets	Physiologic or functional heart murmurs
		Previous Kawasaki disease or rheumatic fever without valvular dysfunction

ASD = atrial septal defect.

current practice in 15 pediatric gastroenterology centers showed that only 20% give antibiotics for upper endoscopy and 33% for lower endoscopy, yet no data on the rate of infectious complications were reported.[74] Patients carrying a central line, a ventriculoperitoneal shunt, or an orthopedic implant are also problematic patients, for which no recommendations are published. In the same study, current practice indicates that 20% will give antibiotics for upper endoscopy and 40% for lower endoscopy.[74] The final decision should be made case by case, leaving room for clinical judgment and experience.

Gram-positive bacteria are the most commonly implicated germs. Therefore, in case of cardiac risk, the recommended regimen is as follows[73,74]:

- A combination of ampicillin (50 mg/kg, maximum 2 g) and gentamicin (2 mg/kg, maximum 120 mg) intravenously or intramuscularly 30 minutes prior to the procedure. Some centers will give an additional oral dose of amoxicillin (25 mg/kg) 6 hours later or ampicillin (25 mg/kg, maximum 1 g) intravenously.
- In patients allergic to penicillin, amoxicillin is replaced by vancomycin (20 mg/kg, maximum 1g) or teicoplanin (6 mg/kg).

In addition to cardiac risks, several conditions need special attention:

1. In neutropenic patients, infections can be caused by anaerobes; as a result, metronidazole (7.5 mg/kg) is added to the above regimen.
2. In patients with central lines, prosthetic material (especially orthopedic), ventriculoperitoneal shunt, or ascites,[87] some centers recommend the use of prophylactic antibiotics.
3. During interventional procedures (stricture dilation, sclerotherapy, percutaneous endoscopic gastrostomy [PEG]), a prophylaxis is mandatory because the risk of complication following infection is higher. For example, the rate of skin infection is higher in PEG without antibiotic prophylaxis.[88]

AFTER THE PROCEDURE

Monitoring

The monitoring set during the procedure will be continued, particularly for small infants for the next 15 to 30 minutes, either in the recovery room or on the ward. If asleep, the patient is placed in the lateral position. If midazolam was used, the child stays on the ward for a minimum of 2 hours. Parents are informed that amnesia is a common effect of the drug and can last up to 8 hours. Drinks are allowed 1 hour after the end of the endoscopy; special attention is brought to the deglutition if anesthetic spray was used to avoid choking.

Cleaning the Scopes

Contaminated equipment can transmit infection either from one patient to another or, less commonly, to staff. Implicated germs can be either pathogenic or opportunistic in the case of the immunocompromised patient. Proper and adequate cleaning is a major concern for the patient's and staff's safety. Thus, guidelines have been formulated and modifications made in recent years by several societies.[67,89–92]

Legal Rules. Endoscopes, accessories, disinfectants, sterilizing devices, and washing machines are submitted to local laws. For example, in Europe, they must be in conformity with the European rules.

Levels of Disinfection. Three categories to which medical devices can be assigned are critical, semicritical, and noncritical. Noncritical items (eg, floors, walls, blood pressure cuffs, and furniture) come into contact with intact skin but not with mucous membranes. Semicritical items are devices that come into contact with intact mucous membranes or skin that is not intact. In general, these items should be free of all microorganisms, with the exception of small numbers of bacterial spores. The flexible scopes (gastroscope, duodenoscope, and colonoscope) are referred to as semicritical or class II. They need a high level of disinfection with mycobactericidal, viricidal, and sporicidal activity, the necessary exposure time being determined by the time it takes to inactivate 10^6 resistant non–spore-forming test microorganisms, including, for example, hepatitis B virus, human immunodeficiency virus (HIV), and *Mycobacterium tuberculosis* var. bovi. Items assigned to the critical category present a high risk of infection because they penetrate skin or mucosa or come into contact with normally sterile tissues or the vascular system. They need sterilization when possible; if not achievable, liquid chemical germicides can be used with long exposure. Accessories are defined as such; therefore, grasping forceps, polypectomy snares, injection needles, and cytology brushes should be sterilized or disposed of.

Disinfectants. Two percent glutaraldehyde is the most widely used product. At room temperature, it inactivates most bacteria in 1 minute, HIV in 2 minutes, and hepatitis B virus in less than 5 minutes.[93–98] For hepatitis C virus, the risk persists because ribonucleic acid can be present in

the operating channel and on the biopsy forceps, and a longer washing time (20 minutes) is necessary.[95,96,99] The same washing time will eliminate microbacteria, in particular *M. tuberculosis*. Although this risk has not been described in digestive endoscopy, it is important to remember that some equipment can be shared with bronchoscopes, a device that can be in contact with such germs.

Glutaraldehyde creates frequent adverse reactions that can be severe. Reports of allergy, dermatitis,[100] conjunctivitis,[101] and rhinitis and asthma [102–104] in staff and colitis in patients, owing to improperly cleaned scopes, have been made.[105,106] To limit these disadvantages, procedures take place in a dedicated room, well ventilated with a minimum of 12 volumes/hour.

A suitable alternative is peracetic acid (0.2–0.35%), which has the advantage of being less of an irritant; however, it is more expensive and less stable than glutaraldehyde. It acts by releasing free oxygen and hydroxyl radicals. It has rapid activity against vegetative bacteria, mycobacteria, fungi, and viruses.[107–109] It can cause cosmetic damage to the scopes, but without functional alterations. It can be used in association with hydrogen peroxide (7.5%). It has bactericidal and viricidal activity after 5 minutes and kills spores and mycobacteria in 10 minutes.

Chloride acid and superoxide water are highly microbicidal and are used in some units. The ASGE recommends a final rinse with 70% alcohol for its drying effect on the channels.

Tap water is usable for manual washing of semicritical scopes, but sterile water is necessary for the cleaning of critical ones. For the washer or disinfectors, the water has to be of level II (< 10 opportunistic microorganisms/100 mL at 22°C and 37°C, without *Pseudomonas aeruginosa*). This quality of water is obtained by using filters (0.2–5 µm).

Biologic Controls. Hospital tap water should be controlled on a regular basis, in particular for the presence of *P. aeruginosa*. Final rinse of the scopes requires a microbiologic quality of level I: < 100 opportunistic microorganisms/100 mL at 22°C and 37°C, without *P. aeruginosa* per 100 mL.

Regular checking (once per trimester) of the scopes is necessary by swabs at the level of the canals, exits, outer sheath, and biopsy cap. This allows the identification of poor technique and the modification of clinical practice.[110] In case of contamination after glutaraldehyde sterilization, 50 mL of a sterile mixture containing Tween 80–lecithin is injected in each canal or 200 mL from a common irrigator. If the bottles of liquid lavage, the cleaning water, and the knobs are autoclaved, the vehicle responsible for the contamination is often the biopsy channel. A new washing cycle needs to be performed, including an alkaline enzymatic washing product for 15 minutes and a phase of sporicidal disinfection for 60 minutes. If the problem persists, the scope should be sent to the manufacturer, which will decide if the internal sheaths need to be changed. The remaining water in the washer or disinfectors, along with the incoming water, needs to be checked monthly.

Flexible endoscopes cannot be autoclaved. For the material that tolerates it, water vapor at a temperature of 134°C for 18 minutes should be used after a wash without glutaraldehyde.

Recently, there has been concern about Creutzfeldt-Jakcob disease (CJD) and neurodegenerative diseases in general. Their causative agent, the prion, is resistant to most physical and chemical inactivation methods; therefore, endoscopy should be reconsidered and avoided whenever possible. In pediatric endoscopic procedures with no potential risk, the above disinfection rules are estimated as sufficient by most sanitary authorities. On the contrary, the recommendation from the Gastroenterologists Working Party of the British Society of Gastroenterology Endoscopy Committee is to destroy and incinerate material used in a patient with definite disease because no safe way to guarantee prion eradication exists.[111–113] This point of view is more severe than the recommendation from infectious disease specialists suggesting that standard cleaning and high-level disinfection protocols would be adequate for reprocessing.[114] In patients suspected of CJD, no endoscopy should be scheduled before confirmation of the disease. Any patient presenting with neurologic signs or recent progressive dementia should be suspected of CJD. In patients at risk of CJD (having received extracted growth hormone or gonadotropin, a family member of a potential or confirmed case, neurosurgical intervention before 1994), the washing of the scope includes two cycles with alkaline without aldehyde for a minimum of 15 minutes before a rinse with tap water and then disinfection with glutaraldehyde. The infectivity of the variant CJD seems to affect the peripheral tissues before the brain. The protein prion (PrPsc) has been found in lymphoid tissues (tonsil, rectum,[115,116] appendix[117]). Although declared cases are rare (less than 150 people globally),[118] the endoscopy remains a risk for infection, and a supplementary chemical inactivation after the two added washes is recommended. Its efficacy on prion has not been proven. Sodium hypochlorite at 6°C or bleach can be used if it does not damage the scopes.

Cleaning of the Scopes. M*anual*. Because nonimmersible endoscopes have practically disappeared from practice, only the steps of cleaning and disinfection of immersible ones are addressed in this section. Disinfection is carried out at the start of the session, between cases, and at the end of the day. Scope attribution is decided before the start of the list to allow alternation and diminish waiting time and stress.

Pretreatment takes place in the endoscopy room. Still connected to the light source, air and water channels are flushed with water for at least 15 seconds to expel all organic material using a special valve supplied by the manufacturer for this purpose. The aim is to thoroughly remove all organic material and blood prior to any contact with disinfectant. Premature contact with the latter will fix the proteins, creating debris in which organisms can become imbedded and keeping them out of reach. All channels are flushed with a detergent solution, without aldehyde. The instrument is then disconnected, and caps are fitted when required (videoendoscopes). A cleaning

brush is passed through the suction or biopsy channel until it comes back visually clean.

The instrument is tested for leaks and checked for faults or damage before being fully immersed in neutral or enzymatic detergent. All removable parts (water or air, suction valves, biopsy cap) are removed, the scope is washed, and the distal end, knobs, and valves are individually scrubbed with a soft toothbrush. An all-channel irrigator is put in place, and the channels are irrigated with the solution (minimum of 150 mL) for at least 5 minutes. This step is crucial because it markedly reduces microbial contamination load[119,120] and contamination of multiple-use forceps.[121] The scope and accessories are rinsed under fresh tap water and the channels are irrigated (minimum 300 mL) before air is insufflated to remove fluid residue. All of the equipment is immersed in the disinfectant for the correct contact time, depending on the level of disinfection that needs to be achieved: with 2% glutaraldehyde, according to the ASGE and the French Society of Digestive Endoscopy (FSDE), 10 to 20 minutes for intermediate level and 60 minutes for high level, and, according to the ASGE, FSDE, and the Asia-Pacific Congress of Digestive Endoscopy, 10 to 20 minutes before/after storage[92,122–125]; with peracetic acid, 5 minutes for intermediate level and 10 minutes for high (sporicidal) level.[113,124] The dilution needs to be respected and not fall below 1 to 1.5%.[114] Endoscopes and valves are rinsed with a large volume of water, 300 mL passed through the channels to avoid toxic reactions (colitis). Tap water, preferably with filter, is used when an intermediate level of disinfection is necessary and sterile water if a high level is wanted. Once more, the agent is eliminated by air insufflation. Endoscopes are connected to the light source and forced air-dried. They are then stored hanging vertically in a designated ventilated cupboard. Valves and the biopsy cap are removed and lubricated with silicone oil.

Disinfectant solution needs to be changed depending on the physicochemical stability of the product itself and the number of procedures carried out. Any cloudy solution should be renewed.

Automated Washer and Disinfectors. These machines are being used increasingly in the endoscopy suite. They need regular maintenance and control. These machines have the advantage of providing standardized disinfection and rinse, heat to optimize the process, filtered tap water, automatic record of the washing parameters, and a closed system diminishing exposure to fumes. It should be stressed that some crucial cleaning steps still need to be performed manually: the cleaning itself, the check for leaks, the alcohol rinse, and forced air drying.

Accessories. Reprocessing of these medical devices is a subject of discussion. The complexity of the material (crevices, wire coils, retractable components) and the fact that they breach mucosa classify them as critical. Therefore, they need to be sterilized or disposable. The standardized protocol for reprocessing has been shown to be reliable.[126] Recommendations are that single-use accessories are encouraged when available. Reprocessing and reuse of medical equipment intended for single use has clinical and legal implications.[127] Some working groups propose that consent should be obtained if reuse is intended.[123] However, the cost implications also raise some concerns.[128]

Some accessories that are difficult to clean can be ultrasonically (> 30 kHz) cleaned prior to disinfection or autoclaving. Sterilization should be achieved with water vapor at 134°C for a minimum of 18 minutes, the so-called "prion cycle."

Environment. Owing to common adverse reactions to glutaraldehyde, specific criteria relating to exposure levels have been established. They are defined in terms of average exposure standard and maximum exposure level, which are issued in most countries. The maximum exposure level is 0.05 ppm of glutaraldehyde in the United Kingdom and 0.2 ppm in France.

Staff. Endoscopy staff should be trained not only in the correct use of the equipment but also in case of spillage. All staff coming in contact with glutaraldehyde need to complete a health questionnaire and perform yearly lung function tests. Gloves and disposable aprons should be worn and changed regularly because they absorb the substance. Staff are also strongly advised to be vaccinated against hepatitis B.

INDICATIONS

The indications vary with age because newborn babies do not present with the same pathologies as adolescents. Table 67.2-4 shows the indications divided into three age groups.

Gastroesophageal Reflux

One of the major indications for EGD is gastroesophageal reflux (GER) and its complications. GER is defined by the involuntary passage of gastric content into the esophagus. The main pathophysiologic cause of GER is transient relaxation of the lower esophageal sphincter. Patients can present with dysphagia, odynophagia, hematemesis, anemia, weight loss, failure to thrive, epigastric or retrosternal pain, unexplained vomiting, spitting, or irritability depending on their age. Furthermore, abnormal anatomic conditions, such as hiatal hernia, can lead to GER. The diagnosis of hiatal hernia is made when the ascension of

TABLE 67.2-4 INDICATIONS OF ESOPHAGOGASTRODUODENOSCOPY

NEONATES AND INFANTS	TODDLERS	TEENAGERS
Vomiting	Abdominal pain	Abdominal pain
Hematemesis, melena, hematochezia	Hematemesis, melena	Dyspepsia
Apnea	Vomiting	Hematemesis, hematochezia, melena
Failure to thrive	Dysphagia, odynophagia	Weight loss
Diarrhea	Foreign body	Chronic reflux symptoms
Irritability, Sandifer syndrome	Caustic ingestion	Chronic diarrhea
	Chronic diarrhea	Iron deficiency anemia
	Chronic constipation	Caustic ingestion
	Suspected polyp	Cancer surveillance

the Z line is observed more than 2 cm above the esophageal hiatus. Although in newborns, the junction between the pale pink esophageal epithelium and the darker red gastric one takes place at the level of the diaphragmatic hiatus (pinch), with age, it has a tendency to move upward. The Z line is slightly irregular or undulating. The disappearance of multiple small linear vessels at this level helps to identify it. In moderate to severe hiatal hernia, the mucosal gastric folds slide above the diaphragmatic pinch, giving an aspect of pouch (Figures 67.2-1 and 67.2-2). With a deep breath, this becomes even more apparent as the folds move over the hiatus, particularly in retrovision.

The diagnosis of peptic esophagitis is made endoscopically. The typical lesion is a round or linear erosion with focal erythema, exudate, or ulceration usually perpendicular to the longitudinal axis. It is always localized in the lower third of the esophagus. When multiple lesions are present, they can converge and give a stellar shape. The response to treatment and prognosis depends on the gravity of the lesions seen. Thus, it is crucial to evaluate the severity of the esophagitis, which is graded from 0 to 5 (Table 67.2-5). Grade 0 corresponds to a normal esophagus; grades 1A, 1B, and 1C to reflux lesions; and above grade 2 to different severity of esophagitis. It is important to avoid confusion of grade 2 with the normal circumferential cardial redness seen in the newborn (Figures 67.2-3 and 67.2-4). This characteristic aspect is due to specific distribution of intramural veins running in the lamina propria at the level of the upper esophageal sphincter. These vessels can be seen only with the new generation of video-endoscopes.

The exact localization of the lesion is noted. The importance of biopsies remains a subject of controversy because good-quality material is difficult to obtain.[129,130] The percentage of uninterpretable biopsies can be as high as 59% for grasp and 23% for suction. With an adequate technique, good mucosal biopsies can be obtained with grasp forceps and evaluated under a microscope. Erosions and ulcerations associated with an inflammatory infiltrate are seen only in patients suffering from severe esophagitis. In fact, it is useful to take biopsies in a patient suspected of GER with a macroscopically normal esophagus. Two biopsies will be taken 2 or 3 cm above the Z line and fixed in formol.[131] The ESPGHAN has established criteria to help the correlation of histologic findings with diagnosis (Table 67.2-6). The presence of basal zone hyperplasia of the epithelium, elongated stromal papillae, and vascular ingrowth reflects reflux, whereas inflammatory infiltrate, ulceration, or modification of the epithelium confirms a microscopic esophagitis.[129,131–134]

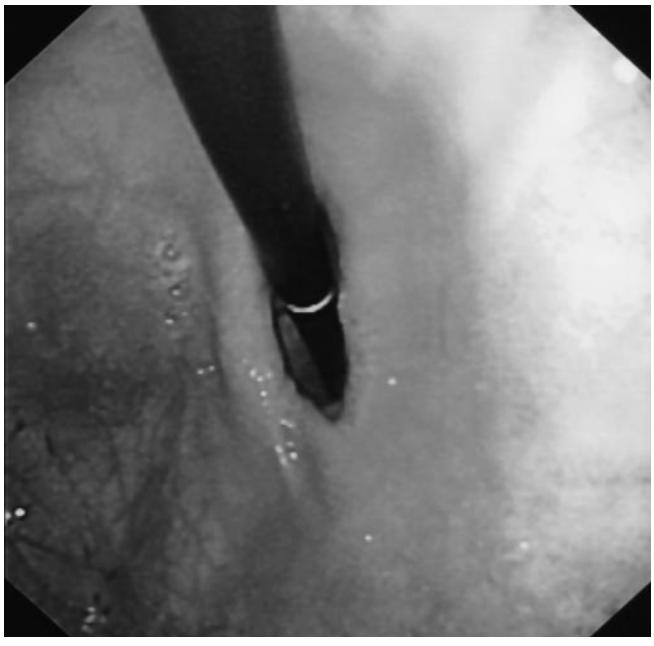

FIGURE 67.2-1 Hiatal hernia in retroversion.

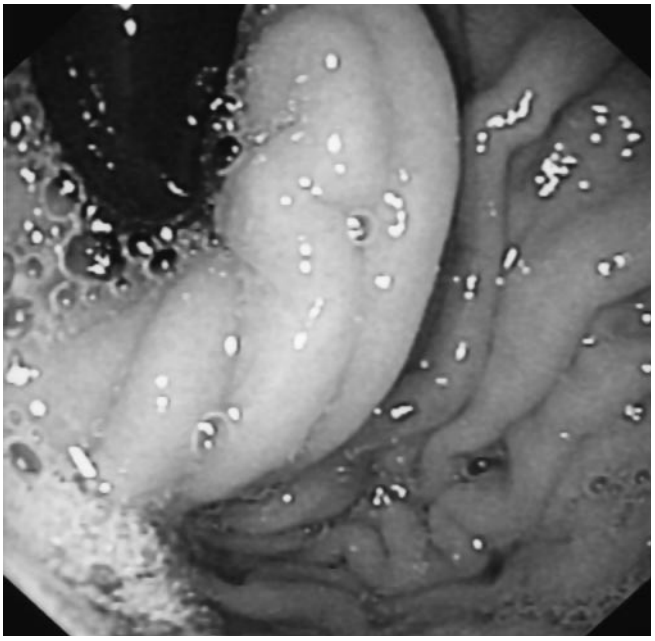

FIGURE 67.2-2 Nissen fundoplication in retroversion.

Endoscopic examination is the only way to diagnose and establish the extent of Barrett esophagus. The typical lesion is an orange-pink spot standing out on the gray-white squamous mucosa (Figure 67.2-5).[135] Because it is frequently described in published pediatric series, it should be suspected in cases of peptic stenosis. Its existence is possible when the Z line is more than 3 cm above the superior limit of the gastric folds, with or without the presence of hiatal hernia. The use of vital colorants, such as Lugol or

TABLE 67.2-5 ESOPHAGITIS GRADE

GRADE	ASPECT
0	Normal mucosa
1	Unique or multiple, nonconfluent erythema, loss of vascular pattern or exudate appearing as red patches or stiae
2	Longitudinal noncircumferential erosions with a hemorrhagic tendency of the mucosa, with friability (bleeding to light touch: 2A) or spontaneous bleeding (2B)
3	Identical lesions with circumferential tendency
4	Ulcers, metaplasia (4A) or stricture (4B)
5	Endobrachyesophagus associated with any of the above lesions

4	Ulceration	
5	Aberrant columnar epithelium	

methylene blue,[136–141] has been proposed. These methods do not help in the most important difficulty: defining the exact position of the esogastric junction. As a time-consuming method, it is not recommended. In conclusion, the diagnosis of Barrett esophagus is made with certainty only when multiple, large biopsies are taken under direct vision and a detailed histologic map is established.[142] The evaluation of the severity helps in predicting healing rate with medication.[143,144] When stenosis is present, biopsies are made only after dilatation. The risk of adenocarcinoma exists (one case was reported in an 11-year-old child[142]) and imposes a surveillance with an EGD and multiple biopsies every 2 years after 10 years of age. As a matter of fact, upper endoscopy is a crucial tool in the diagnosis and follow-up of peptic esophagitis and Barrett esophagus.[145]

Upper Digestive Hemorrhage

There is little doubt that EGD has a superior yield to barium meal in localizing an upper digestive hemorrhage,[146–148] identifying the lesion in more than 80% of cases.[148,149] Ideally, endoscopy is performed in the 6 to 12 hours after stabilization of the patient. In the case of severe hemorrhage, surgeons should be informed and ready to intervene. In young individuals without signs of active bleeding, it can be delayed up to 12 hours, to a maximum of 24 hours.[148] If the patient shows an altered state of consciousness, the procedure is performed under general endotracheal anesthesia to protect the lungs. An endoscope with axial vision adapted to the age of the patient must be employed. The operating channel is often blocked by blood clots; therefore, an endoscope with an operating channel of a diameter of 2.8 mm at least should be chosen

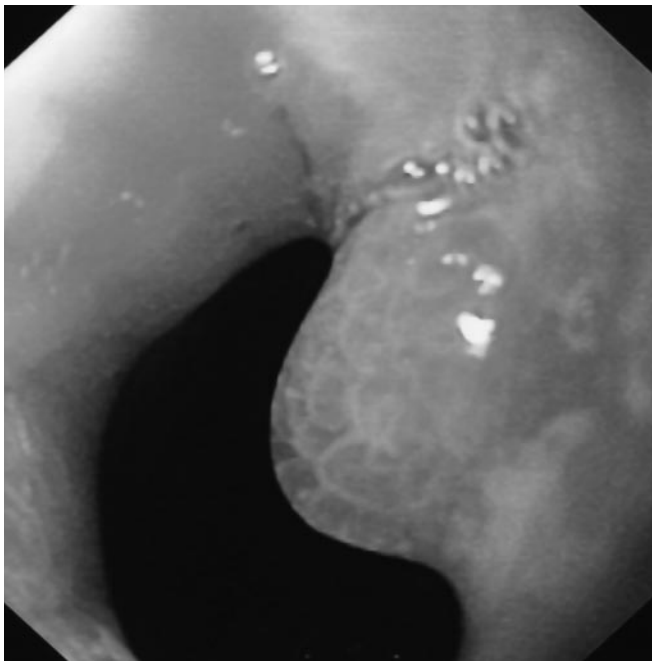

FIGURE 67.2-4 Inflammatory polyp of lower esophagus.

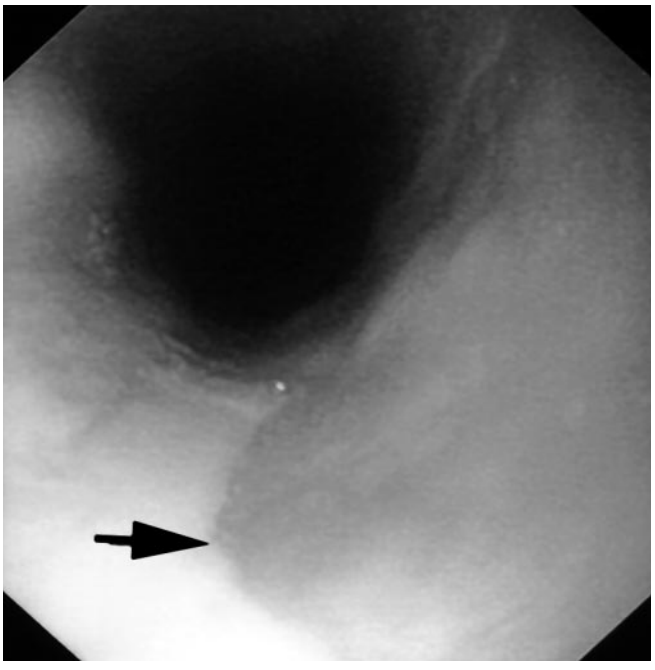

FIGURE 67.2-5 Esophageal gastric heterotopy (*arrow*).

when possible. The exploration is made with slow progression to find the origin of the blood. The instrument is advanced at least up to the genu inferius (Figures 67.2-6 through 67.2-9). Most lesions are to be found in the antrum or in the bulb. The exploration by retrovision of the fundus and the cardial regions is, however, necessary to examine these areas correctly. It might be necessary to change the patient's position to shift the blood from the great curvature. Unless the EGD takes place straight after the event, no active bleeding is normally seen. When the bleeding is still active, its cause is evident at endoscopy unless profuse bleeding obliterates the vision. When the hemorrhage has stopped, it is possible to see a stigma, generally a vessel or a clot adherent to it. In most cases, the clot only partly covers the erosion. In a few hours, the clot disappears, leaving behind a few brown spots. A hemorrhagic base indicates active bleeding within the last 48 hours. In the absence of such signs with a single lesion, it is assumed to be the cause; if multiple erosions are present, no certainty can be reached. Although common in adults, this presentation is rare in children.

At the end of the emergency EGD, three situations can be encountered: in about 70% of cases, the origin of the hemorrhage is found[148,150] or the diagnosis remains uncertain because multiple lesions have been found; finally, no mucosal lesion is seen; therefore, no diagnosis can be reached. This eventuality decreases with the delay of the endoscopy from 82% before 24 hours to 48% after 72 hours.[150] In the case of a negative endoscopy, a second procedure can be performed within 24 hours if bleeding recommences. The origin of the hemorrhage can be found in the esophagus, stomach, or duodenum depending on the age. The most frequent etiologies are shown in Table 67.2-7. Etiologies differ from one center to another and include esophagitis (Figure 67.2-10), Mallory-Weiss tears, esophageal varices (Figure 67.2-11), gastritis (Figure 67.2-12), gastric ulcers (Figure 67.2-13), duodenitis, and duodenal ulcers (Figure 67.2-14). In addition, some specific causes are seen in newborns and infants, such as swallowed maternal blood, neonatal esogastritis, coagulopathy, vascular anomaly, and gastrointestinal duplication.[151] Some of these causes are related to *Helicobacter pylori*.[152] A nodular aspect of the antrum is highly suggestive of the presence of *H. pylori* (Figure 67.2-15).

FIGURE 67.2-7 Normal aspect of cardia, angle fold, and fundus in the same view.

Caustic Ingestion

The ingestion of caustic substances is frequent in the pediatric age group.[153] It justifies an EGD in the 12 to 24 hours after the intake, with the exception of bleach. A thorough

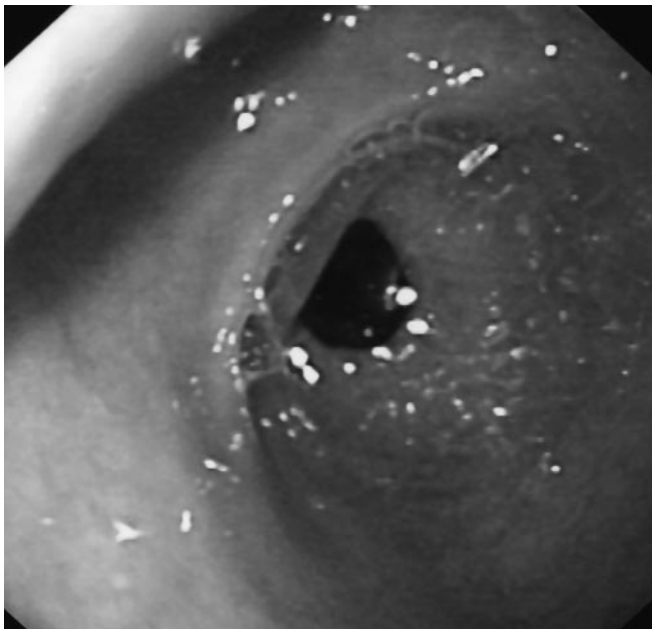

FIGURE 67.2-6 Normal aspect of lesser curvature and open pylorus.

FIGURE 67.2-8 Normal retroversion of fundus of stomach.

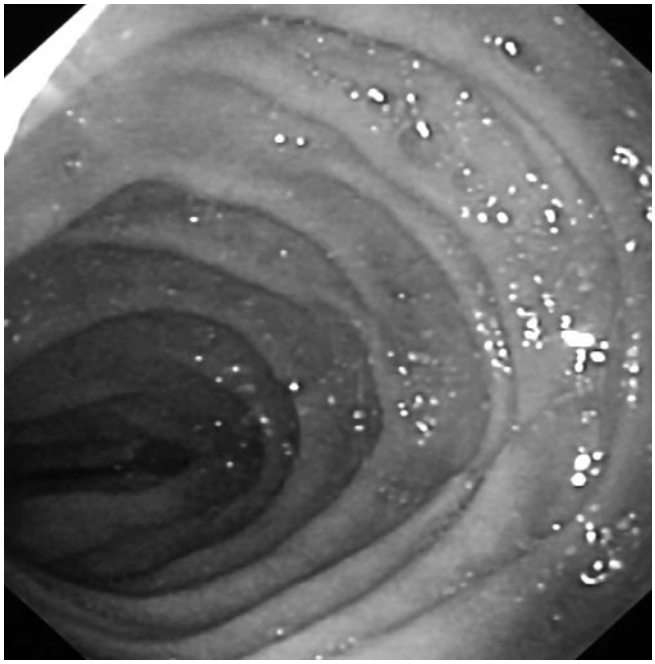

FIGURE 67.2-9 Kerckring fold in normal descending duodenum.

examination of the mouth and pharynx is not sufficient because the presence or not of lesions at this level cannot predict the gastroesophageal integrity. Half of the patients with oropharyngeal lesions have none in the esophagus, whereas around 15% of those without lesions in the top part will have an esophageal injury (J. F. Mougenot, unpublished data, 1997). Alkalis cause a deep liquefaction necrosis extending up to the muscles of the stomach and the esophagus. Acids are responsible for 15% of ingestions, causing a coagulation necrosis that will affect preferentially the stomach, the esophagus being exempt of lesions in 80% of cases (J. F. Mougenot, unpublished data, 1997).

Rigid scopes have been used in the past, but the risk of perforation is high because the instrument becomes blocked at the first proximal lesion. Flexible fibroscopes and videoendoscopes make the endoscopy safer. They can be passed down into the stomach even in the most severe cases. Fibroscopy is used to assess the extent and severity of the lesion, remembering that early examination can underestimate the injury. Early and late complications can be anticipated by the initial extent of the tissue injury. However, it has been suggested by several studies that asymptomatic children following alkali ingestion are not at risk of complications and thus do not need endoscopic examination.[154–159] In summary, the real impact of early endoscopy remains to be proven. A grading system can be used to assess mucosal injury: grade 0, normal mucosa; grade 1, hyperemia and edema; grade 2a, erosion, superficial ulceration, hemorrhage, and white membranes; grade 2b, deep or circumferential 2a lesions; grade 3, multiple ulcerations and areas of necrosis; 3b, extensive necrosis.[160]

Abdominal Pain

Subacute epigastric abdominal pain (present for more than a day and less than 3 months), with anorexia, dyspepsia, weight loss, anemia, and tiredness, that keeps the child awake or away from school needs to be investigated with an upper endoscopy. In our study of 695 consecutive endoscopies in pediatric patients, the association of an epigastric, nocturnal pain related to food intake had a predictive value on the presence of peptic disease with a sensitivity of 90% and a specificity of 37%.[161] The pathologies are shown in Figure 67.2-16. In our opinion, endoscopic examination must be reserved for abdominal pains with organic characteristics.

Recurrent chronic abdominal pains (at least 12 weeks within the preceding 12 months) are present in 10 to 15% of school-age children.[162] They represent one of the most frequent causes of specialized consultation (around 40%). In these cases, a careful clinical examination is crucial before EGD is considered because in only 20%, the investigation will be positive.[162,163] The Rome II criteria can be helpful to individualize functional abdominal pain as recurrent, periumbilical, and diurnal.[164]

Diarrhea and Malabsorption

The EGD with multiple biopsies has succeeded the suction capsule (Crosby, Kugler, Watson, Carey) introduced orally,[165] especially when investigating a malabsorption or a protein-losing enteropathy.[166] Some rules must be respected: three biopsies are taken at the genu inferius to make sure that at least one is well oriented. Some are fixed in formol, whereas others, if needed, are fixed in glutaraldehyde for electronic microscopy or frozen to allow the dosage of the brush border enzymes.

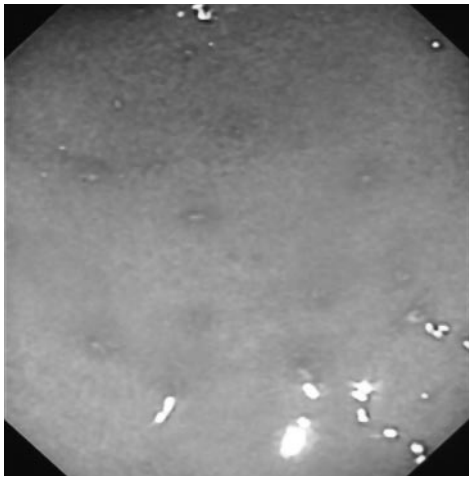

FIGURE 67.2-12 Erosive gastritis.

Some diseases can give a special aspect to duodenal mucosa and should be recognized by the pediatric gastroenterologist: in lipoprotein deficiencies (abetalipoproteinemia, hypobetalipoproteinemia, Andersen disease), a white discoloration of the duodenal mucosa and lipid droplets within the intestinal absorptive cells at biopsy are characteristic owing to the inability of the intestinal cells to export lipids as chylomicrons into the lymphatics[167,168]; a diagnosis of intestinal lymphangiectasia is highly suspect when white villae and/or spots, associated with white nodules and submucosal elevations, are seen.[169,170] Although severe intestinal villae atrophy can be diagnosed with the naked eye when duodenal folds have disappeared, biopsies are compulsory.[166]

Small Bowel Transplant

Control of rejection remains the most difficult problem after intestinal transplant because the intestine seems more susceptible to rejection than any other organ. Because clinical diagnosis of graft-versus-host disease is difficult, endoscopy has become an essential tool in assessing its presence in the allograft.[171–173] An ileostomy is created at the time of the transplant to facilitate regular small bowel biopsies and histologic examination of the intestinal mucosa. The endoscopic appearance of a denuded, hemorrhagic mucosa usually correlates closely with the histologic diagnosis of severe rejection. Early changes can be too subtle to be detected with a standard endoscope, and zoom videoscope is used nowadays to look for edema, blunting of the villae, and expansion of crypt areas by a mononuclear cell infiltrate.[174]

Other Indications

The barium meal has a higher diagnostic yield than EGD for the diagnosis of vessel anomalies and of the esophagotracheal fistula, in which the esophageal orifice is often missed in endoscopy.

FIGURE 67.2-11 Grade II–III esophageal varices.

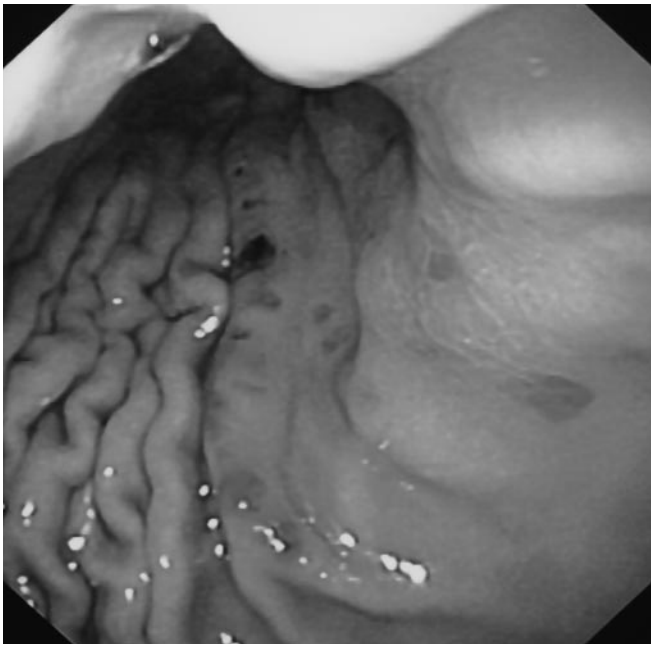

FIGURE 67.2-13 Gastric ulcer with multiple large erosions.

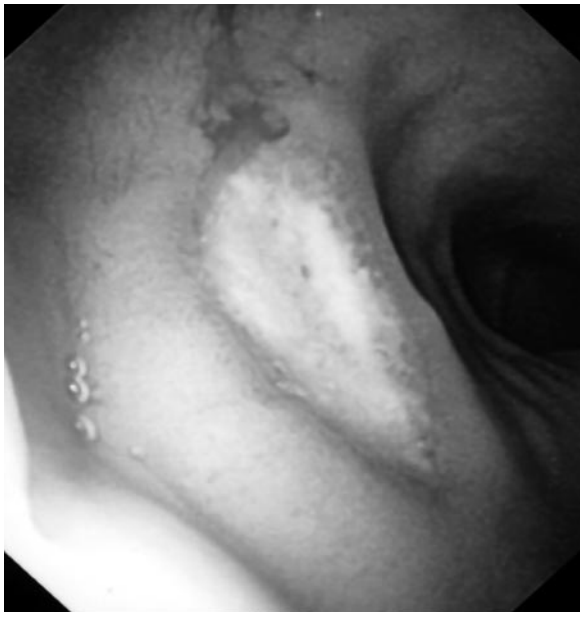

FIGURE 67.2-14 Ulcer of the bulb.

In pyloric stenosis, the first evaluation is made by ultrasonography. In case of doubt, upper endoscopy or barium meal should be performed. Indeed, small endoscopes such as GIF-N-30 (Olympus, Volketswil, Switzerland) and FG-16 X (Pentax, Walliselen, Switzerland) can be passed through a stenosis. Some authors have also proposed balloon dilation of pyloric stenosis.[175]

Despite the fact that primary gastrointestinal cancer is rare in children, EGD can be necessary in cancer surveillance. Endoscopic surveillance is warranted for polyposes syndromes with a higher risk of cancer development. Another indication for EGD can be Munchausen syndrome by proxy, which can present with a broad spectrum of manifestations, such as vomiting, abdominal pain, diarrhea, and failure to thrive.[176] Diagnosis is often delayed, and as there is a risk of mortality due to Munchausen syndrome by proxy, invasive investigation can be mandatory. EGD in this condition has both diagnostic and legal implications.

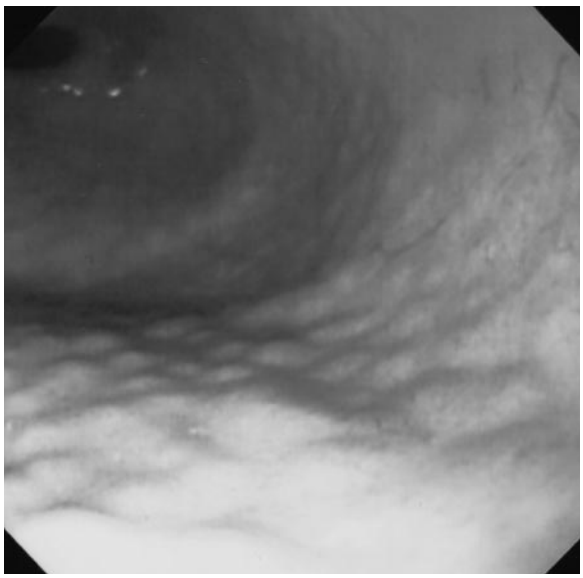

FIGURE 67.2-15 Nodular gastritis due to *Helicobacter pylori* infection.

EGD is an efficient method for follow-up of postsurgical treatment of peptic lesions.

Finally, an upper endoscopy is part of the initial evaluation in suspected inflammatory bowel diseases, and its role is also diagnostic because up to 28% of the granulomas are found only in the upper intestinal tract.[177,178] The integrity of the upper intestinal tract should no longer exclude ulcerative colitis,[177,179] and focally enhanced gastritis does not signify Crohn disease.[180]

CONTRAINDICATIONS

Absolute medical contraindications of upper endoscopy are few and include cardiovascular collapse, an unstable airway, intestinal perforation, peritonitis, and cervical traumas. On top of these pathologies, absences of consent or of competent medical personnel are also situations in which the endoscopy should be either delayed or cancelled.

Relative contraindications are the following: recent digestive surgery, bowel obstruction, coagulopathies, severe thrombocytopenia, and recent food intake. The latter needs to be corrected prior to the procedure.

The major risk with insulin-dependent diabetes is a hypoglycemic episode. The patient should be first on the endoscopy list and advised to reduce the amount of morning insulin.

In a child with hematemesis, an abdominal radiograph must be obtained to eliminate an intestinal obstruction or perforation.

INSTRUMENTATION

ENDOSCOPES

Two types of endoscopes are available that differ in the method of transmitting the image. Both systems require a fiberoptic light guide and a complex objective lens at the distal end to focus the image. The fiberoptic endoscopes use optical fibers. Imaging transmission of light is made by a bundle of glass fibers contained in a cylinder made of a material of inferior refraction index. Each fiber is made of coated glass. The coating acts as a mirror that reflects light through the fiber into the eyepiece. When the light entering the extremity of the optic fiber hits the interface between the glass with a high reflexion index and the material with a low index, it is transmitted by a series of internal reflexions up to the opposite extremity of the flexible fiber glass. A fiber alone could not do the job, but thousands put together make the transmission of an image possible. For the same image to be reproduced at the extremity as the one seen at the other extremity, the individual fibers need to occupy exactly the same position at the two ends of the scope.[181]

Videoendoscopes use advanced charge-coupled device (CCD) technology. The photo-sensible surface of the CCD is made up of a huge number of tiny image elements or pixels that gather the light. The electric charge of these pixels

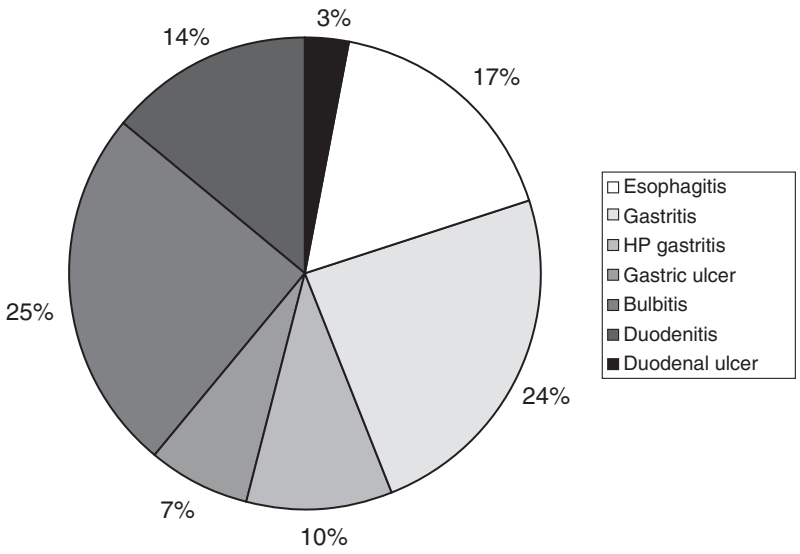

FIGURE 67.2-16 Peptic pathologies found in 695 consecutive endoscopies in a pediatric gastroenterology unit in Geneva, Switzerland. HP = *Helicobacter pylori*.

depends on the intensity and not on the color of the light. Therefore, a CCD is a black and white captor. The color image is created either by the single-plate simultaneous-color CCD chip method or the single-plate red, green, and blue (RGB) surface scanning method. In the former method, a color CCD chip built into the distal tip of the endoscope contains multicolor pixels and can simultaneously capture different color wavelengths of light: red, green, and then blue. Subsequently, the three monochrome images, specific in the intensity and position of the three colors, memorized in the microprocessor are visualized simultaneously, thus reproducing the original picture on the video monitor. In the latter method, the tip of the endoscope incorporates a monochrome CCD chip that can only provide black and white signals, with a multichrome filter added. The last generation of this type of endoscope can have a polychrome chip. This image from the filter (either RGB or a mosaic yellow-cyan-white) is passed through the video processor to modify it in the three primary colors. From a four-pixel block (one yellow, one cyan, two white), in this case, three pixels receive information about the red, four about the green, and three about the blue. The CCD converts the light into an electronic signal, which is then sent to the processing unit, where it is converted for output as a video signal for the monitor to display or to other peripherals (printer, personal computer, monitor, light source) in either RGB mode or Y-C (luminance-chrominance). With the image being directly transmitted to a color video monitor, the inspected areas can be examined fatigue free and simultaneously by several experts when required. However, the cost of the videoendoscope and accessories limits its acquisition.

All fibroscopes and videoendoscopes are waterproof, permitting appropriate washing, decontamination, and disinfection. They house an instrument channel to pass instruments (grasping forceps, polypectomy snares, injection needles, cytology brushes, extractors, retrievers, laser, guidewires, dilating balloons, bougies, diathermic snares) and two accessory channels to insufflate air and inject and aspirate water. Through the smallest diameter of operating channel, 2 mm, fit 5 French instruments, facilitating therapeutic endoscopy in small children (injections, polypectomy). The midsize endoscopes have a 2.8 mm diameter, allowing the passage of 7 French wires. Apart from the duodenoscopes used for endoscopic retrograde cholangiopancreatography, all scopes have an axial vision.

The light source is composed of a generator of cold light (150–300 W halogen or xenon lamps), a light transmission system with automatic light adjustment to ensure sufficient brightness that maintains optimum brightness, and a high-speed rotation filter (20–30 tours/s), which is needed for the sequential RGB videoscope.

Gastroscopes with axial vision, owing to their flexibility and the amplitude of quadridimensional bending capacity (up, down, right, and left), give a full view of the upper intestinal tract from the esophagus to part 3 of the duodenum, including the cardia. An important part of the procedure is to choose the appropriate scope, depending on the size of the patient. The following rules can help in this choice: up to 15 kg, a 9 mm tip diameter can be used; from 5 to 15 kg, 8 to 9 mm; in newborns 2.5 kg to 4 kg, 5 to 8 mm; and in newborns less than 2.5 kg, only 5 mm is possible. In other words, the GIF-N30 (Olympus), the EG-1870K, and the FG-15W (both Pentax) are the only scopes usable in newborns. The GIF-XP20, GIF-XP160 (Olympus), FG-6W (Pentax), and FG-100PE (Fujinon, Wayne, NJ) are usable in term infants up to 4 years of age. Above that age, it is better to use the GIF-P30, P140, or P230. The EG-450PE5 can be used from 1 year of age. In patients older than 10 years, the GIF-XQ40, GIF-160, EG-450WR5 (Fujinon), and EG-2570K (Pentax) are preferable. The scopes incorporating an instrument channel size of 2.8 mm are better for therapeutic use. Under general anesthesia, they can be used in patients as young as 12 months old. Table 67.2-8 resumes the technical characteristics of gastroscopes that can be used in pediatrics.

Forceps

A range of biopsy forceps exists apart from standard models: the "crocodiles" have teeth on the edge to help in grasping the mucosa. Others have a spike in the center to facilitate the grip on the mucosa and avoid sliding.

Technique

Endoscopy can be performed either single or two handed. In the first method, the endoscopist keeps the right hand on the shaft throughout the procedure, while the left hand is on the controls. The middle finger helps with the up/down wheel and the thumb reaches the right/left wheel. This method needs considerable practice but has the advantage of leaving the driver independent, needing less personnel. In the second method, the two hands are used to maneuver the controls, the shaft being pushed or withdrawn by a second person. The right hand is then used to move the right/left control. Easier from the start, this method can be performed more rapidly.

The help of experienced personnel is crucial. A minimum of two people, in addition to the operator, are present in the room. It is preferable that they could have met the parents and child before the endoscopy to answer questions. One will be responsible for the patient, making sure that the patient is safe and comfortable at all times. The second will assist the operator and operate the forceps when necessary.

At the start of the procedure, the patient is usually positioned on the left side, although some gastroenterologists will put the patient flat on the back. A small pillow under the head, but not the shoulder, will straighten the neck. The head is slightly flexed forward. In children with teeth, the use of a mouthguard with or without straps is recommended because bites to instruments can damage the fibers. It also helps keep the instrument on the midline. The scope is checked (suction, insufflation, and light on; zoom and brakes off) once more before lubrication is applied. Lastly, up and down movements are rehearsed to make sure that they are made in the axis of the pharynx. The room light is dimmed to allow good vision for the endoscopist. The introduction of the scope is a delicate moment owing to the extreme sensibility of the oropharynx. Two crucial rules are to be respected throughout the procedure if complications are to be avoided: never advance blindly and, if lost, come back. Four landmarks should be recognized during the procedure: cardia, angulus, pylorus, and superior duodenal angle (see Figures 67.2-6 through 67.2-8).

Three basic methods exist to intubate the esophagus:

- The safest way is under direct vision (Figure 67.2-17). The shaft is held at 30 cm and slowly introduced with the tip deflected downward up to the cricopharyngeal sphincter. In passing, the tongue, arytenoids, and vocal cords are localized to avoid impaction on the piriform fossae. If, in advancing, the teeth are seen, the shaft is twisted to put it back on the midline. Whenever landmarks are lost, withdrawal and starting again are the simplest and safest solution. The cricopharyngeal sphincter closes the entrance to the esophagus, making it difficult to locate. After a short waiting time, it will relax, allowing the intubation of the upper posterior esophagus. Insufflation of air or gentle pressure can help to relax it. In a cooperative child, swallowing will relax the upper esophageal sphincter, but it is often not obtainable in pediatrics.
- Another method uses blind manipulation. Holding the scope as before, the shaft is passed up to the back of the mouth. At this level, the tip is deflected upward and gently pushed forward. This will stretch the mucosa and allow the passage of the cricopharyngeal sphincter. Constant reorientation is necessary because the shaft easily comes out of the midline.
- An alternative method is with finger guidance. Probably the easiest for the inexperienced practitioner, it does, however, carry the risk of bites to either the scope or the fingers. The shaft is held with the right hand at about 5 cm, the mouthguard slipped over it. The shaft is pushed while the second and third fingers of the left hand are put over the tongue to help guidance. The cooperation of the patient is required as the sphincter is passed by active swallowing.

Under vision, the scope is progressively pushed forward to the lower sphincter. The Z line, the junction between the esophageal squamous mucosa and the gastric columnar, is located, usually 1 cm above the diaphragmatic hiatus. Its position in centimeters is recorded, remembering that it might be difficult to spot in newborns and infants. The diaphragmatic hiatus is situated between 12 and 40 cm from the incisors, depending on the age and size of the patient. The lower sphincter is often passed blindly owing to its contraction. The tip of the shaft is bent gently downward and to the left because the esophagus angles to the left side to avoid impaction in the fundus wall. To improve vision, air is insufflated, the lesser

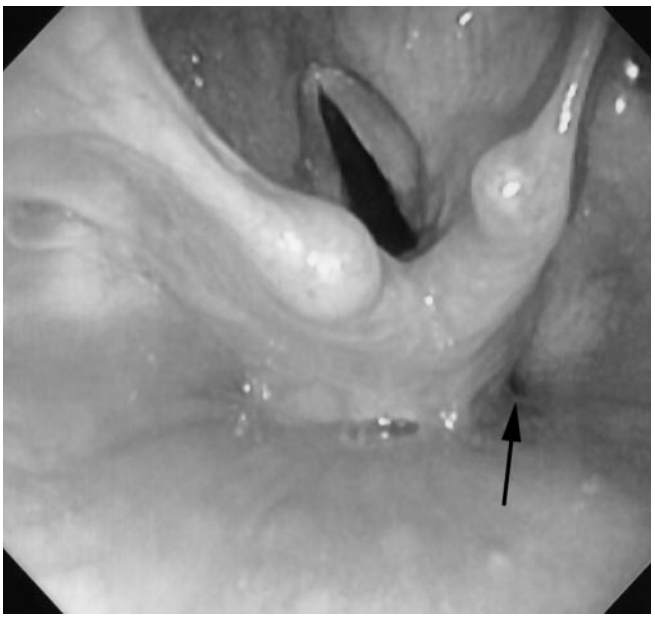

FIGURE 67.2-17 Normal laryngeal and pharyngeal structures. Upper esophageal sphincter (*arrow*).

curvature being on the right, the angulus in the distance. When liquid is present, suction is used to eliminate any risk of aspiration. At this point, most endoscopists will-progress rapidly to the duodenum, careful examination of the mucosa being achieved on the way back. This method implies experience to avoid traumatic lesions (suction or rubbing) that could cause confusion afterward. Yet it has the advantage of avoiding the overinflation required for retrovision that causes discomfort. Progression is made with a clockwise (left) rotation of 90°, bending the tip upward. This double maneuver brings the pylorus into view. The bending can be quite extreme in a young child or infant because the angle is acute. To put the pylorus into the antrum axis, the tip is angled down. At this point, it helps to reduce the amount of air present in the stomach. The shaft is then advanced toward the pylorus, which will open, either spontaneously or with stimulation, by air insufflation. The intubation of the pylorus is achieved with the tip slightly bent down and right. Past the pinch, the tip tends to get impacted because the gastric loop straightens up. Withdrawal and air insufflation confer a view of the pale mucosa of the bulb, the anterior wall placed to the left and the posterior wall to the right. The superior duodenal angle is visualized before passage to the second part of the duodenum is attempted. This progression, usually carried out blindly because of the sharp angle, needs to be made with care. Pushing will bring the tip in front of the duodenal angle; it is then bent to the right and finally rotated simultaneously at 180° to the right and up (150°). Finally, to obtain an optimal view, withdrawal is normally necessary because of the paradoxical progression of the endoscope owing to the straightening of the gastric loop. Sometimes rectification of the last maneuver is needed with deflection of the tip upward and to the left. Often the Vater papilla is seen. Biopsies are taken before withdrawal. Most endoscopists will use this moment to carefully examine the duodenal, bulbic, gastric, and esophageal mucosa. Circumferential movements with air insufflation will provide well-distended mucosa in order not to miss small lesions. A retroversion maneuver in the stomach (J maneuver) is the only way to fully visualize the fundus, the lesser curvature, and the cardia. While back in the proximal part of the antrum, a 180 to 210° angulation is imposed to bring into view the angulus and the lesser curvature. Keeping the angulation, a 180° rotation around the shaft's axis will allow visualization of the greater curvature and the fundus. The withdrawal of the instrument will bring the cardia into view.

Taking biopsies is one of the main reasons for performing an endoscopy, along with visualization of the mucosa. Most gastroenterologists agree that they should be obtained even in the case of a normal mucosa.[10] The primary sites to biopsy are the distal duodenum, antrum, and esophagus. To achieve good-size specimens, some rules have to be followed. The forceps is approached at a 90° angle to the mucosa and not tangentially. The forceps protrudes no more than 3 cm from the tip of the scope to allow good control over it. This is important not only for the quality of the specimens but also to reduce the risk of perforation and hemorrhage. A fold biopsy is more effective because a "double" biopsy is obtained. In a limited space such as the esophagus, a good trick is to sharply bend the tip of the shaft. Firm pressure needs to be applied to the mucosa before slowly closing the forceps. Multiple specimens are taken, especially in the duodenum, so as not to miss focal villae atrophy in case of lesions. Biopsies are transferred with the help of the needle onto a piece of paper and flattened. To avoid crushing, stretching, or puncture injuries to the tissue, the back of the needle is used. The mode of fixation depends on which pathology is suspected. Clo-test (Astra Zeneca AG, Zug, Switzerland) will typically require a fresh antral biopsy, to test for the presence of *H. pylori*, by its production of urea. When cultures are needed, a small drop of saline is placed on top, and they are sent to the appropriate laboratory immediately. If special immunocytochemistry or disaccharidase levels are wanted, frozen specimens are needed. Finally, for electron microscopy, glutaraldehyde should be ready.

The whole procedure with collection of biopsies takes around 15 minutes in experienced hands.

COMPLICATIONS

Complications are uncommon during endoscopy when performed by well-trained pediatric gastroenterologists—probably less than 1%.[182] They are mainly due to the anesthesia or to the procedure itself. Endoscopy in children tends to be performed under deep sedation, making a hypoxic episode possible. On the introduction of the tube, the saturation usually drops by 5% from the basal level before quickly recuperating. However, in Bendig's series, desaturation (< 90%) was observed in 7 of 60 children.[183] Nasal oxygen is usually sufficient to correct the hypoxia. In the rare cases in which no amelioration is obtained, withdrawal of the scope is necessary. Difficulties mainly arise from inefficiency of the sedation. Aspiration is always possible, although respected fasting time reduces the risk. Allergic patients can react to the medications or to the latex. Finally, rare complications are hypotension, arrhythmia, and malignant hyperthermia.

If we now look at the complications arising from the actual procedure, they mainly consist of perforation, hematoma, air embolism and infections:

- The complications described in children owing to the actual procedure are the following: Perforation can occur, usually owing to excessive force or air insufflation on an already damaged mucosa. This mostly involves the esophagus. The majority of reported cases are due to therapeutic endoscopy and are discussed in other chapters. Mucosal tears without perforation have been described in children,[184] yet this seems to be a complication seen more frequently in the elderly presenting with hiatal hernia.[185] To minimize the risk, it is crucial to never push forward without vision. At times, it is impossible to avoid having the scope against the mucosa. In these circumstances, as long as the vessels are seen passing by in front of the camera, this means

that the scope is sliding on the mucosa and that there is no danger. In contrast, if the mucosa turns white, too much pressure is being applied, and the scope needs to be withdrawn. In case of perforation, surgical referral is urgent to choose between a conservative and surgical treatment. Nevertheless, signs of perforation can appear with some delay.

- Intramural duodenal hematoma has been reported after endoscopic biopsies.[186–195] Although it is a rare complication, it seems to occur more often in children than in adults.[189] The clinical presentation mimics abdominal occlusion with severe abdominal pain and vomiting, usually starting in the 12 hours postendoscopy. Often it is associated with pancreatitis.[189,190,192,195] Spontaneous resolution is always obtained between 4 days and 2 weeks, with fasting, nasogastric suction, and fluid replacement. Total parenteral nutrition is sometimes necessary. Surgical drainage, although sometimes performed, is unnecessary and therefore contraindicated.
- Fatal massive air embolism has been reported in a 10-year-old and a 4-month-old child who had been subjected to a Kasai procedure[196,197] because of potential vessel leakage.
- Infectious complications can result from the patient's own microbial flora (autologous), from patient to patient by way of the endoscope (exogenous), or between the patient and the staff. The most frequent microorganisms depending on the mode of transmission are *Salmonella* spp, *P. aeruginosa*, *Mycobacterium* spp, and *H. pylori*.[182,198] These can be seen in cardiac-risk patients (see the antibiotic prophylaxis section); only one case of sepsis has been reported in a child without increased risk.[199] Bacteremia seems rare[52,54,57]; therefore, prophylactic antibiotics are given only to selected patients.

CAPSULE

The invention and development of more sophisticated endoscopes have allowed gastroenterologists to see further into the gut. Whereas in adults, push enteroscopy has enabled the further enhancement of possibilities and visualization of up to 90 to 120 cm beyond the ligament of Treitz,[200,201] experience in children is limited.[11] Another technique, sonde enteroscopy, in expert hands, allows us to see approximately 50 to 70% of the small bowel, the ileocecal valve being reached in only 10%.[202] Nevertheless, 30% of the small intestine could not be visualized, lying beyond our reach. Twenty years ago, Dr. Iddan had the idea of developing a video camera that would fit inside a pill.[203] Technology was not ready, and the idea was put on hold. With the turn of the millennium, engineering breakthroughs, particularly in the area of complementary metal oxide silicon, application-specific integrated circuit, and white light-emitted diode (LED) technologies, allowed all of the components of the camera to be put on a single chip, reducing both its size and power consumption. The wireless capsule endoscopy was born,[204] giving access to the so-called gut "black box."

The advantage compared with conventional upper endoscopy is that neither anesthesia nor air insufflation is necessary, making the whole procedure much more pleasant for the patient. Yet it cannot replace endoscopy for the following reasons. First, although the capsule often passes into the colon while the videotaping continues, its battery runs out before the journey through the colon is complete, not allowing a full view. However, a bowel preparation would be necessary. Furthermore, an important limitation is the inability of the device to take biopsies, although the manufacturers anticipate that improvements may permit this within the years to come. Therefore, the capsule does not replace traditional endoscopy in disorders in which a histologic diagnosis is necessary, for example, celiac and Crohn disease. Another drawback is that it may be difficult to determine the exact location of an abnormality seen. Because of these limitations, the capsule does not replace traditional endoscopy.

Indications

The main indication is obscure gastrointestinal bleeding[205] or iron deficiency anemia after a negative panendoscopy. However, it has been used to diagnose specific disorders that were otherwise difficult to establish, such as vascular abnormalities, polyposis,[206] and suspected Crohn disease.[207,208]

After animal studies demonstrated effectiveness, capsule endoscopy was used in small human prospective studies and proved to better define bleeding sites (55–76%) compared with conventional diagnostic procedures (21–30%).[209–211] When compared with barium studies, the capsule was considered diagnostic in 45% of patients versus 27%, with 31% versus 5% of the causes of obscure bleeding being found.[206] Reported diagnostic yield reaches up to 62.9%.[212] The amount of literature demonstrating its superiority in diagnosing the cause of blood loss is growing, but pediatric trials are needed.

Contraindications and Complications

A small risk exists that the capsule may become lodged in the intestinal strictures or diverticulae. The incidence, estimated around 1%, increases if the patient has undergone major abdominal surgery or suffers from a stenotic disorder.[213] We advise practitioners to perform a barium and follow-through prior to using the capsule to exclude stricture. Abdominal radiography should be considered in patients who do not observe passage of the capsule and whose imaging result does not indicate passage of the device into the cecum. The manufacturers themselves say that the capsule should not be used in patients with symptoms of a bowel obstruction, including nausea and vomiting and abdominal distention.

Instrumentation

The only wireless capsule endoscope available is produced by Given Imaging Ltd, Yoqneam, Israel, the M2A Capsule Endoscope, and is currently available in 33 countries worldwide. The Food and Drug Administration in the United States[214] and the Health Protection Branch of Health and Welfare in Canada recently approved its use in

adults only. The capsule, measuring 11 × 26 mm, has a weight of about 4 g and contains a magnifying (1:8) color camera, four light sources, a radio transmitter, and batteries. With a 140-degree viewing angle, the capsule allows relatively complete viewing of the small intestine, but neither the velocity nor the direction can yet be controlled. Insufflation of air is unnecessary because the focal point of the lens is 1 mm. Images taken twice per second are continuously transmitted to wires placed on the body and captured on a recording device much like a Holter monitor, worn on a belt. The battery power is able to take 50,000 to 60,000 color images and lasts about 6 to 8 hours. These images are downloaded on a computer and viewed by the gastroenterologist as a video; analysis can take up to 2 hours. There is a learning curve in recognizing abnormalities even for experienced gastroenterologists because the aspect of the images is different to that acquired in a conventional way. A blood-sensing algorithm, using color pattern recognition, has recently been added to the software to help detection of intraluminal blood.

Technique

The capsule is swallowed with a glass of water by the patient in the morning and then travels down the gut propelled by peristalsis. Neither bowel preparation nor sedation is needed, the patient having fasted 6 hours prior to the study. Although the minimal age mentioned by the manufacturer is 11 years, it has been used in younger children. The actual limitation is due to the capacity of the patient to swallow it and not the size of the capsule itself. To overcome this problem, some centers insert the capsule endoscopically in children as young as 4 years old. Patients may then perform their regular daily activities while wearing the recording device for the next 8 hours. The capsule has a mean gastric transit time of 80 minutes and a mean small intestinal transit time of 90 minutes.[204] The disposable capsule is usually passed, in the absence of any marked motility disorder, in the next 24 to 48 hours.

INTERVENTIONAL PROCEDURES

Foreign Bodies

Foreign body ingestion is a relatively common reason for consultation in the pediatric emergency room. More than 50% of cases are children aged 5 years or less, and most are boys. The ingestion of the foreign body is not generally voluntary, except for neurologically impaired or psychiatric patients and youngest siblings. A large variety of small objects and toys can be ingested, although coins are the most frequent (Figure 67.2-18). The vast majority of foreign bodies pass through the entire gastrointestinal tract without any problem. Indeed, only 10 to 20% will become impacted. The most frequent localization of impaction is the cervical esophagus. However, it can also occur in the medial and distal parts of the esophagus. When foreign bodies have passed through the esophagus, 95% will be spontaneously eliminated in 4 to 6 days, sometimes longer (3–4 weeks). If they pass through the esophagus, they can become lodged in the pylorus, genu inferius of the duodenum, or ileocecal valve or on acquired or congenital stenosis. As to size, foreign bodies of a diameter of more than 20 mm or a length more than 50 mm (30 mm for infants) are particularly prone to impaction.[153] In more than 80% of cases, the foreign body is opaque, most frequently a coin.[215] The nonopaque foreign body is mainly retained food, often associated with a known history of previous repair for esophageal atresia.

Whenever a foreign body is suspected, thoracic and abdominal radiography must be performed. Every esophageal foreign body that is blocked for more than 24 hours must be removed immediately by endoscopy. Some studies have compared endoscopy, Foley catheter, and bougienage technique, especially for coin removal.[215,216] They favor Foley catheter or bougienage on a cost-effective basis.

For intragastric foreign bodies, interventional endoscopy is performed immediately only in cases of risk factors (a large foreign body with high risk of incarceration, a sharp foreign body with risk of perforation or hemorrhage, and all symptomatic ingestions). In other cases, a more conservative approach can be chosen, with an endoscopy only after 3 days to 4 weeks of nonprogression of the foreign body, depending on the experience of the center.

The special case of battery ingestion should be mentioned.[217] All types of batteries contain potassium or sodium hydrochloride and are not completely watertight. Consequently, their ingestion can lead to esophageal, gastric, or intestinal lesions such as burns or perforation, which can be lethal. Consequently, ingested batteries must be removed within 24 hours.

The endoscopic removal of foreign bodies must be performed under endotracheal anesthesia for all localizations to ensure airway protection, especially in case of an inadvertently released object.

Several devices are available: rat tooth and alligator forceps, polyp snares, retrieval nets, helical baskets, and hooded sheaths. Their specific use is related to the type of

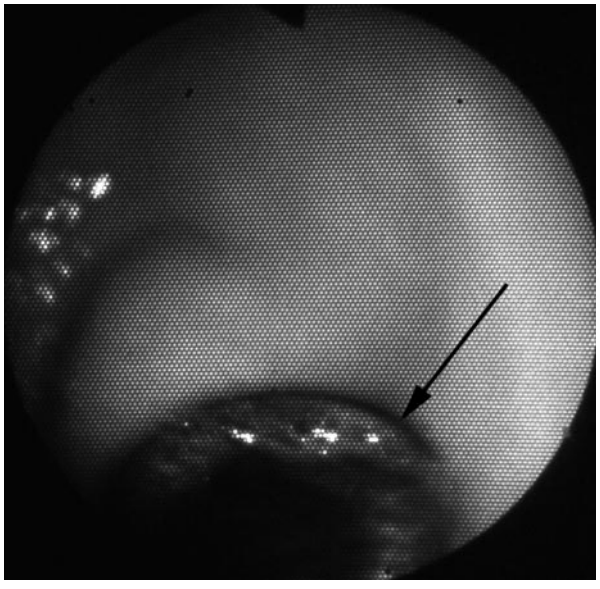

FIGURE 67.2-18 Antral foreign body (*arrow*: coin).

foreign body. It is mandatory that the removal should be carried out under view control and with optimal positioning (pointed end trailing and object close to the tip of the endoscope or in a protective device covering the end of the endoscope) to avoid unsafe removal, especially for sharp objects.

A postremoval surveillance of 12 hours is recommended.

Stricture Dilation

Esophageal stenosis dilatation is indicated in case of esophageal strictures, which can be secondary to several origins: congenital, postoperative, peptic, caustic, infectious, postvariceal sclerotherapy and postradiotherapy. Postoperative strictures are common complications in up to 50% of patients after surgery for esophageal atresia.[218] Peptic stenosis can also be secondary to severe GER with esophagitis, especially in neurologically handicapped children.

Since Trendelenburg in 1883, esophageal stenosis has been dilated either by antegrade or retrograde bougienage, when a gastrostomy can be used. Several types of bougie dilators are available. They develop an axial force along the esophagus, with a high risk of perforation. They are used both blindly following introduction through the mouth or on a guidewire.

An effective and safer alternative to bougienage is the balloon catheter dilation (Figure 67.2-19). Its major advantage is that it dilates uniformly the esophageal stenosis with local stationary radial forces owing to balloon inflation.[219] Indeed, a Gruentzig balloon was developed in 1981 and has been used successfully since.[220] At present, several balloon catheters are available. They can be used under radiologic control with an angiographic guidewire, with a rate of resolution of symptoms of 100% and 70% for congenital and acquired anomalies, respectively.[221]

On the other hand, other balloon devices can be used directly in the operating channel and are called the TTS system ("through the scope" system). However, the maximal dilation diameter is of 8 mm for a 2.8 mm channel and of 12 mm for a 3.5 mm channel. With this technique, the balloon can be placed across the stricture under view control. Then the balloon is inflated with a constant pressure between 3,000 and 4,500 mm Hg for 1 to 3 minutes. The benefit of this procedure is due to the fact that endoscopists can immediately visualize the effect of the dilation on the stricture. In our unit, we use larger balloon catheters (maximum 20 mm diameter), which are introduced by mouth in an antegrade approach. Simultaneously, a flexible endoscope of small size (5 mm) is introduced to control the proper passage of the structure, as well as the positioning of the balloon. Using this method, we have not experienced perforation during the last decade.[222]

This procedure can be performed under antibiotic prophylaxis, and a thoracic radiograph is obtained in case of suspicion of perforation. The reintroduction of nutrition is recommended after 24 hours if the patient remains asymptomatic. The number of dilations and their frequency depend on the type and size of the stricture. Consequently, an exact agenda cannot be recommended but will be modulated by the efficiency of the first dilation.

Note that an antisecretory medication (eg, omeprazole) can be useful after dilation to avoid relapse.

Achalasia is a special indication for balloon dilation. The treatment of this condition necessitates the use of a 35 to 40 mm balloon to reach a pressure of 500 mm Hg, to allow the rupture of the muscular layer gradually over at least two or three sessions. The results of this technique compared with conventional surgery are contradictory but are comparable to the latter in some studies.[223] The rate of esophageal perforation for achalasia is between 1.4 and 4%, with a rate of mortality around 0.5%. Recently, the injection of botulinum toxin in the lower esophageal sphincter was described as a potential alternative to balloon dilation or Heller surgery.[224,225]

Bleeding Control

Nonvariceal hemorrhage can be endoscopically treated either by thermal or nonthermal methods. Thermal coagulation includes laser, heater, monopolar, or multipolar probes. Nonthermal coagulation consists of injection of agents that can be either sclerosing or vasoconstrictive. Both seem to have the same efficacy, yet the injections are easier and cheaper and can be done with smaller endoscopes.

The two main clinical applications are active bleeding of an ulcer and a visible vessel. In active bleeding, injection of epinephrine (5–10 mL of 1:10,000) in the four angles of the lesion is the method of choice. Bleeding stops in 80 to 85% of cases.[226] Addition of a sclerosing agent, such as 1% polidocanol, is recommended in cases of visible vessels.[227] Some factors are responsible for failure: the ulcer's size (> 2 cm), hypovolemic shock, localization on the lesser curvature, and the presence of active bleeding.[228] Therapeutic endoscopy for active bleeding needs a visual control 24 hours later.

In case of severe hemorrhage, with an unsuccessful therapeutical endoscopy (5 to 8% of the adults, exceptional in children), surgery might be needed.[226]

Endoscopic Therapy of Variceal Hemorrhage

Variceal bleeding is the most common cause of severe gastrointestinal bleeding among children and accounts for one-third of all deaths related to cirrhosis in adults. However, the hemorrhage can be due to intra- or extrahepatic causes in childhood. Indeed, extrahepatic portal venous

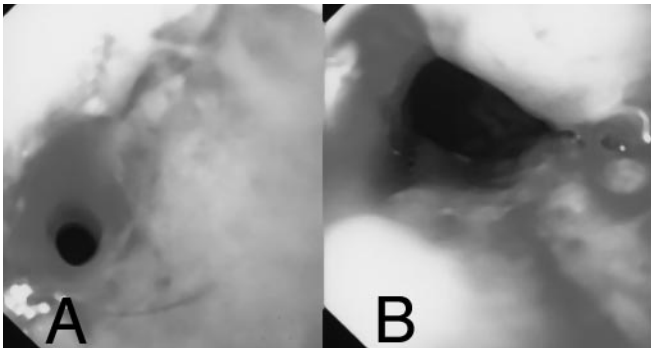

FIGURE 67.2-19 Severe esophageal stricture due to gastroesophageal reflux: *A*, before, *B*, after balloon dilation.

obstruction is a more frequent cause of bleeding in children when compared with adults. Unlike patients with cirrhosis, mainly owing to biliary atresia, those with extrahepatic portal hypertension have a better prognosis because of their liver function preservation.[229] The causes of death attributable to variceal bleeding include recurrent variceal hemorrhage, liver failure, hepatic encephalopathy, and infections. Portal hypertension is characterized by a pressure above 15 mm Hg, which leads to an impaired blood flow into the portal system. In portal hypertension, the mediastinal veins are organized in esophageal varices and in paraesophageal mediastinal veins. Esophageal varices can develop under the effect of pressure higher than 10 to 12 mm Hg.[230] However, their rupture does not seem to be due to a direct relationship between bleeding risk and exact level of portal pressure but to an imbalance between portal hypertension and resistance of the vessel wall.[231]

Endoscopic diagnosis of esophageal varices must be precise. Esophageal varices can be white or blue and are classified in four grades.[232] Grade I corresponds to varices that disappear with air insufflation, grade II corresponds to nonconfluent varices that remain identical with air insufflation, and grade III corresponds to confluent varices that cause an obstruction of the esophageal lumen (see Figure 67.2-11); the addition of red signs (cherry red spots, red wale markings, hematocystic spots, telangiectasia, varices overlying varices) leads to grade IV, with a higher and more precocious risk of bleeding. The classification of gastric varices is simpler: grade I in case of potential presence and grade II when the varices are overt, with red signs, which are easy to differentiate from gastric folds (Figure 67.2-20). Finally, the hypertensive gastropathy is secondary to the hyperkinetic syndrome owing to portal hypertension (Figure 67.2-21). It can be moderate or severe with purpuric spots, vessel ectasia, or erosions. Gastrointestinal bleeding secondary to portal hypertension is mainly due to rupture of esophageal varices. Among children, this situation represents only 15% of the causes of upper gastrointestinal hemorrhage, but it is often severe and life threatening. In specialized centers devoted to liver diseases and transplant, this percentage can be higher.

Adult guidelines for the diagnosis and treatment of gastrointestinal bleeding secondary to portal hypertension were published by the American College of Gastroenterology Practice Parameters Committee.[233] Some good reviews are available for children,[234,235] but no guidelines exist. Consequently, the optimal approach and treatment of children are still controversial, often depending on each center's competences and experience.

The diagnosis of variceal rupture is possible in up to 50% of cases.[236] The endoscopy can reveal a diffuse or localized deposit on a varice. The main localization of the variceal rupture is in the last 3 to 4 cm of the esophagus. Some endoscopic signs have a good positive predictive value for future bleeding, such as large-sized varices, cherry red spots, and varices of the cardia. Seventy-five percent of children with bleeding present with all of these signs.

To date, many modalities for treating variceal bleeding have been recommended, including pharmacologic therapy, endoscopic treatment, surgical approach, and radiologic shunting. Unfortunately, none of the existing methods of treatment are optimal because the association of different therapies can be helpful.

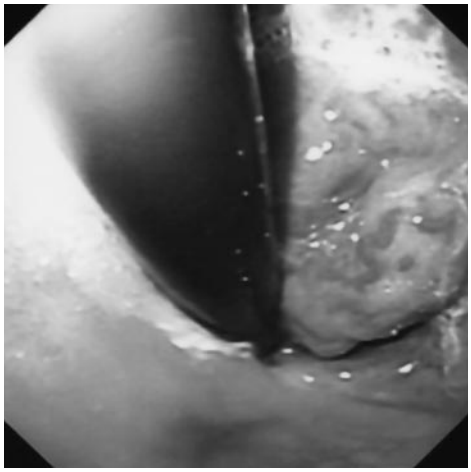

FIGURE 67.2-20 Cardial varices with red signs.

Endoscopic Sclerotherapy. Endoscopic sclerotherapy (EST) was the first efficient endoscopic approach in both adults[237] and infants[238] to treat both acute bleeding and risk of relapse, with less morbidity and mortality when compared with surgery (Figure 67.2-22). Ideally, EST is realized after a short delay (eg, 24 hours) and under endotracheal anesthesia. The timing of EST is weekly for 3 weeks and then monthly until the total eradication of the esophageal varices. Three techniques have been used: paravariceal, intravariceal, and both para- and intravariceal injections. At present, the most common procedure is the intravariceal injection. The most popular sclerosing drug in Europe is polidocanol 1 to 2%. Note that sodium morrhuate, ethanolamine, and absolute alcohol are also used. With a mean dose of 2.5 mL of polidocanol for each injection and a total amount of 10 to 12 mL, the eradication of

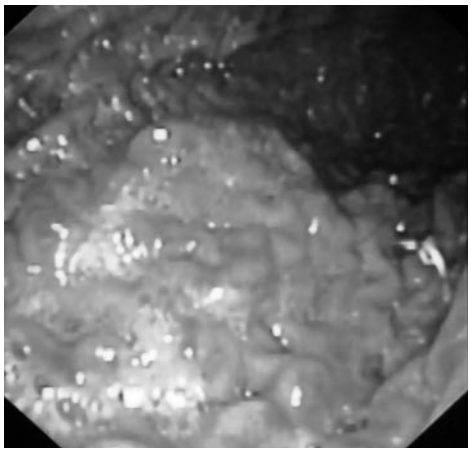

FIGURE 67.2-21 Congestive gastropathy due to severe portal hypertension in patient with cystic fibrosis.

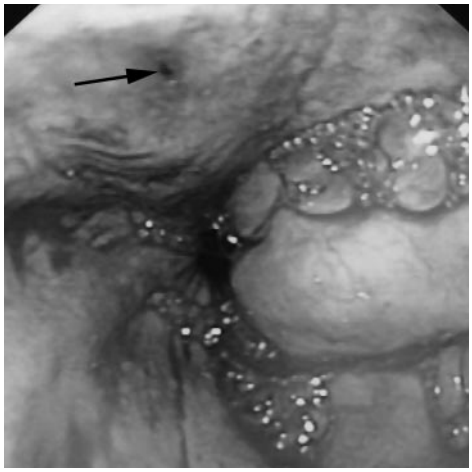

FIGURE 67.2-22 Esophageal varice after sclerotherapy with polidocanol and methylene blue. *Arrow* indicates injection point.

the varices is obtained after four to five sessions of EST. In a recent pediatric study, 95% of the patients had their varices successfully eradicated after a mean of 4.5 EST sessions.[239] The risk of a recurrence of bleeding is different among the studies depending on the realization of a liver transplant or a surgical shunt, ranging from 2[239] to 26%.[240] A rate of 10% must be considered realistic even if the rate of recurrence of varices is higher.

EST causes numerous side effects. Up to 50% of patients complain of dysphagia lasting for 2 days. Owing to the chemical properties of the sclerosing products, ulcers can appear in 17% of cases.[239] They can be responsible for precocious, severe rebleeding. Sucralfate, anti–histamine$_2$, or proton pump inhibitor drugs can be used to accelerate ulcer healing. Strictures are also potential complications of EST and were encountered in around 20% of cases.[239] The most serious complication of EST is perforation, which was described in up to 4% of the series[241] and in 1.4% of this recent study.[239] Its mortality is high. Perforation can also lead to esopleural or esobronchial fistulae. Infrequent complications such as sepsis,[182] bacterial peritonitis,[242] bacterial meningitis,[243–246] cerebral abscess,[245,246] and permanent paraplegia[247] have also been reported. Consequently, prophylactic antibiotics are prescribed because they have been shown to reduce bacteremia and bacterial peritonitis. The use of *N*-butyl-2-cyanoacrylate (Histoacryl), which coagulates instantaneously on contact with blood, is rare among pediatric patients and only related to bleeding of fundus varices. The risks of permanent obstruction of the channels of the endoscope are high. For other localization of bleeding varices, such as the duodenum or rectum, the procedure must be evaluated in each case by the operator.

Endoscopic Variceal Ligation. Endoscopic variceal ligation (EVL) was reported more recently and seen as a safe and quick procedure in adults.[248] EVL was introduced for pediatric patients only recently.[249,250] This procedure is limited in children by the size of the ligation device and by the fact that fewer bands can be applied per session owing to the small esophageal lumen. Apart from these restrictions, EVL is easy to realize, with a low complication rate. The latter is related to the mechanical strangulation of varices with little tissue inflammation and injury. The only serious complications are related to the use of an overtube: laceration, perforation, and punching injury of the esophagus. These lesions can provoke retrosternal pain or dysphagia.

Comparison of Different Modalities of Endoscopic and Medical Treatment. Most studies reported that EVL is superior to EST in terms of speediness, safety, rebleeding, and complications in adults.[237] EVL was also compared with EST in pediatric patients in a recent study.[251] No significant differences were found between EVL and EST in stopping bleeding and achieving variceal eradication. EVL eradicated varices in fewer endoscopic sessions and had significantly lower rebleeding and complication rates. However, recurrence of esophageal varices was similar in both EVL and EST groups after eradication. Consequently, both adult and pediatric data seem to favor EVL rather than EST to prevent risk of rebleeding.

Both EVL and EST are more effective when associated with vasoactive agents than alone. On the contrary, the combination of EVL and EST in the same session does not seem to be recommended because the complications increase more than the benefits.

Finally, endoscopic therapy is less effective than radiologic transjugular intrahepatic portosystemic shunt (TIPS) in terms of variceal rebleeding. However, TIPS must be considered as a rescue procedure before a liver transplant because the risk of occlusion in TIPS is high, as well as the development of encephalopathy.

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

In the early 1980s, Ponsky and Gauderer developed a PEG,[252] drastically changing the pediatric approach to enteral feeding, in particular in patients with swallowing difficulties. This minimally invasive, sutureless method is nowadays used worldwide to help provide appropriate nutritional intake

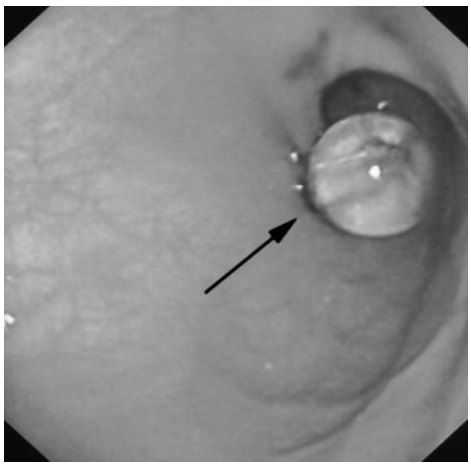

FIGURE 67.2-23 Gastrostomy button MYCKEY type (*arrow*).

with comfort and easy care. Ethical and moral concerns were raised with the increasing number of procedures, and guidelines for indications have been drawn.[73,74]

In the pediatric population, the intervention takes place under general anesthesia on a fasted patient. The patient is at high risk of infection, and antibiotic cover is recommended by gastroenterologist societies[73,74] because it reduces the rate of both peristomal and systemic infections to less than one-quarter.[252–257] At even higher risk are patients suffering from diabetes mellitus.[258] The most commonly recommended regimen is amoxicillin or intravenous cephalosporin.

Although the risks and potential benefits of enteral access catheter placement must be weighed in each patient, certain anatomic and pathologic conditions may increase the likelihood of complications. The absolute contraindications to percutaneous feeding tube placement are uncorrectable coagulopathy and unfavorable anatomy, with inability to bring the anterior gastric wall in apposition to the abdominal one. Relative contraindications are massive ascites, peritoneal dialysis, active gastritis or peptic ulcer disease, and gastric varices. Examples of unfavorable anatomy include malrotation; interposition of the colon, spleen, or liver between the stomach and anterior abdominal wall; intrathoracic stomach; and previous gastrectomy. Hepatomegaly, severe scoliosis, and obesity are not contraindications but may impede gastric transillumination and subsequent placement of the PEG.

A portion of patients needing gastrostomy suffer from conditions associated with reflux, such as neurologic impairment, myopathies, cystic fibrosis, and chronic respiratory failure. The indication of performing a simultaneous fundoplication is still a subject of controversy[88] because it seems to bear a higher complication incidence.[259] In addition, contradictory data result from the studies performed, some showing that the PEG procedure tends to aggravate the reflux, at times antireflux treatment being necessary,[260–263] whereas some show no effect.[259,264–266] Careful evaluation of the clinic and the severity of reflux will provide the elements to decide for a prophylactic fundoplication in a case by case approach, systematic antireflux surgery being increasingly abandoned.

Three techniques have been described to insert the stoma: the "pull-through," in 1980, by its inventor[261]; the "push-pull" technique, in 1981, by Sacks and Vine[267]; and, finally, the "introducer" technique by Russell and colleagues 3 years later.[268] Only the techniques most commonly used in pediatrics are described here. Patients lie flat on their back. The abdomen is disinfected with an antiseptic solution. An endoscope is passed down to the stomach and air is insufflated to approximate the stomach to the abdominal wall. The tip of the endoscope is then applied against the anterior wall, with transillumination helping to choose the exact place for the gastrostomy. The site of choice is located at the junction of the external two-thirds of a line drawn between the umbilicus and the midportion of the left inferior costal margin. Gastric indentation is created by digital pressure on the abdominal wall to check the final stoma position. After a small incision of the skin, the needle is passed into the gastric cavity. At this point, it is important that the endoscopist keep the stomach well inflated to avoid interposition of either the spleen, the liver, or, especially, the transverse colon. A string is then passed through the needle, to be seized by endoscopic snare or forceps and brought out through the mouth of the patient together with the gastroscope. The feeding catheter is then fixed to the oral end of the wire and is gently pulled back through the patient's mouth into the stomach and pulled out through the abdominal wall. The feeding tube ends with a stabilizer or "bumper," shaped either as a crossbar, an X, a T, or a cup, allowing it to be retained in the stomach. The maintenance of apposition of the peritoneal and serosal surfaces will create adherence. One should make sure that no excessive tension is applied to the wall by viewing it directly with the endoscope. An external retaining crossbar helps to maintain the right pressure. Daily rotation to 90° will avoid not only skin lesions but the proliferation of the gastric mucosa. Feeding through the device can start 6 hours postintervention. When the feeding tube is no longer necessary, the device is cut at the skin level. Good practice recommends performing it with endoscopic assistance to retrieve the bumper. Bowel obstruction and perforation caused by the internal part, left within the stomach to pass spontaneously, have indeed been reported in the literature.[269–271]

The feeding tube can be replaced in a second time by a button (Bard [Bard Medica, Volketswil, Switzerland], with a mushroom, or MYC-KEY [Cosanum, Schlieren, Switzerland], with a balloon as a bumper [Figure 67.2-23]). These devices, more esthetic and easier to conceal under the clothes, contain an antireflux valve that helps to avoid skin lesions. Once the gastrostomy tube or the button has been removed, the orifice will close itself in 48 hours. Delay of gastrostomy closure has rarely been observed up to 2 years later.[272]

The rates of adult morbidity and mortality are lower than those for surgical gastrostomy: 3 to 12% versus 30% for morbidity and 1 to 12% versus 16% for mortality.[273–276] Therefore, it should be preferred to surgical gastrostomy if no contraindications are present. In children, severe complications are observed in 3% of the PEG cases, including aspiration bronchopneumonopathies and migration of the bumper at the tip of the gastrostomy tube inside the abdominal wall, also called the "buried bumper syndrome." The condition resulting from excessive traction on the tube, sometimes secondary to growth of the patient, is the most common complication encountered. The button seems more likely to cause it than PEG.[272] Endoscopically, the bumper is partially or not seen, buried in the mucosa. Direct viewing will distinguish it from newly described pseudotumoral proliferative gastric mucosa, revealing an ulcerate mass or polyps. Peritonitis occurs immediately after insertion of the PEG or at the time of button change. It is due to stomal separation, tube malposition, or leakage. Rare cases of gastrocolic fistula have been reported in children, probably owing to misplacement of the colon at the time of insertion.[272,277,278] Risk factors are abdominal surgery that took place prior to insertion of the PEG and

insufficient transillumination. Head supraelevation might reduce this risk by displacing the colon to the lower abdomen. Necrotizing fasciitis starting around the site and ulcers are rare complications. Two cases of hemoperitonitis have been personally encounted by one of the authors. The bleeding is caused by the lesion of parietal gastric vessel and can be fatal if the diagnosis is not made.

Less severe complications happen in 7 to 13% of the interventions, mainly represented by peristomal infections and pneumoperitonium, proving air leakage around the hole. When minor complications, such as granulation, are counted, the rate goes up to 44%.[272] When it takes place immediately after PEG insertion, simple traction on the feeding tube will abolish it by reducing the space between the stomach and the abdominal walls. Feeding through the tube should be delayed. If still present at 48 to 72 hours, laparoscopic exploration needs to be discussed. Local infections need to be taken seriously because they can lead to sepsis. Complication can also occur during replacement, the tube being not well introduced in the stomach. Endoscopic control will avoid missing such a problem. Secondary displacement of the button end has been seen. Granulation tissue sometimes grows around the site, occasionally causing oozing of blood. Treatment consists of chemically burning the tissue by topical application with silver nitrate ($AgNO_3$) sticks.

3. *Ileocolonoscopy and* Enteroscopy

Mike Thomson, MB ChB, DCH, FCRP, FRCPCH, MD

This chapter focuses on technique and clinical application of ileocolonoscopy and enteroscopy in childhood. The impact of endoscopic investigations and therapies on specific disease processes and comparison with alternative methods are also discussed. Topics to be covered include the following:

- Patient preparation
- Bowel preparation
- Endoscopy facilities
- Monitoring and sedation or anesthetic
- Equipment
- Basic and advanced techniques in diagnostic and therapeutic ileocolonoscopy
- Indications
- Complications
- Follow-up and surveillance ileocolonoscopy
- New diagnoses
- Diagnostic comparison with noninvasive investigations
- Enteroscopy: indications, techniques, and complications

ILEOCOLONOSCOPY

Safe, informative, and effective ileocolonoscopy performed in a child-friendly environment with the minimum of distress to child and parent alike is a sine qua non for best-practice care of children and adolescents with conditions affecting the ileum and colon, such as inflammatory bowel disease, allergic colitis, and polyposis syndromes.

The care of children and adolescents differs in important ways from that of adults. This is reflected in the emphasis placed on various aspects of ileocolonoscopy, such as the frequent use of general anesthesia, the number and location of mucosal biopsies, and the routine inclusion of ileal intubation during a complete examination. The question of who should conduct the procedure continues to receive attention among pediatric gastroenterologists. It is generally accepted that a pediatrician, preferably with experience in pediatric gastroenterology, should be involved in the care of the child or adolescent and, ideally, should carry out the procedure. There can be few more satisfying experiences in medicine than making a clinical judgment and diagnosis in a child, confirming the nature and extent of the disease oneself by endoscopy, treating appropriately, and then visually demonstrating the success of such endeavours to child and parent by a follow-up procedure.

The practice of pediatric ileocolonoscopy has evolved dramatically over the past 15 to 20 years. Improvements in skill and technique have followed the advances in technology, from the advent of fiberoptic endoscopes used in pediatrics during the late 1970s[1] to the latest small-diameter, electronic videoendoscopes designed specifically for younger children.[2–8]

TRAINING

Much debate has surrounded the issue of the minimum procedure number required during training to achieve competence because a paucity of data exists to support one view or another. Guidelines issued by the North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) in 1997 recommended a minimum of 50 colonoscopies. The guidelines were revised in 1999, increasing the threshold number to 100 and including numbers for therapeutic techniques such as snare polypectomy (20), stricture balloon dilation (15), and injection therapy or electrocautery (20).[9–11] It is apparent that some ongoing skill assessment is needed during training. A logbook of procedures undertaken with a trainer's assessment of skill level will undoubtedly become common practice in recognized training centers. This will shift the emphasis from "number counting" to skill assessment, which is sensible given that trainees learn at different rates. However, some minimum numbers are likely to remain.

It has previously been suggested that training on endoscopy stimulators may reduce the time needed to reach competency in endoscopy. Ferlitsch and colleagues randomly allocated beginners in adult ileocolonoscopy to either receive training on the GI-Mentor (Symbionix Ltd, Lod, Israel 71520) or no training for 3 weeks after baseline assessment.[12] They were subsequently reassessed on the endoscopy simulator, and a statistically significant difference between the two groups was seen. The Royal Free Centre for Paediatric Gastroenterology has a Symbionix GI-Mentor (Figures 67.3-1 and 67.3-2; <www.symbionix.com>), to which trainees now have access. Looking at the ileocolonoscopy skill graphs (Figure 67.3-3), it is clear that three individuals (numbered 8, 9, and 10 in the figures) exhibited much steeper learning curves and seemed more competent having completed a smaller number of procedures than the other seven. These three had had a 6-week program of training on the ileocolonoscopy simulator prior to their first "live" ileocolonoscopy. The trainees log their performance by saving it under their own identifiable code, and the trainer can assess this at any time by logging into the simulator in

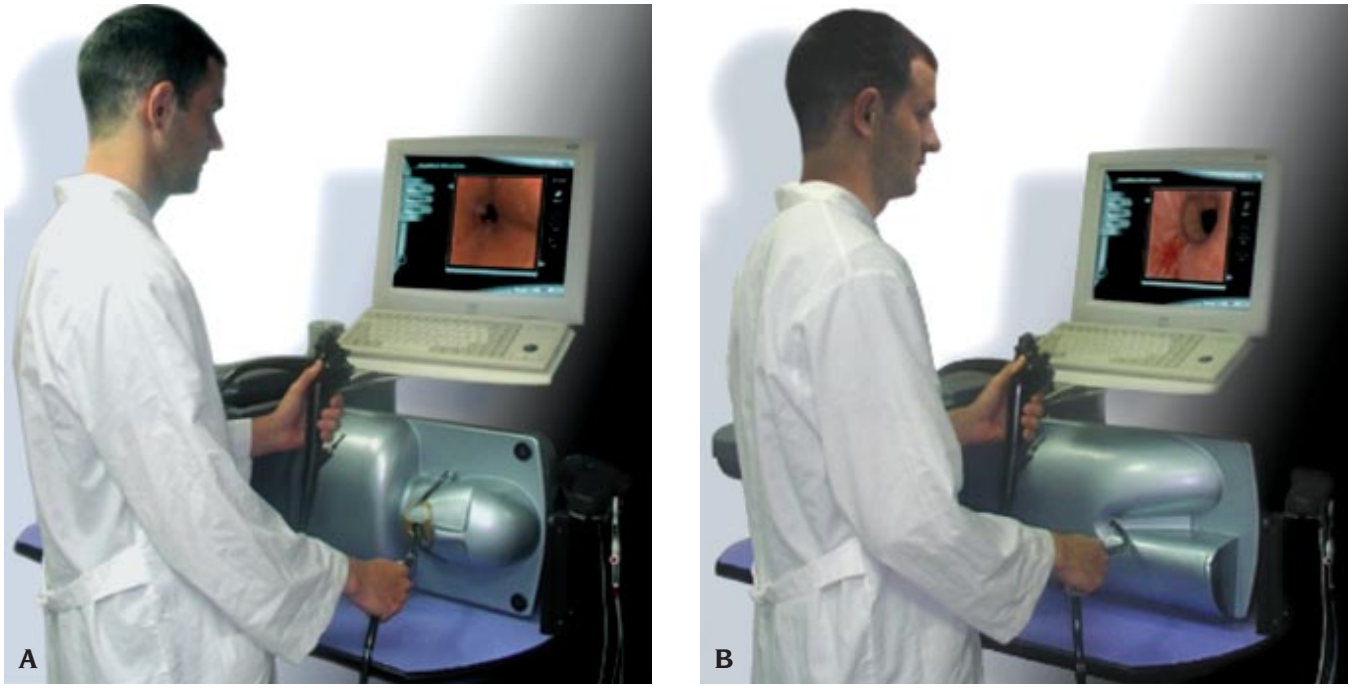

FIGURE 67.3-1 Symbionix GI-Mentor simulator for *A,* endoscopy and *B,* colonoscopy training.

trainer mode and so assess and feed back to the trainees their performance. This interactive approach is flexible and accelerates the learning process.

It is clearly preferable and more effective to learn the basic techniques on a model rather than a patient, and this approach does seem to work, at least on the basis of this preliminary experience. As these tools become more widely available, they are likely to become the first step and would seem to be the ideal introduction to training in pediatric endoscopy and ileocolonoscopy, before actual patient procedures are undertaken.

To collate the views of all pediatric gastroenterologists, the recent World Congress on Pediatric Gastroenterology convened a working group on endoscopy, and one of its remits was to examine the issue of training.[13] This has recently been updated to coincide with the 2004 World Congress meeting in Paris but is not yet published. Three main areas requiring attention were identified: the estab-

lishment and recognition of "Centers of Excellence in Pediatric Endoscopy," the use of training videotapes, and attendance at live and "hands-on" courses in pediatric endoscopy. The recommended goals for training were similar to those of the NASPGHAN position paper of 1999:

1. The ability to recommend endoscopic procedures based on the findings of a personal consultation and recognize indications, contraindications, and diagnostic or therapeutic alternatives for endoscopic procedures
2. To perform procedures safely, completely, and expeditiously
3. To correctly identify most endoscopic findings and perform endoscopic intervention as needed
4. To integrate endoscopic findings into a management plan
5. To understand risk factors and to recognize and manage complications
6. To recognize personal and procedural limitations and know when to request help
7. To be familiar with national organizational guidelines regarding sedation and monitoring for pediatric gastrointestinal procedures
8. To identify age- and indication-appropriate endoscopic equipment
9. The proper cleaning and maintenance of endoscopic equipment with special attention to infection control measures

Quality assurance has received little attention to date and is an issue that may begin to assume more importance, for instance, in the United Kingdom, where Clinical Governance and increased accountability are taking place. A multidiscipline body has been set up in the United Kingdom to address training issues, the Joint Advisory Group on gastrointestinal endoscopy (<www.thejag.org.uk>), and it oversees all training issues; ongoing assessment, revalidation, trainer and training center accreditation, and certification in endoscopic training are just some of the difficult issues now being dealt with effectively by this body, the

view being that only through proper training can standards be improved in general. Striking differences in technical standards and appropriateness of ileocolonoscopy between centers emerged in one study in adult practice in Italy.[14] Quality improvement has been addressed by the American Society for Gastrointestinal Endoscopy.[15]

ENDOSCOPY FACILITY AND PATIENT PREPARATION

Ideally, both the child and the parents should be offered a preparatory visit to the endoscopy unit to answer questions and defuse any potential concerns and anxieties regarding the procedure and admission. Younger children undoubtedly benefit from preadmission visits and the involvement of a play therapist to enable some understanding of what is to take place and why.[16–18] Diagrams may help in explanations to older children. Preparatory videotapes are also useful for informing the patient and parent regarding what to expect. Units can benefit from devising a sample videotape specific to their own facility. A reduction in anticipatory anxiety may even reduce the amount of intravenous sedation required.[19] A child-friendly decorated endoscopy room with age-appropriate videotapes and familiar faces is important at this time of high stress. Parents may stay to watch the procedure in some units when intravenous sedation is provided. Most anesthesiologists would object to having parents present during administration of a general anesthetic, beyond the initial induction. Improved medical compliance and belief in the treatment are potential advantageous consequences of allowing parents to directly view the initial disease and its remission at follow-up ileocolonoscopy.[20] Young children often request photographs or a videotape of the ileocolonoscopy, and even older adolescents may view the procedure themselves.

A full screening is important to identify potential sedation or anesthetic risks. Although there is little correlation of mildly deranged peripheral coagulation indices with hemorrhage after mucosal biopsies, more pronounced bleeding diatheses may require forethought and appropriate blood product backup.[21] Properly informed consent should be obtained with an information sheet detailing potential complications and their incidence, and a separate consent should be signed in the event of research biopsies being requested.

Guidelines concerning antibiotic prophylaxis in children with lesions susceptible to endocarditis or in the immunocompromised child are available in the literature.[22] A low rate of bacteremia owing to bacterial translocation across the bowel wall has been demonstrated following pediatric ileocolonoscopy.[23] A combination of intravenous or intramuscular ampicillin (50 mg/kg, maximum 2 g) and gentamicin (2 mg/kg, maximum 120 mg) 30 minutes before and 6 hours after the ileocolonoscopy is generally recommended. Vancomycin (20 mg/kg slow intravenous infusion 1 hour before) can be substituted for ampicillin in those with documented penicillin allergy. It would seem reasonable to administer antibiotic prophylaxis in the rare case of percutaneous cecostomy or sigmoidostomy as for percutaneous gastrostomy insertion.

BOWEL PREPARATION

Poor bowel preparation is a major factor that may prevent or impede successful ileocolonoscopy. Although administration of regimens is not always easy, modern protocols can be remarkably effective in clearing the colon and ileum. Until 5 or 6 years ago, large volumes of oral electrolyte lavage solutions were used with variable success, coupled with the significant disadvantages of nasogastric administration and potential for fluid-electrolyte shifts in smaller children and infants. In one study, 40 mL/kg/h resulted in clear fecal effluent after a mean of 2.6 hours.[24] Subsequently, more favorable results and compliance were reported with low-volume oral agents and enemas, along with decreased oral intake.[25–28] Use of sodium phosphate preparations was associated with a transient rise in mean serum sodium and phosphate but with no change in serum calcium.[26,27] Refinements were made to these oral and enema regimens as newer preparations, which were more acceptable to children, became available; low-volume nonabsorbable polyethylene glycol preparations are becoming increasingly popular in pediatric units and are well tolerated, with no observable electrolytic disturbance.[29,30] Table 67.3-1 outlines several low-volume regimens that have been used successfully in children. The regimen employed in our unit, shown in Table 67.3-2, combines the beneficial effects of oral low-volume administration with the backup of an enema 1 to 2 hours beforehand if no clear fecal effluent is observed.[31] No clinically significant fluid shifts or electrolyte imbalances have been observed in over 2,000 colonoscopies over a 5-year period in our unit.

The benefit of an intravenous antispasmodic agent administered directly before the ileocolonoscopy has recently been demonstrated.[32] Hyoscyamine 0.5 mg was

given in this study of adults. An alternative could be hyoscine 20 mg adminstered intravenously. The use of such an agent given just prior to colonoscopy is determined by personal preference. Their use may facilitate ease of luminal visualization, but it also may increase the compliance of the colon, theoretically allowing a greater chance of loop formation. They are certainly of benefit in spastic colonic situations. It should be remembered that they work only for a short period of time, however—perhaps as short as 5 minutes—and they may be readministered in certain situations, such as when one needs to relax a haustral fold if a polyp is just beyond and obscured by it, or occasionally when one needs to relax a spastic ileocecal valve.

MONITORING AND SEDATION

Debate has surrounded the relative merits and safety of sedation and general anesthesia for upper gastrointestinal endoscopy and ileocolonoscopy in children for the past 5 to 10 years.[33–35] The use of sedation for endoscopy has been comprehensively reviewed recently.[35] The proponents of general anesthesia maintain that sedation is merely a financial or logistic expedient when the services of an anesthesiologist are less accessible.[33,34,36] In one US study, the cost of an endoscopy under general anesthesia was twice that under sedation.[37] It is generally agreed that children should receive, at a minimum, an analgesic in combination with a hypnotic for potentially painful or frightening procedures.[38]

It is also acknowledged that the concept of "conscious" (or "safe") sedation is not the prevailing clinical scenario in sedation in gastrointestinal endoscopy in pediatrics, and to get the requisite cooperation, and therefore a properly conducted procedure with mimimum distress to the child, deep sedation is usually necessary. It is further recognized that there are attendant safety issues of airway maintenance in this situation, and at the very least, a specific individual with appropriate advanced pediatric life support skills should be responsible for the child's cardiorespiratory welfare during such a procedure. The vast majority of pediatric gastrointestinal endoscopy under the age of 8 years in the United Kingdom, for instance, now occurs under general anesthesia.

When a child is sedated, resuscitation equipment should be easily accessible, and one or more people trained in pediatric advanced life support should be responsible for maintaining the airway and monitoring respiration, heart rate, blood pressure, and oxygen saturation.[39,40] Older children can sometimes benefit from conscious sedation such that they can participate in observing their ileocolonoscopy.[20] Sedation of younger children can be aided by environmental comforts such as a soothing voice or dimmed lights.[41] In all age groups, it is often necessary to use deep sedation because of the pain that can be associated with this procedure.[42] With deep sedation, it is clear that the risks are significant, including hypotension, respiratory compromise, and even respiratory arrest.[43] Combinations of benzodiazepines (midazolam in preference to diazepam) and opioids (pethidine or meperidine and fentanyl) are reported, with the occasional report of ketamine.[35,44] Table 67.3-3 lists some of the commonly used sedation regimens with the reversal agents.

Recent studies examining the safety of general anesthesia for day-case ileocolonoscopy in children refute claims that there may be more risk of perforation because the operator cannot judge the degree of discomfort as a marker of impending traction injury.[45,46] There is indeed a lack of evidence to support the contention that there is a higher complication rate with a general anesthetic than with sedation.[47] In fact, the airway is protected in a more effective and safer manner than with sedation, especially in upper endoscopy, with an improved operator satisfaction.[48]

EQUIPMENT

Most modern units employ adult and pediatric videocolonoscopes, and the general technical specifications for the pediatric instruments differ little between manufacturers (Table 67.3-4). When and in whom to use a pediatric colonoscope is mainly a matter of personal preference. We use personal judgment based on age and/or body weight. In general terms, the lower limit for the adult colonoscope is 3 to 4 years of age and/or 12 to 15 kg. The extra stiffness of the adult versions diminishes the likelihood of forming sigmoid loops, but extra care must then be taken, especially in younger children and with general anesthesia, not to advance against undue resistance, to avoid the unlikely complication of colonic perforation. The larger diameter of the adult colonoscopes can also lead to problems of

TABLE 67.3-3 SEDATION AND REVERSAL MEDICATIONS COMMONLY EMPLOYED IN PEDIATRIC ILEOCOLONOSCOPY

Midazolam: IV initial dose 0.05–0.1 mg/kg then titrate to maximum 0.3 mg/kg or 10 mg, whichever is lower[3]
Oral dose 0.75 mg/kg or 15 mg, whichever is lower[34]
Fentanyl: IV initial dose 0.5–1.0 μg/kg, then titrate to maximum 5 μg/kg[3]
Meperidine/pethidine: IV initial dose 0.5 mg/kg, then titrate to maximum 2 mg/kg or 75 mg, whichever is lower[34]
Flumazenil: IV dose 0.02 mg/kg (maximum 0.2 mg) and repeat every minute to maximum of 0.05 mg/kg or maximum 1 mg[3]
Naloxone: IV dose 0.1 mg/kg (maximum 2 mg) and repeat every 2–3 min to maximum 10 mg[3]

maneuverability within the smaller colonic lumen of a young child. The variable stiffness colonoscope (see Table 67.3-4) may negotiate some of these problems. A control dial on the upper shaft of this small-diameter colonoscope (Olympus XCF-240AL/I, Olympus Corporation, Tokyo, Japan) allows an increase in the stiffness of the insertion tube when passing through the sigmoid and transverse colon to avoid looping.[49]

More recently, magnifying colonoscopes have been developed, and their value in combination with dye spray or chromoscopy in various gastrointestinal diseases has been described.[50] For instance, the decrease in the number of cryptal openings in ulcerative colitis can be observed and correlated to disease activity,[51] but this does not substitute for histologic assessment.

For insufflation, there may be some advantage awarded by the use of carbon dioxide in place of air because it is more rapidly absorbed, leading to less patient discomfort and, theoretically, less risk of perforation.[52,53]

ILEOCOLONOSCOPY BASIC TECHNIQUE

Getting Started and Patient Positioning

The patient is usually positioned in the left lateral knee to chest position, although some operators prefer the right lateral position, citing easier sigmoid negotiation. Certainly, if the procedure is not subsequently allowing easy access to the splenic flexure, then patient repositioning from one side to the supine and then to the other side may be advantageous. In general, frequent turning of the patient is conducive to easier ileocolonoscopy as a whole and is to be advocated. An assistant stands on the operator's left to administer any abdominal pressure that may subsequently be deemed necessary to control, or try to prevent, loop formation in the sigmoid or transverse colon.

Practical Tips in Ileocolonoscopy

One important "trick" in learning ileocolonoscopy is to grasp the concept of the lumen and the positions of a clock face. For instance, if the lumen is at 9 o'clock, then to enter this requires anticlockwise rotation combined with upward deflection of the scope tip from the "neutral" position of 12 o'clock. Similarly, a combination of upward deflection of the tip with clockwise rotation of the colonoscope will allow entry of the lumen, suggested by a dark crescent, if seen at anywhere clockwise from 12 o'clock to 6 o'clock. Obviously, one may equally use downward tip deflection combined with the opposite rotatory control to that with upward tip deflection, and the execution and teaching of this concept are at personal discretion. With either approach, this is the most important maneuver that can be learned to assist in three-dimensional spatial orientation in the colon.

Prolonged "side viewing" of the bowel wall as it slides by should be avoided. Generally, the only place where, very temporarily, the lumen should be out of view is the occasional difficult negotiation of the splenic flexure. The patient's position may be changed throughout the procedure to facilitate removal of loops and to allow a better view of the lumen because the gravity-dependent material in the colonic lumen changes position. Relatively minimal insufflation of air is desirable in the sigmoid colon because excess air may increase the chance of sigmoid loop formation (carbon dioxide, provided by a specific commercially available delivery system attached to the colonoscope, because the insufflatory gas of choice may be preferable because it is absorbed much more quickly, decreasing pain and the very unlikely chance of perforation; see "Complications").

In handling the colonoscope, it is good practice to have a flat unimpeded surface on which to place the remainder of the colonoscope that is not yet inserted; this is particularly important because then any resistance encountered by the operator to forward advancement of the colonoscope can be attributed to colonic obstruction or loop formation within the child's colon. Hence, relatively quickly, the trainee can acquire a realization of the normal expected resistance to scope advancement. This, in turn, allows understanding of the likelihood of loop formation, without any external resistance to scope advancement, causing confusion with regard to the behavior of the colonoscope within the patient.

Generally, in ileocolonoscopy, gentle scope advancement with clear lumen visualization is desirable, and, usually, only the forefinger and thumb will be required to advance the colonoscope. If greater pressure is required, then the operator is not performing an optimum procedure, and loop formation is likely to have occurred.

Rectal Intubation

Prior to any colonoscopy, it is considered good practice to perform an anal and then a rectal digital examination, the latter to avoid missing, by colonoscopy, very low-lying rectal polyps (although, where possible, retroflexion of the colonoscope in the rectum should occur prior to removal of the instrument to avoid missing lesions close to the anal

margin). Adequate water-soluble lubrication, avoiding the tip of the instrument, allows easy passage into the rectum, which can occur with or without digital guidance from the operator's index finger. Posterior positioning of the tip and air insufflation will allow visualization of the rectal mucosa and the three semilunar folds, or valves of Houston, occurring on alternating sides of the lumen. Subsequently, direct visualization of the bowel lumen is mandatory, except in some circumstances at the splenic flexure. If, at any point, a maneuver results in loss of visualization of the lumen, then reversal of what the operator has just done will often return the lumen to view; if not, the gentle scope retraction combined with minor tip deflections using the wheels and minor rotation of the scope in both directions will usually result in reorientation in the lumen. Obviously, if luminal contents are blocking the view, then lens cleaning will help.

Sigmoid and Descending Colon

Gentle torquing of the shaft clockwise and anticlockwise combined with upward or downward tip deflection and scope advancement is ideal for negotiating the sigmoid colon—the so-called "torque-steering" technique. The initial sigmoid fold or valve can usually be passed by 90 to 120° of anticlockwise torsion. The different loops encountered in the sigmoid are demonstrated in Figure 67.3-4. A so-called N loop may be overcome by transabdominal pressure by an assistant on the apex of the loop pushing toward the feet (see Figure 67.3-4A). This often allows a so-called α loop to form, which can usually be tolerated as the instrument advances toward the splenic flexure (see Figure 67.3-4B). Reducing an α loop is accomplished by initial clockwise rotation and then slow removal of the colonoscope, keeping the lumen in the center of the field of vision. This may not be possible until the transverse (or even ascending) colon has been entered, in which case, it may be assisted by hooking the tip of the scope over the splenic flexure. Paradoxical movement of the tip forward may be observed as the instrument is withdrawn and the bowel "concertinas" over the colonoscope. Abdominal pressure in the left iliac fossa may be helpful. The sigmoid and descending colon are relatively featureless, with less haustral folds than more proximally in the colon.

Splenic Flexure and Transverse Colon

Nonlooped colonoscope length used at this point might be 40 cm in older children and even 20 to 25 cm in those

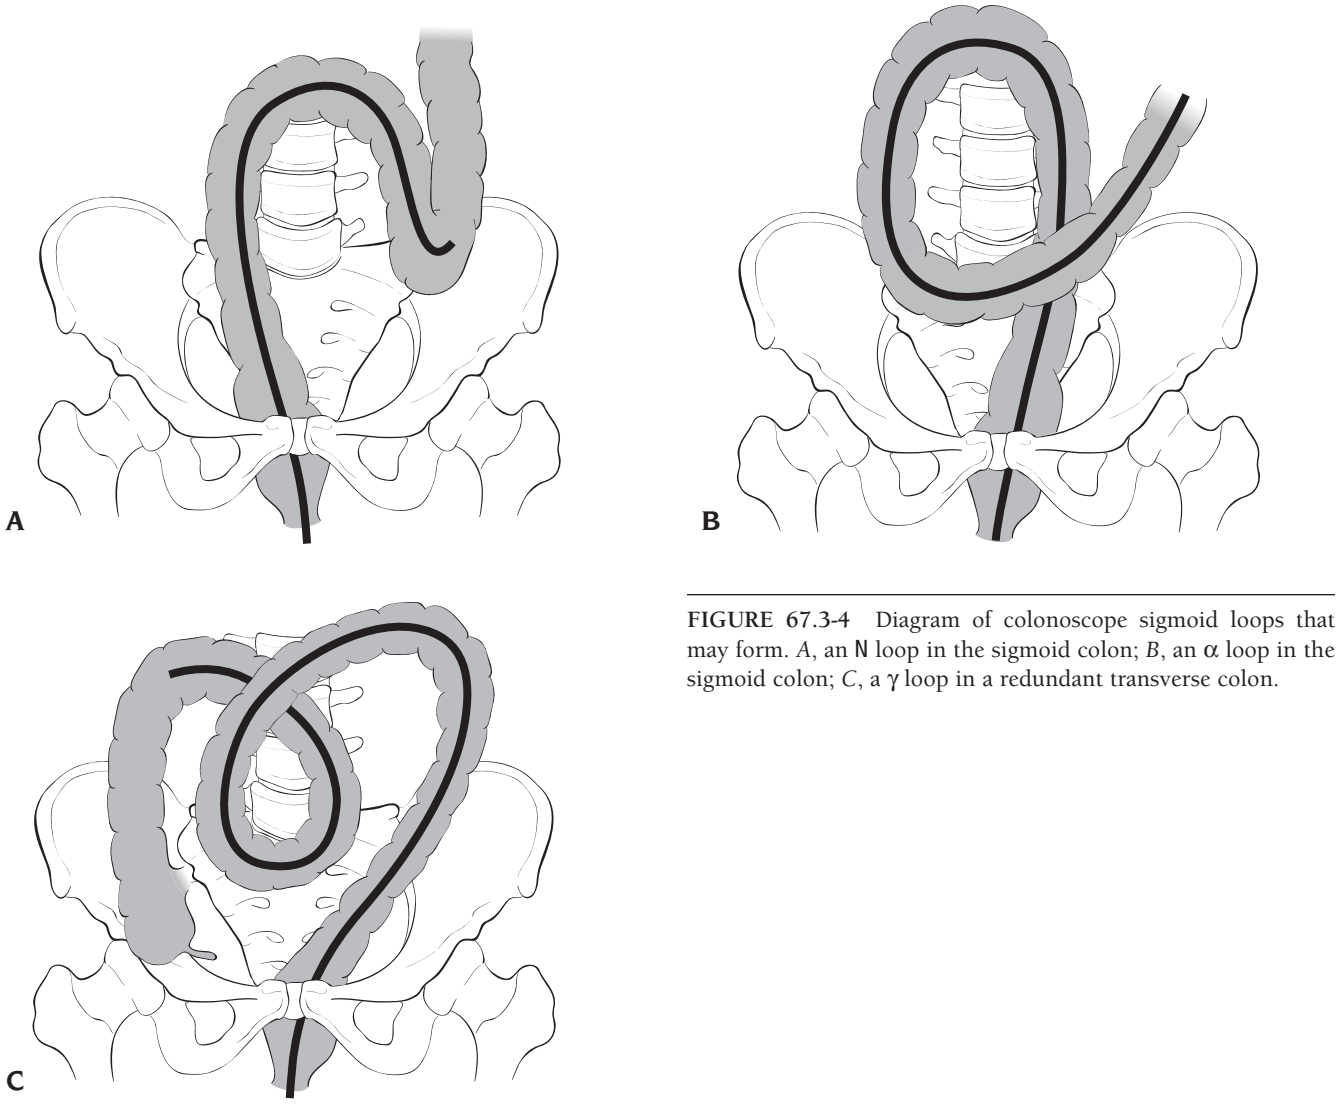

FIGURE 67.3-4 Diagram of colonoscope sigmoid loops that may form. *A*, an N loop in the sigmoid colon; *B*, an α loop in the sigmoid colon; *C*, a γ loop in a redundant transverse colon.

under the age of 3 to 4 years. This is valuable in determining whether a loop is present. At the splenic flexure, the spleen may then be seen as a dark blue transmural discoloration (Figure 67.3-5). When negotiating the splenic flexure, the most successful combination of tip maneuvers is that of clockwise, right, and up followed by anticlockwise after passing the flexure. Occasionally, placing the patient in the right decubitus position may assist. The transverse colon is recognized by the triangular haustral folds and is usually easily passed. Supine or right decubitus positioning may ease this. A loop in the shape of a U may occur in a dependent transverse colon, which is supported by abdominal pressure. The more difficult γ loop may occur in a redundant transverse colon (see Figure 67.3-4C). In addition, a good bit of advice is to apply gentle suction as the tip is advanced again in an attempt to concertina a potentially long dependent transverse colon over the colonoscope, thus maintaining a relatively short colonoscope and, hence, good control and maneuverability.

Hepatic Flexure and Ascending Colon

Nonlooped colonoscope length used at this point might be 60 cm in older children and even 40 cm in those under the age of 3 to 4 years. This is valuable in determining whether a loop is present. The hepatic flexure is also recognized by the dark, usually blue, discoloration seen through the bowel wall, and positional change to the supine or right decubitus may again facilitate identification of the lumen. The combination of right, up, and clockwise followed by anticlockwise rotation and suction down into the ascending colon once around the sharply angled hepatic flexure is usually the most effective maneuver, but various combinations, including position change and scope withdrawal, may be required. Another tip is to remember that it is easy to be too far advanced into the vault of the hepatic flexure, leading to advance into a blind end, and often slight withdrawal of the instrument may reveal the fact that one is trying to negotiate this blind-ended area. The two or three sharp folds then observed may then be most successfully negotiated by tip deflection using both up/down and left/right wheels with minimal advancement of the scope. This is most easily performed in the supine patient position, however.

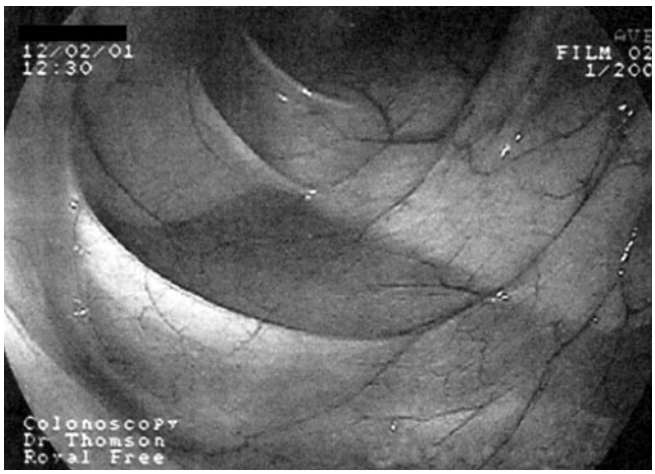

FIGURE 67.3-5 Dark shadow of spleen seen through colon at splenic flexure.

Once the hepatic flexure is negotiated, the transverse colonic γ loop may be reduced with anticlockwise or clockwise rotation followed by withdrawal of the colonoscope and suction. Loop withdrawal is essentially informed guess work initially. Studies with the colon Map guider developed by Dr. Christopher Williams and Olympus, based on using a colonoscope with an inbuilt electromagnetic loop that allows accurate real-time colonoscope three-dimensional positioning by detection using an external positioning device and displayed on a screen next to the patient, have shown that even expert colonoscopists get the type of loop present wrong in half of the cases.[54–56] Once one starts to remove the loop, using rotation only initially, a tip is to gently start to remove the colonoscope and try to determine whether within-patient resistance is increasing or whether the colonoscope is trying to push your hand away from the patient as the loop unfolds. Usually, trying clockwise or anticlockwise combined with instrument withdrawal will, with experience, allow early determination of which rotation direction is likely to be successful in "delooping" the colonoscope. It is best to try to maintain good luminal vision during this procedure, but, not infrequently, the lumen is lost; however, if this loop removal technique is effective, it is then not unusual to find oneself then looking at the appendiceal orifice and hence the cecum because the scope will have naturally traveled down the ascending colon. It is important to remember that the ascending colon, which in children is of variable length, may be as short as 5 cm in some younger cases.

Cecum

Three useful ways to ensure that one has reached the cecum are as follows:

- Observing the colonoscopic illumination in the right iliac fossa (using the specific high-intensity light transillumination application available with some colonoscopes is not usually necessary in children, excepting with some obese adolescents, for whom it can be helpful when applied in a dark environment)
- Digitally indenting the abdominal wall over the right iliac fossa and observing the corresponding effect on the colonic wall with the colonoscope
- Identifying the triradiate fold, appendicele orifice, and (especially if gas bubbles or ileal effluent are being excreted from it) the typical two lips–like appearance of the ileocecal valve (Figure 67.3-6A)

A good maxim is that if there is any doubt in the operator's mind about having reached the cecum, then one is usually at the hepatic or even splenic flexure. Only about 80 cm of scope from the anus is needed when all loops are removed in an adult, and in smaller children, only 40 to 60 cm may be needed. This assumes normal anatomy of the ascending colon and cecum. Obviously, cecal strictures can confuse the picture.

Ileal Intubation and Its Importance

The ileocecal valve is present approximately 1 to 4 cm distal to the appendicele orifice opening into a smooth asymmetric fold and opens perpendicular to the axis of the colon. Figure 67.3-6 shows the steps of the easiest technique for ileal intubation. Removal of any colonic loops is important to allow for a responsive scope with no paradoxical movement. Figures 67.3-6B and 67.3-7 show the valve maneuvered to the 6 o'clock position, usually after clockwise rotation of the scope and wheel-tip deflection to maintain a centered cecal view. Anticlockwise rotation can also be used but is less efficient. If too much gas is present, then the cecum may be "tented," and this should be suctioned prior to an ileal intubation attempt. Figures 67.3-6C and 67.3-8 show the insertion of the biopsy forceps such that just the tip or the first few millimeters are visibly exposed beyond the end of the scope. The scope is then inserted just beyond the fold (using the downward deflecting wheel with the scope as above already in the 6 o'clock position), and the tip is inclined downward so that the forceps gently press into the wall. Slight left inclination may be required at this point to open the valve like a pair of lips on slight withdrawal of the scope (see Figure 67.3-6C). Once the valve is opened, the scope may be passed into the ileum with further downward deflection. Often this is facilitated by small right and left deflections with an assistant pressing on the abdomen over the transverse colon to support a dependent transverse and also prevent loop formation. In the absence of ileocecal valve strictures, and with practice, this technique will allow an ileal intubation rate of 100%. Perforation of the cecum or ileum with this technique is a theoretical concern raised by some observers unfamiliar with this technique, but this has not occurred in our experience of over 5,000 ileocolonoscopies and is extremely unlikely.

An alternative technique is "blind" intubation of the ileocecal valve. This involves the same positioning of the valve at 6 or 9 o'clock and then slowly withdrawing the scope back from just beyond the valve's fold while insufflating with air and deflecting the scope tip downward. The disadvantage of this technique is that it is not under direct vision.

Ileum

The ileal mucosa will have the typical velvet-like appearance of small bowel, with the presence of smoother raised areas, which are Peyer patches, and, occasionally, lymphonodular hyperplasia of varying degrees. Villi are more easily seen if the lumen is flooded with water. The ileal surface is shown in greater relief with a spray of standard blue or black ink (methylene blue in a 1:20 dilution may also be used); this is also useful in showing the detail of sessile polyps in the colon. Deeper intubation of the ileum by either technique is similar to duodenal negotiation during upper gastrointestinal endoscopy, and up to 40 cm of ileum can be observed.

It is pertinent here to discuss the diagnostic need for entering the ileum in children suspected of inflammatory bowel disease. Williams and colleagues, in 1982,[7] reported

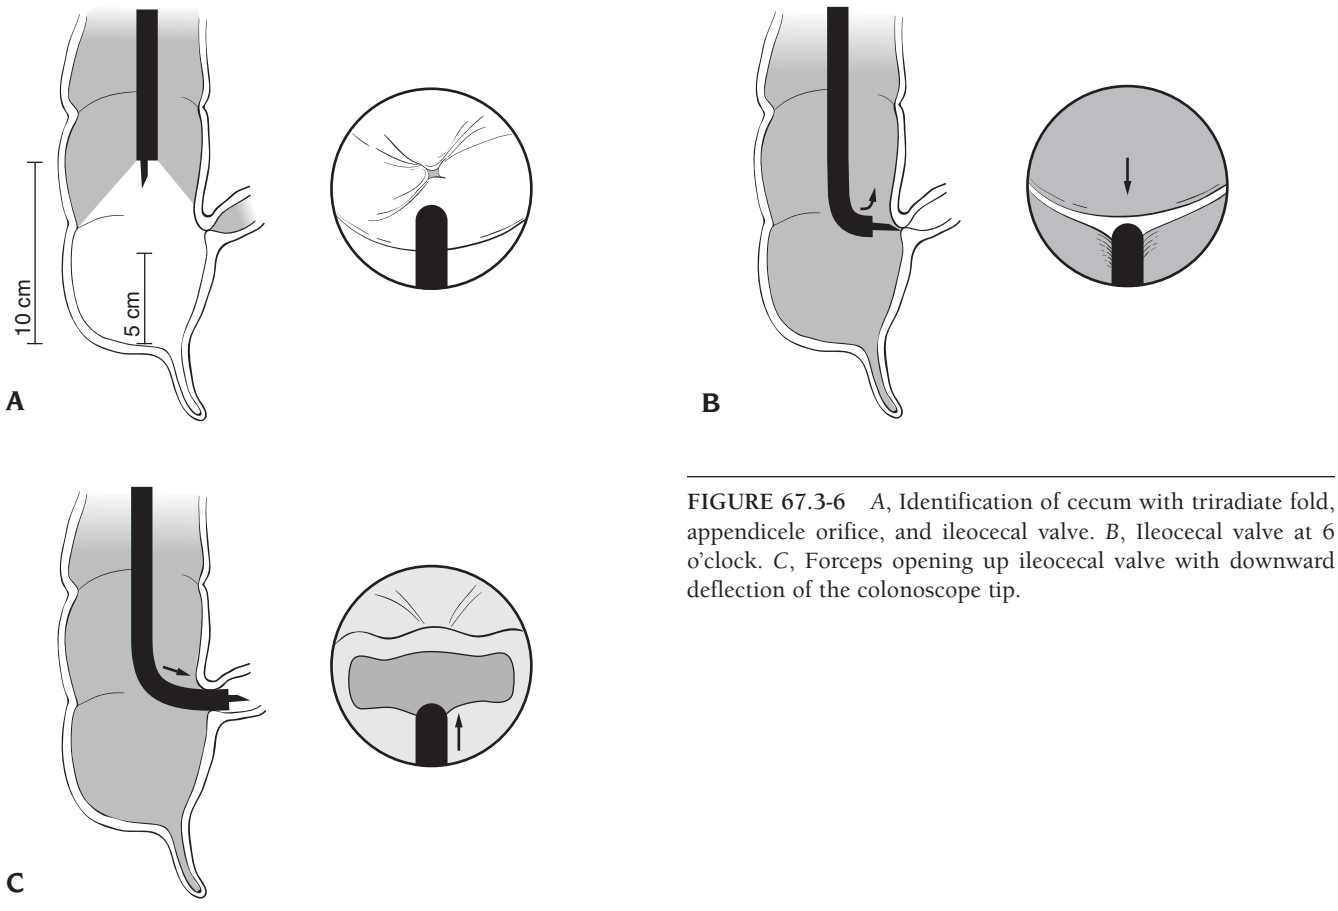

FIGURE 67.3-6 *A*, Identification of cecum with triradiate fold, appendicele orifice, and ileocecal valve. *B*, Ileocecal valve at 6 o'clock. *C*, Forceps opening up ileocecal valve with downward deflection of the colonoscope tip.

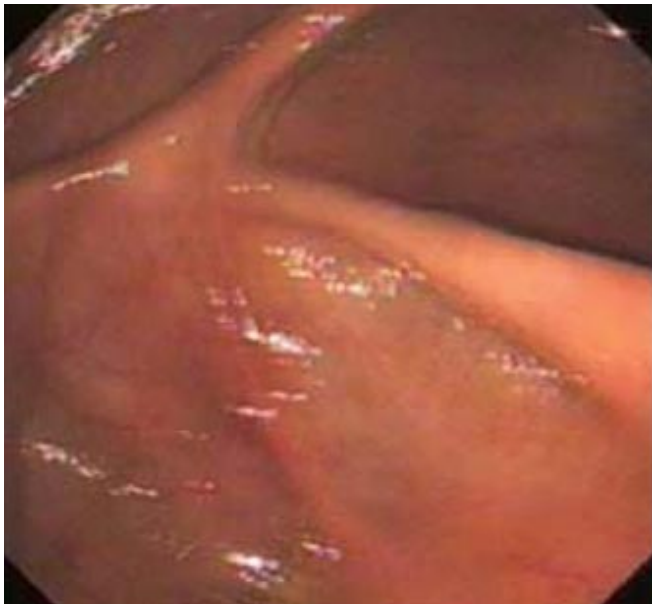

FIGURE 67.3-7 Ileocecal valve at 6 o'clock.

their experience of total ileocolonoscopy in children in which the terminal ileum was examined in 63 patients. In 6 children, ileitis detected by ileocolonoscopy was the sole finding of Crohn disease, which was previously unrecognized by radiologic contrast studies. Lipson and colleagues compared ileoscopy and barium studies, with an endoscopy specificity of 0.96 for diagnosis of Crohn disease in the terminal ileum.[57] In 14 of 46 children, ileoscopy revealed diagnosis, which would otherwise have been missed. This study also made clear that the endoscopic appearances could be completely normal, yet the diagnosis of Crohn disease could be made histologically by the presence of granulomata. Also, a pronounced lymphoid hyperplasia pattern was present radiologically in 24% of children and would have been a source of error in two cases had contrast radiographs been relied on to make the diagnosis without ileoscopy. More recently, Deere and colleagues showed that sigmoid, colonic, and rectal biopsies confirm the diagnosis of inflammatory bowel disease in only 60% of cases, and diagnosis based on morphologic criteria was possible in only 85% of cases when the cecum was reached without ileal intubation.[58] Geboes and colleagues assessed 300 patients, including adolescents and children, and found endoscopic and histologic ileal lesions in 123 and 125, respectively, of whom no colonic disease was present in 44.[59] Ileal biopsies were essential for the diagnosis in 15 patients and contributory in 53. There are, of course, other reasons apart from the principal one, that is, diagnosis of chronic inflammatory bowel disease, for entering the ileum in children. For instance, ileoscopy will facilitate diagnoses of other causes of ileitis such as infection with tuberculosis or *Yersinia*.[60] In addition, therapeutic dilation of short terminal ileal strictures by per endoscopic balloon catheter may be attempted.

Scope Withdrawal

A more careful inspection of the colon is necessary on withdrawal of the scope, especially for the presence of polyps, which may have remained hidden behind a haustral fold during the initial insertion of the scope. Biopsies should be taken from all areas, including normal-looking mucosa to allow for accurate histologic diagnosis. Biopsy technique is similar to esophagogastroduodenoscopy, with the exception that many colonoscopic biopsy forceps have a central barb, allowing more than one biopsy to be taken each time the forceps are passed.

Lastly, before removing the scope from the anus, a retroflexion maneuver obtained by maximum upward and right or left tip deflection and slight advancement of the scope into the rectal vault, followed by rotation clockwise and anticlockwise through 180°, completes the examination. This is necessary to observe the anorectal junction and distal rectum. Distal ulcers, inflammation, or even polyps can be missed if this is not done.

ADVANCED TECHNIQUES

Polypectomy

This is the most common therapeutic intervention, and the requirements for safe and effective polyp identification and removal include the following:

- Adequate sedation or general anesthetic to prevent patient movement
- Adequate bowel preparation
- Careful observation on insertion and withdrawal, changing the patient's position as needed
- Familiarity with the cauterization technique and power settings
- Availability of hemostasis techniques
- Normal or corrected coagulation indices

If bowel clearance is not good, then small or medium polyps may be missed, and feces may hamper their

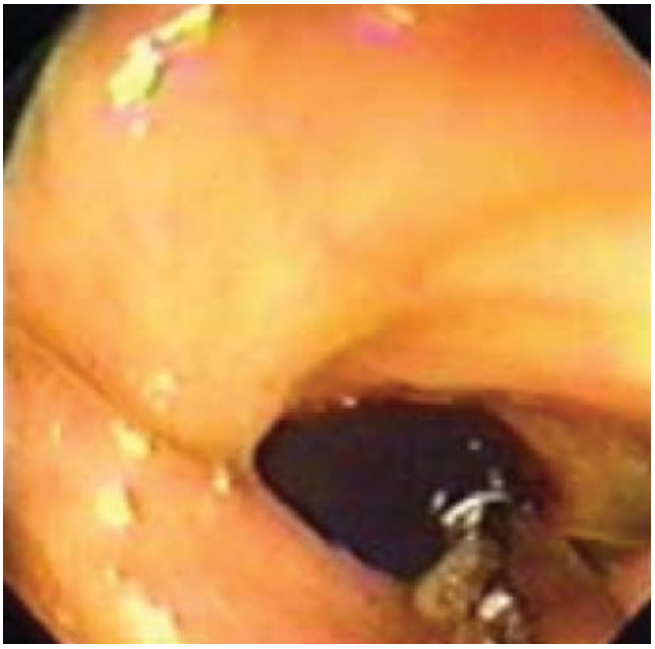

FIGURE 67.3-8 Forceps opening up ileocecal valve with downward deflection of the colonoscope tip.

removal. Sudden movement of the patient may cause premature removal of an ensnared polyp without electrocautery and lead to hemorrhage. Ensnaring the polyps may also be impeded. Delayed postpolypectomy hemorrhage is rare, but parents should be advised as to this possibility, although this is not a reason for routine overnight observation in the hospital following the procedure.

Polyps should be removed when first encountered because they may be difficult to subsequently locate. The size of a polyp and whether it is pedunculated or sessile determines the mode of removal. Those less than 5 mm in diameter may be removed by normal "cold" or monopolar or bipolar "hot" biopsy forceps (Figure 67.3-9). Monopolar forceps provide tissue for histology and cauterize surrounding tissue, whereas bipolar forceps ablate most of the tissue, making histologic interpretation more difficult.[61,62] Minisnares (15–20 mm long) may also be used for removal of small polyps by cold technique or cautery.[63] Generally, polyps greater than 5 mm require an electrocautery snare, which are available in varying sizes and shapes (eg, hexagonal, oval, crescent) (Figure 67.3-10). Most are monopolar, and the advantages of bipolar snares are not compelling.[64]

Polyps with stalks are ensnared around their neck, and if a monopolar current is employed, the colonoscope is used to angle the polyp away from the colonic wall. Otherwise, current is transmitted from the polyp to contact areas on the colonic wall with the potential for perforation (Figure 67.3-11). "Pulsed cut" (also called "blended cut and coagulation") and pure "coagulation" set at 15 to 30 watts are the favored types of current rather than pure "cut," which will not adequately cauterize the stump. The assistant slowly tightens the snare while current is applied to prevent garrotting of the polyp. Excess current may occasionally lead to transmural damage, with the potential for perforation. For larger polyps with attendant larger stalks, other methods may prevent excessive hemorrhage, for example, attachment of a metal clip to the base of the stalk,[65] prior injection of the stalk with 1:10,000 epinephrine,[46] attachment of detachable loop snares to the stalk prior to polyp removal,[66] and piecemeal removal with specially designed "endo-scissors" and "endo-forceps." This latter technique is particularly useful for large sessile polyps, in which submucosal injection of saline may divide the tissue planes and allow for endoscopic mucosal resection of the polyp (Figure 67.3-12). Rubber bands may be applied to elevate a sessile polyp prior to resection[67] or to the bleeding stalk postpolypectomy.[68] Techniques of endomucosal resection and polyp removal can also be aided by prior endosonographic assessment.

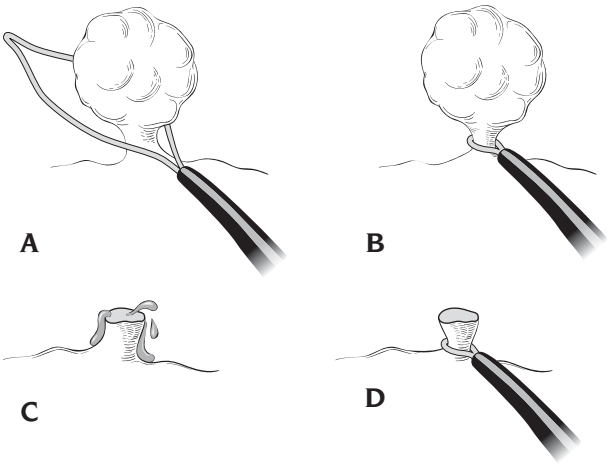

FIGURE 67.3-10 Technique of snaring larger pedunculated polyps. *A*, Polyp lassoed by snare; *B*, snare closed; care not to amputate without coagulation current; *C*, if stalk bleeds, inject base with 1:10,000 epinephrine; *D*, snare assisted coagulation of stump.

Retrieval also depends on size. Small polyps may be sucked up through the suction channel and caught in a suction trap. The snare itself may be used to retrieve larger polyps, or specific retrieval devices such as baskets, grasping forceps, or nets may be helpful. Without a net to gather the polyps, one may need to repeatedly remove and reinsert the scope to collect all of the polyps. Alternatively, when many large polyps are encountered and removed, it may be easier to sift the feces subsequently.

Dilation of Strictures

Through-the-scope balloon dilators are appropriate for ileocolonic dilation, employing the same concept and method as for upper gastrointestinal strictures, employing radiologic screening control. Long-term symptomatic relief can be afforded in some carefully selected patients, including adolescents in reported studies.[69,70] Pressures of 35 to 50 psi in balloons of 12 to 18 mm are available. Theoretically, as for neoplastic or diverticulitis-associated strictures in adults, stent placement could be used as a last resort in inflammatory bowel disease–type strictures, but there are no reported cases of this occurring in childhood as yet.

Percutaneous Endoscopic Cecostomy

Percutaneous endoscopic cecostomies have been successfully placed in a number of children with intractable constipation using the same technique as for gastrostomy insertion using the pull-through technique. This approach followed reports of effective treatment of obstipation and fecal impaction in children by appendicostomy and intestinal button implantation using antegrade continence enemas, the so-called ACE procedure.[71] Intraoperative ultrasonography was used to confirm the position of the cecum just below the layers of the abdominal wall. No complications were reported in one series.[72]

A newer technique of percutaneous sigmoidostomy has recently been reported for the treatment of low left-sided refractory constipation, again employing a pull-through technique, with some success.[73]

Therapy of Lower Gastrointestinal Bleeding

Interventions used to prevent bleeding during polypectomy and mentioned earlier may also be used to manage post-polypectomy bleeding. Apart from colitis and polyps, other causes of bleeding are angiodyplasias and arteriovenous malformations. Angiodysplasias are rarely reported in childhood (mean age 2–3 years) and are more easily diagnosed by selective regional angiography than by ileocolonoscopy despite occurring in the left hemicolon. In children, control of bleeding has required surgical excision.[74] Arteriovenous malformations must be subject to angiographic assessment before any endoscopic therapy is contemplated because many of these apparently innocuous-looking luminal lesions may have large vascular beds. Examples of equipment that may be used to stop a localized lesion from bleeding include heater probes,[75] bipolar cautery probe, hot biopsy forceps, neodymium:yttrium-aluminum-garnet laser set for thermal coagulation,[76] and argon plasma coagulation.

ENDOSONOGRAPHY

Endoluminal ultrasonography of the rectum has been an established technique for years; however, more recently, an echocolonoscope has allowed combined examination of the mucosa and the bowel wall. This is a forward-viewing colonoscope with the transducer (7.5 MHz) situated in the rigid tip of the scope.[77] Alternatively, an ultrasound miniprobe can be introduced via the biopsy channel (7.5 or 12.5 MHz). A fluid interface is necessary for all endosonography, and this can be achieved either with a fluid-filled balloon or filling the relevant colonic segment with water. Because this may be time-consuming, it is easier to concentrate on the region of interest rather than attempt to examine the entire colon. In adult practice, staging of cancers is the major indication for endosonography. In children and adolescents, indications for this technique might include suspicion of early invasive cancer arising from an adenoma, assessment of the extent and depth of sessile polyps to guide reception technique, assessment of colonic strictures/fistulae/anastomoses, assessment of the extent and depth of inflammatory bowel disease, assessment of the extent and depth of vascular lesions, examination of rectal and colonic portal hypertension with varices, and suspicion of lymphoma.

Inflammatory bowel disease appears as wall thickening and subsequent loss of the normal layer structure of the colon with progressive inflammation. Although theoretical differentiation between ulcerative colitis and Crohn disease is possible owing to the transmural nature of Crohn disease, it has been shown recently that active ulcerative colitis can have echotexture changes extending into the submucosa and that these changes correlate with disease activity.[78] Surgical decisions were made in one study of patients with Crohn disease[79] in which endoscopic ultrasonography was used to differentiate between superficial and transmural involvement. An ileoanal pouch was undesirable when transmural disease was identified. Perirectal and pericolonic fistulae and abscesses have been seen using the rigid rectal ultrasound probe, and this is a potential application for endoscopic ultrasonography.[80] Catheter probe–assisted endoscopic ultrasonography in inflammatory bowel disease has advantages over an echocolonoscope, which may be technically difficult to use. One study recently showed that wall thickness was twice as great in active inflammatory bowel disease, but ulcerative colitis could not be differentiated from Crohn disease.[81] Loss of wall structure correlated with disease activity score in the Crohn disease group, and wall thickness correlated with disease activity in the ulcerative colitis group. Other parameters, such as superior mesenteric artery maximum flow velocity and increased Doppler ultrasonography–demonstrated mural blood flow, are being examined as viable noninvasive substitutes for determination of post-treatment ileocecal Crohn disease activity, thus potentially avoiding the need for follow-up ileocolonoscopy, as some units advocate.

FOREIGN BODY REMOVAL

Foreign bodies in the lower gastrointestinal tract are rare in childhood. Occasionally, objects such as percutaneous endoscopic gastrostomy flanges or other ingested foreign bodies may become impacted at the ileocecal valve, necessitating endoscopic removal.[82]

REDUCTION OF INTUSSUSCEPTION AND SIGMOID VOLVULUS

Pneumatic reduction of intussusception has been described with simultaneous identification of the intussuscipiens, in one case a polyp, which was removed, and in another case, terminal ileal lymphonodular hyperplasia.[83,84] I have used air insufflation to reduce an ileocecal intussusception caused by terminal ileal Crohn disease. Reduction of sigmoid volvulus is a more common indication, particularly among patients with chronic constipation.

PER ENDOSCOPIC MANOMETRY

Per endoscopic manometry has limited application but has been studied in adults specifically identifying abnormal motor patterns and hypertension of the ileocecal valve.[85]

COMPLICATIONS OF ILEOCOLONOSCOPY

Complications, excluding those due to sedation, are summarized in Table 67.3-5. The literature to date reveals over 3,000 colonoscopies under 20 years of age reported, with 5 perforations—4 postpolypectomy and 1 in a patient with severe ulcerative colitis. Ten procedure-related minor complications are noted, including four small postpolypectomy hemorrhages, three cases of postprocedure abdominal pain with spontaneous resolution, one common peroneal nerve palsy secondary to periprocedure positioning, and two with a postprocedure fever for more than 24 hours.[1,4,5,45,46,75,86,87] This equates to a complication rate owing to the procedure itself of approximately 0.3% and, without polypectomy, of about 0.05%. This is in keeping with the British definition of "minimal" risk and the American definition of "minor risk over minimal."[88]

Perforation itself may well be relatively operator independent, occurring often in those with underlying connective tissue disease. Even enema treatment for constipation can cause perforation in patients with Ehlers-Danlos syndrome.[89] A single case of a child with serosal surface tears owing to a rigid colonoscope and a large sigmoid loop was reported in 1974.[90] Flexible pediatric colonoscopes or the new variable-stiffness colonoscopes may prevent this nowadays. Following electrocautery removal of a polyp, the stalk and the contralateral wall should be examined closely for evidence of mucosal perforation. The merits of conservative therapy of selected cases of colonic perforation have been discussed,[91] and it would seem reasonable to adopt conservative management, for instance, in the case of silent asymptomatic perforations and those with localized peritonitis without signs of sepsis who continue to improve clinically without intervention.[92] In one study in adults, only 3 of 21 patients were managed nonsurgically, and there was no difference in the morbidity or mortality between primary repair and resection and anastomosis.[93] In another, conservative management was successful in 13 of 48 patients, and 12 of the 13 were postpolypectomy perforations.[94]

In contradistinction to adults, bacteremia has not been detected in children after ileocolonoscopy.[23] In addition, modern cleaning machines seem to largely prevent the glutaraldehyde-associated colitis reported in the past.[95]

Polypectomy is the main cause of hemorrhage, and, as noted above, there are very few reported cases of this occurring in pediatrics. Hassall and colleagues noted minor bleeding, which stopped spontaneously in 2 children from 38 polypectomies in 136 children,[4] and there are no cases reported that required transfusion in children. Resnaring a bleeding stalk and maintaining pressure for 10 to 15 minutes are the first steps and, if unsuccessful, can be followed by injection of 1:10,000 epinephrine or thrombin or further electrocoagulation. Later bleeding has been reported in adults with a median delay of 37 hours in about half of one series.[96]

Splenic rupture is rarely seen and will present with hypovolemia and shoulder tip or abdominal pain within 24 hours of the ileocolonoscopy.[97] Similarly, direct trauma to the tail of the pancreas is the proposed mechanism of injury in the rare case of pancreatitis reported.[98]

Because of the rarity of complications in pediatrics, most pediatric endoscopists, when presented with such a clinical situation, will be unfamiliar with the etiology of the symptoms, and colleagues' opinions should often be sought.[99]

TABLE 67.3-5 PROCEDURE-RELATED AND POSTPROCEDURE COMPLICATIONS IN PEDIATRIC ILEOCOLONOSCOPY

DIAGNOSTIC PROCEDURE RELATED
Vasovagal reactions
Hemorrhage
Perforation: traction serosal, direct transmural
Pancreatitis
Splenic trauma
THERAPEUTIC PROCEDURE RELATED
Perforation
Hemorrhage
Thermal injury: transmural
POSTPROCEDURE
Distention and discomfort (less if CO_2 insufflation used)
Delayed evidence of perforation or hemorrage

INDICATIONS FOR ILEOCOLONOSCOPY

The main indications, both diagnostic and therapeutic, for ileocolonoscopy in childhood and adolescence are set out in Table 67.3-6. The most common indication in the pediatric age group is, of course, suspicion of inflammatory bowel disease. As part of first-line investigation, an upper endoscopy is also indicated because up to 20% of inflammatory bowel disease cases can be differentiated into either Crohn disease or indeterminate colitis by upper gastrointestinal endoscopy.[100]

The mucosal appearances of ulcerative colitis and Crohn disease are well described and are not reiterated here.[3,101] Ileocolonoscopy of acute colitis is generally held to be a safe and reliable tool in expert hands and can help to differentiate ulcerative colitis from other pathologies and also allow prognostication.[102,103] Per rectal bleeding is also an important indication for ileocolonoscopy. With col-

TABLE 67.3-6 DIAGNOSTIC AND THERAPEUTIC INDICATIONS FOR ILEOCOLONOSCOPY IN CHILDREN AND ADOLESCENTS

DIAGNOSTIC
Suspected inflammatory bowel disease
Follow-up for assessment of efficacy of inflammatory bowel disease treatment
Suspected allergic colitis
Suspected colitis owing to other causes, eg, chronic granulomatous disease
Lower gastrointestinal hemorrhage
Chronic diarrhea
Cancer surveillance
Graft-versus-host disease
Endosonography
Manometry
THERAPEUTIC
Polypectomy
Foreign body removal
Percutaneous cecostomy
Stricture dilation
Reduction of intussusception

itis, the blood will usually be mixed in with the stool and may be associated with pain, whereas polyps are the most common cause of painless rectal bleeding.[104] Follow-up ileocolonoscopy allows assessment of treatment efficacy and can demonstrate to older children and parents these beneficial effects, promoting continued compliance.

Allergic enterocolitis usually presents in the first year to 2 years of life and may present even in the exclusively breastfed infant whose mother is ingesting antigens such as cow's milk protein.[105] A case can be made for removing the potentially offending antigen from the diet of the child or, if breastfed alone, from the mother. Ileocolonoscopy is not usually needed in such a circumstance, although it has been advocated as a diagnostic tool—the so-called "colonoscopic allergen provocation," in which, in one study in adults, 77% had a positive local visible mucosal reaction with histologic evidence of recruitment of mast cells and activation of eosinophils.[106] Simple dietary manipulation is usually sufficient to make the diagnosis in infants. Ulcerative colitis and Crohn disease are extremely rare under the age of 2 years. If appearances at ileocolonoscopy or on histology of biopsies are in keeping with such diagnoses, then it is important to think of other underlying reasons for these findings in this age group. This may include diagnoses such as enterocolitis of infancy,[107] glycogen storage disorders, chronic granulomatous disease, neutrophil chemotactic defects, and infectious enterocolitides, among others. Rare enteropathies such as tufting enteropathy may also involve the colon.

It must not be forgotten that infections such as amebic dysentery, *Campylobacter*, *Salmonella*, *Shigella*, and other common enteritides can mimic idiopathic colitis, and *Yersinia* and tuberculosis can cause ileitis that mimics Crohn disease.[51,60,108]

Enterobiasis has also been reported to cause ileal and colonic ulceration.[109] Thicker 5 μm sections stained with Ziehl-Neelsen and analysis of tissue samples by polymerase chain reaction may improve detection for tuberculosis.[60,110]

Vascular anomalies may be a rare cause of lower gastrointestinal bleeding. These lesions may have minor mucosal involvement but an extensive intra- and extramural vascular supply. Endoscopic ultrasonography with or without Doppler may help to delineate the extent of such lesions before angiography is considered or treatment is attempted. Because of the large size of some vascular lesions, simple mucosal injection, sclerosis, or heat coagulation may lead to greater bleeding. Blue rubber bleb nevus syndrome is another unusual example of vascular malformation, as is angiodysplasia, which can easily be missed if the colon is not very clean after bowel preparation.[74] Vasculitis, masquerading as inflammatory bowel disease, may have similar ileocolonic mucosal appearances. Clues to this diagnosis are the involvement of other organs and systems such as loss of beat to beat variation on electrocardiography representing atrioventricular node ischemia owing to vasculitis, perinuclear antineutrophil cytoplasmic antibody positivity, and skin lesions. Celiac axis, renal, and superior or inferior mesenteric angiograms may reveal multiple microaneurysms.

Polyps are found in 80% of instances within the rectosigmoid colon alone, reach peak incidence around 5 to 6 years, and are not usually seen in infancy.[111] Hamartomas make up the vast majority and are termed juvenile, inflammatory, or retention polyps. Approximately one-third of juvenile polyps cause anemia and often are lost by autoamputation. Even in expert hands, 10% or so of polyps can be missed at ileocolonoscopy, and the technique affording the best chance of detection is noted above. One in five rectosigmoid polyps will be accompanied by additional polyps in the proximal colon—hence the need for a full examination even if a polyp has been removed from a distal site. The recurrence rate may be 25%, but this is not well documented. Juvenile polyposis coli is often defined as the presence of more than 5 polyps, although there may be as many as 100 or more, and they may not be confined to the large bowel.[111,112] Dysplastic change with a carcinoma risk of 15% by age 35 years and 68% by 60 years is reported.[113] Adenomas can occur rarely and macroscopically are difficult to distinguish from hamartomas, dictating the need for histologic confirmation, and mixed polyps have been reported.[114,115] Familial adenomatous polyposis, an autosomal dominant disorder associated with the *APC* gene,[111] typically has hundreds or thousands of adenomas in the colon; screening in both of these conditions is dealt with in the following section. Several other syndromes may manifest with polyps and include Peutz-Jeghers, Turcot, Cronkhite-Canada, and hereditary flat adenoma syndromes.[116]

There are less than 200 cases of colonic carcinoma reported in the literature in children, and these represent less than 1% of all childhood tumors. Carcinoma has been reported in the absence of familial adenomatous polyposis or hereditary nonpolyposis colon carcinoma germline mutations.[43] Abdominal pain is the most common presenting symptom, occurring in 95% of patients,[117] and an abdominal mass is the most common finding, occurring in more than 50% of cases. Rectal bleeding is less common than in adult studies. Carcinoembryonic antigen had a

specificity of 77% and a sensitivity of 68% in those under 18 years in a recent study.[118] Because this is too low to be clinically reliable, the requirement is for full ileocolonoscopy.[119]

Graft-versus-host disease (GVHD) following bone marrow, kidney, or liver transplant can have colonopathy in both acute and chronic forms. Focal apoptosis of the glandular epithelium is typical in acute GVHD,[120] and mucosal changes reminiscent of chronic idiopathic inflammatory bowel disease occur in chronic GVHD.[121]

FOLLOW-UP AND SURVEILLANCE ILEOCOLONOSCOPY

It is the practice in many units to perform a follow-up ileocolonoscopy 2 to 3 months after the start of treatment in a newly diagnosed case of inflammatory bowel disease. This practice is based on a number of premises, including evidence from studies such as those by Modigliani and colleagues, which showed that only 29% of adults with Crohn disease in clinical and biochemical remission actually achieved endoscopic remission.[122] This has a number of advantages. It allows the physician to observe the mucosal efficacy of the therapy because, in many instances, such as steroid use in colitis, the clinical improvement of the patient may not be mirrored by the mucosal improvement, which is regarded by most as the most important meter of a successful treatment regimen.[20] Ileocecal transcutaneous Doppler ultrasonography may be of benefit as a noninvasive alternative to repeat ileocolonoscopy in this situation, as noted above. In addition, the activity of mucosal inflammation may determine the long-term risk for carcinogenesis in the bowel.

NEW DIAGNOSES

Appreciation of more subtle lesions and pathology has been possible more recently as a consequence of combining high-definition videoendoscopy with sophisticated diagnostic techniques of mucosal immunology such as immunohistochemistry and gated flow cytometry. One such example is that of the histologically nonspecific colitis and ileal lymphonodular hyperplasia (Figure 67.3-13), which has been recognized recently in children with regressive autism or pervasive developmental disorder, and it is not considered to be due to any exogenous trigger, as has widely and wrongly been reported with respect to the measles, mumps, and rubella vaccine, but to be entirely independent of this or other triggers and may well be of autoimmune origin, but this is yet to be fully explored.[123,124] Nonspecific colitis appears macroscopically as granularity, loss of vascular pattern, pronounced lymphoid follicles surrounded by erythema described as the "red halo" sign (Figure 67.3-14), and aphthoid ulcers in a small proportion of cases (Figure 67.3-15). Diffuse infiltration of the lamina propria with macrophages and lymphocytes and enlarged germinal centers of lymphoid follicles containing tingible body macrophages are noted in the colon. Lymphoid follicular hyperplasia with reactive and expanded germinal centers is found in the terminal ileum.[123] Further work on this observation has revealed a specific lymphocytic colitis less severe than classic inflammatory bowel disease. When compared, however, with cohorts with no histologic or clinical disease, developmentally normal children with ileal lymphonodular hyperplasia, Crohn disease, and ulcerative colitis, this group had significantly increased basement membrane thickness, mucosal $\gamma\delta$ cell density, $CD8^+$ density, and higher intraepithelial lymphocyte numbers. There were also higher CD3 and plasma cell density and greater crypt proliferation, and the disruption of epithelial but not lamina propria glycosoaminoglycans with a negative human leukocyte antigen (HLA)-DR in the

FIGURE 67.3-13 Terminal ileal lymphonodular hyperplasia.

FIGURE 67.3-14 Multiple prominent lymphoid follicles in the colon surrounded by intense erythema. The so-called "halo" sign.

FIGURE 67.3-15 Evolution of inflamed lymphoid follicle into aphthoid ulcer.

epithelium suggested a T helper 2 response.[125] Other groups have reported similar ileocolonic lesions in patients with autism, pervasive developmental disorder of childhood, and attention-deficit/hyperactivity disorder.[126] Upper gastrointestinal pathology such as reflux esophagitis and nonspecific gastritis or duodenitis in this group of patients has also been noted recently.[127,128]

Fibrosing colonopathy has been identified in patients receiving excessive pancreatic enzyme supplements for treatment of both cystic fibrosis[129] and non–cystic fibrosis–related illness.[130]

Collagenous colitis presents with watery diarrhea, crampy abdominal pain, and a distinctive histology of the colon that includes a subepithelial collagen band and prominent chronic lamina propria inflammation with an increase in intraepithelial lymphocytes.[131] There have been only two reports of this in children, and this remains controversial.[132] Most cases occur in women over 50 years of age.

Lymphocytic (also called microscopic) colitis presents in a similar manner and is also idiopathic in origin but occurs equally between the sexes.[96] The histologic appearances are similar but without the collagen band. It is not seen commonly in children.

Diversion (also known as disuse) colitis arises in the colon, which is excluded from the fecal stream. It is time dependent, occurring with increasing frequency the longer the segment of bowel is not used, ranging from 3 to 36 months postsurgery.[133] Histology is typical of nonspecific colitis. The absence of luminal short-chain fatty acids is the most popular theory of pathogenesis because colonocytes require these for energy. Bacterial flora normally produce short-chain fatty acids from undigested carbohydrate and fiber.[134] Surgical reanastomosis is the treatment of choice, but topical fatty acids have been applied successfully when surgery is not possible.[135]

Other, more recently described disorders include autoimmune colitis, associated with autoimmune enteropathy and antienterocyte antibodies, and tufting enteropathy involving the colon.[136]

ILEOCOLONOSCOPY VERSUS OTHER DIAGNOSTIC TECHNIQUES

Although ileocolonoscopy is the gold standard for the diagnosis of pediatric inflammatory bowel disease, other noninvasive modalities may play a role in the diagnosis and assessment of treatment efficacy. Technetium hexamethylpropyleneamine oxime (Tc-HMPAO) labeling of granulocytes does not involve as much radiation burden as indium 111–tagged white cells and has been compared with ileocolonoscopy.[137] Jobling and colleagues showed that a Tc-HMPAO scan had 90% sensitivity and 75% specificity compared with biopsies at ileocolonoscopy, but this study had information from the ileum in only 12 of 39 cases—hence potentially overestimating the sensitivity and specificity of the technique.[138] The main disadvantages of the technique were lack of histologic confirmation of the disease process and lack of localization of the inflammation. More recently, the value of white cell–labeled scanning has been further questioned owing to the lack of accuracy in disease localization and sensitivity levels of approximately 75%.[139] Steroids decrease the white blood cell uptake of Tc-HMPAO by up to 50% and hence may decrease further the sensitivity of this technique. However, disease in the terminal ileum may be identified where it might otherwise have been missed because of unsuccessful endoscopic intubation of the terminal ileum.[140] Charron and colleagues showed that 6 of 106 cases of inflammatory bowel disease would have been mislabeled as ulcerative colitis or Crohn disease by technetium scan alone.[141]

Lipson and colleagues found a barium meal and follow-through to the terminal ileum to be a highly sensitive technique, especially for small bowel disease.[57] Tribl and colleagues reported a lower sensitivity of 91% but a specificity of 100%; hence, the radiologist's experience seems to be important.[142] The disadvantage of lack of histologic confirmation of the type of inflammation remains, and the diagnostic confusion owing to terminal ileal lymphonodular hyperplasia is well documented.[137] The radiation burden is also significant.

In experienced hands, ultrasonography has a sensitivity of 88% and a specificity of 93% for inflammatory bowel disease in children. Transabdominal ultrasonography assesses the bowel wall thickness in different areas, especially focusing on the terminal ileum.[143]

Spiral computed tomography (CT) may be useful in determining the nature of pericolic masses or in fistulating disease. Some authors suggest that Crohn disease can be differentiated from ulcerative colitis on the basis of finding greater colonic mural thickness in Crohn disease and greater submucosal fat deposition in ulcerative colitis, but many CT findings are nonspecific.[144] Three-dimensional CT, used to screen for carcinoma in adults, has potential application for identifying polyps in children, although the disadvantages of

lacking histologic confirmation or therapeutic intervention remain. Current magnetic resonance imaging does not adequately recognize pediatric Crohn disease.[145]

The application of the novel technique of wireless capsule endoscopy (WCE) for visualization of the small bowel for occult pathology such as undiagnosed bleeding sources, mid- to small bowel polyps, and mid- to small bowel inflammatory pathologies is now well documented.[146] The use of this technique for diagnosis by direct vision of mucosal pathology in the ileum is useful (although one shortcoming is its relative contraindication in the presence of strictures) and has also been used to identify lesions in the colon; however, in the presence of good ileocolonoscopic technique and with the inability of WCE to obtain biopsies for histologic confirmation of pathology (although the next generation of capsules may have a limited biopsy facility), its application to colonic investigation remains somewhat limited to date. External steering of the capsule has recently been reported, opening up possibilities of retropulsion in the colon rather than just reliance on normal peristalsis.[147]

ENTEROSCOPY

Enteroscopy, now a standard endoscopic procedure in adult medicine and recently reviewed,[148,149] came of age because of the realization that the small bowel did indeed have specific pathology requiring not only diagnostic but also therapeutic expertise. It is of particular use in those with unexplained gastrointestinal bleeding. Pediatric enteroscopy literature is limited to Sonde-type and intraoperative-assisted push enteroscopy.[150–152] Sonde enteroscopy has largely been abandoned in favor of push enteroscopy,[153,154] given the desire for therapeutic capability. The techniques of per oral push enteroscopy and laparoscopy-assisted enteroscopy continue to evolve. In addition, newer methods of examining the small bowel are being developed and include virtual enteroscopy and WCE small bowel examination (as discussed above).[155] As noted, WCE does not allow therapeutic intervention as yet, but its diagnostic yield is certainly as good as if not better than enteroscopy for pathologies such as occult or obscure small bowel bleeding sources.[147,156]

Instruments and Technique

Although a pediatric colonoscope can be used for enteroscopy, specifically designed enteroscopes up to 230 cm in length are now available. The Olympus SIF Q140 has a diameter of 10.5 mm and is 250 cm long. A push enteroscope, like a colonoscope, allows four-way tip deflection to 160 to 180 degrees. There are no enteroscopes or overtubes specifically designed for pediatric application, reflecting the lack of widespread use of this technique in children. An overtube, typically 60 to 100 cm in length with a soft Goretex tapered tip, stiffens the enteroscope within the stomach and upper duodenum, limiting looping, thereby allowing deeper advancement into the small bowel.[153] An enteroscope can be introduced 120 to 180 cm beyond the ligament of Treitz, and with laparoscopic assistance, even the terminal ileum can be reached, allowing lesions such as a Meckel diverticulum to be found.[152]

Preparation for enteroscopy is the same as for upper gastrointestinal endoscopy, although the procedure may be substantially longer and more uncomfortable. Therefore, it is the practice at my unit to use general anesthesia even in adolescents. Patients are positioned left lateral or semiprone. After normal examination of the esophagus and stomach, air is removed, and minimal insufflation of the stomach allows deeper penetration into the small bowel when not using an overtube. At 60 to 80 cm in older children and adolescents, the ligament of Treitz is found, and extreme tip deflection is needed to find the lumen. The first jejunal loop is more readily identified because it is straighter and travels down to the pelvis. If using an overtube, which has been threaded over the enteroscope prior to oral insertion, this is deployed down the esophagus and into the second part of the duodenum; prepyloric deployment will not aid in deeper small bowel penetration. Some exponents use fluoroscopy to aid in overtube tip positioning.[148] When advancing the overtube, the enteroscope needs to be pulled back with clockwise rotation to straighten it, similar to the maneuver used to achieve the shortened scope position during endoscopic retrograde cholangiopancreatography. Variable-stiffness enteroscopes may soon be developed, which may remove the need for an overtube.

Indications

Table 67.3-7 details potential pediatric indications for push enteroscopy. One of few studies in children investigated the possibility of Crohn disease in children with growth retardation.[157] A number of reports demonstrate the utility of push enteroscopy in adults. In one recent series, a bleeding source was identified in 64% using push enteroscopy and an overtube.[158] Transfusion requirements can be significantly decreased in cases of angiodysplasia in the jejunum when cauterized at enteroscopy.[159,160] Nonsteroidal drugs can cause acute and chronic small bowel hemorrhage, perforation or obstruction, and an enteropathy, all diagnosed by push enteroscopy.[149,161,162]

TABLE 63.7-7 INDICATIONS FOR ENTEROSCOPY IN CHILDREN AND ADOLESCENTS

DIAGNOSTIC
Obscure gastrointestinal bleeding (after endoscopy and ileocolonoscopy)
Iron deficiency anemia (especially if history of nonsteroidal drug use)
Extent of Crohn disease
Polyposis syndrome surveillance
Lymphoma (suspicion or follow-up post-treatment)
Lymphangiectasia
Intestinal obstruction
Graft assessment after small bowel transplant
Enteroclysis
THERAPEUTIC
Therapy of hemorrhagic lesions (eg, cauterizing angiodysplasia)
Polypectomy
Stricture dilation
Nasojejunal tube placement
Percutaneous jejunostomy tube placement

There are no data in children regarding nonsteroidal anti-inflammatory drug small bowel disease. The assessment of graft survival following small bowel transplant can be assessed by push enteroscopy. However, most often a jejunostomy is fashioned through which it is much easier to advance an enteroscope or simply use a standard endoscope. Biopsies taken for disaccharidase activity and histologic assessment are also helpful in early detection of small bowel allograft rejection.[163,164] Indeed, a zoom endoscope has recently been used to detect the early structural changes associated with graft rejection.[165]

Direct percutaneous jejunostomies can be sited using the same pull-through technique employed in percutaneous gastrostomy insertion.[166] Nasojejunal tubes can be placed accurately using a guidewire-assisted technique.[167] Finally, polypectomies can be successfully completed with a normal snare technique.

The indications for Sonde enteroscopy in children are very limited and might include a situation in which initial surgical exploration for a site of suspected small bowel bleeding is deemed undesirable.

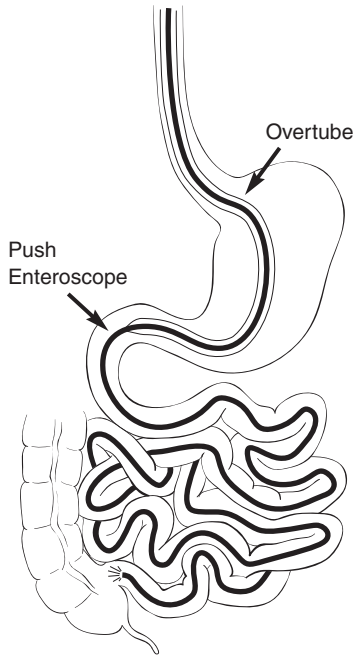

FIGURE 67.3-16 Extent of laparoscopy-assisted enteroscopy.

Intraoperative or Laparoscopy-Assisted Enteroscopy

Intraoperative or laparoscopy-assisted enteroscopy starts with conventional enteroscopic jejunal intubation followed by surgical assistance. The endoscopist's role is relatively passive, deflecting the tip of the instrument while the surgeon, either with hands or with laparoscopic instruments, concertinas examined parts of the small bowel over the enteroscope. Both the mucosal and serosal surfaces can be examined. Very little air is insufflated into the bowel to avoid hindering the surgeon. Dimmed lights in the operating field also help to identify the position of the tip of the instrument. In experienced hands, all of the small bowel is examined in 60% of cases, taking up to 2 to 3 hours (Figure 67.3-16).[168] An enterotomy may be used to insert a sterilized enteroscope in some situations. Lesions can be marked by injection of ink or placement of a suture. Intraoperative or laparoscopy-assisted enteroscopy is the most successful technique for identifying sites of obscure gastrointestinal bleeding with diagnostic yields of between 83 and 100%.[169] Laser or bipolar coagulation can be used, and resection of lesions is recommended if intraoperative.[170] This technique has demonstrable advantages in the assessment of the extent of polyposis syndromes. "On-table" enteroscopy has a better pick-up rate for polyps at laparotomy than external transillumination and palpation.[111] When attempted in Crohn disease, up to 65% of patients have had lesions not previously identified in the small bowel by other investigations, including direct vision of the serosal surface of the bowel.[171] As previously mentioned, occult Crohn disease can be identified in children using enteroscopy.[157] Partial intestinal obstruction and Meckel diverticulum have also been identified at intraoperative enteroscopy.[150,152] Small bowel neoplasia must not be forgotten as the second most common cause of obscure gastrointestinal bleeding in younger patients, accounting for 5 to 10% of cases in young adults.[168] Exploratory laparoscopy and enteroscopy are important in preventing missed diagnoses.

Complications

Complications are not often encountered with simple push enteroscopy, but when the overtube is employed, significant patient discomfort has been described.[153] Other, rare complications of the overtube include pharyngeal tear, Mallory-Weiss tear, gastric mucosal stripping, pancreatitis, and duodenal perforation.[158,172–174] Intraoperative enteroscopy has a 5% incidence of perforation and, in one series, a 50% incidence of mucosal laceration.[152] Prolonged ileus has been occasionally described.[173] None of these rare complications have been reported in the limited studies investigating children.

SUMMARY

Pediatric ileocolonoscopy and enteroscopy differ significantly from their adult parallels in nearly every aspect, including patient and parent management and preparation, selection criteria for sedation and general anesthetic, bowel preparation, expected diagnoses, instrument selection, imperative for terminal ileal intubation, and requirement for biopsies from macroscopically normal mucosa. The basic technique of ileocolonoscopy in children is illustrated and accompanied by discussion of advanced techniques such as endosonography, cecostomy, and therapy of lower gastrointestinal bleeding. The advantages and disadvantages of other noninvasive investigations are compared with those of ileocolonoscopy, and the former are generally held to be second best. The main aim of this chapter is to highlight those differences and to provide a workable guide for those involved or training in the discipline of pediatric ileocolonoscopy or enteroscopy.

4. Gastrointestinal Endosonography

Mini Mehra, MD
Jorge H. Vargas, MD

Gastrointestinal endosonography or endoscopic ultrasonography (EUS) is a relatively new endoscopic procedure in which a high-frequency ultrasound transducer is located on the tip of a flexible endoscope. It is unique in that it is able to obtain ultrasonographic images of the gastrointestinal tract and its surrounding structures. The arrival of EUS in the United States began in March 1980 with publication of a report by DiMagno and colleagues of a gastroscope equipped with an ultrasound probe.[1] Since the inception of EUS, it has been a novel modality looking for a purpose. Through the more than two decades since the first report, the indications for its use have increased but have not reached overall widespread use, especially in pediatrics.

EUS is not currently part of standard training programs in the United States, and few endoscopists are expert in the interpretation and performance of this modality. With further access to and improved technology of the equipment, pediatric endoscopists may develop more indications for this imaging technique.

Current indications for EUS in the adult population include evaluation of gastrointestinal submucosal lesions, cystic and solid pancreatic masses, gastrointestinal malignancy staging, and EUS-guided fine-needle aspiration (FNA).[2] In pediatrics, there has been a paucity of reports in the literature. Many of the adult indications can be applied to our patients, but, recently, there have been some small reports of other indications pertaining specifically to children, which will be outlined in this chapter.

FUNDAMENTALS OF ULTRASOUND IMAGING

Sound is a physical force that is transmitted through solid or liquid as a wave. The frequency of sound waves is measured in cycles formed per second. Their unit of measurement is a hertz. Medical imaging commonly uses frequency of waves in the 3.5 to 20 million Hz or megahertz (MHz).

Sound waves are formed by special ceramic crystals that have a piezoelectric property. The crystals vibrate to form sound waves, which are sent to tissues and reflected from the tissues back to the crystals. The incoming waves are then translated to an electrical signal, creating the ultrasound image. The transducer uses multiple crystals designed in an array to transmit and collect a series of waves to and from the tissue. Because of the multiple crystals, a two-dimensional image is created by multiple reference points that are reflections of the depth and span of the tissue being imaged.

Because sound waves travel at different speeds through different types of tissues, structures can be identified by their differences in hypo- or hyperechogenicity. Sound waves travel easily through fluid but not through air or bone. The speed of transmission is determined by the stiffness of the imaged tissue. Fat and collagen are the most reflective and therefore the brightest layers. Muscle or lean solid mass is less reflective and lighter. Interface between two tissues also creates an image owing to differing acoustic properties. Typically, lower frequencies (5–7.5 MHz) are used to image objects far away from the transducer, whereas higher frequencies (12–30 MHz) give greater detail closer to the transducer (eg, the gastrointestinal wall).

Ultrasound waves are better transmitted through a liquid medium than through an air medium. This phenomenon causes difficulties in transcutaneous ultrasonography because of areas filled with air, such as lungs and bowel. This problem is overcome within the gastrointestinal tract either by distending the gastrointestinal lumen with water or using a water-filled balloon attached to the end of the echoendoscope to improve the transmission of ultrasound waves.

EQUIPMENT AND TECHNIQUE

Current equipment available for EUS includes radial (Figure 67.4-1) and linear array (Figure 67.4-2) echoendoscopes. Both forms of echoendoscope employ regular endoscopy to guide the instrument into position before ultrasound imaging commences. More recently, catheter-based ultrasound probes (Figure 67.4-3) have been developed for use through standard endoscopes.

The original radial array echoendoscope displays a 360° cross-sectional view with gut wall layers and surrounding structures (Figure 67.4-4). The gastrointestinal wall (including the esophagus, stomach, small intestine, and rectum) has a five-layer pattern that correlates to the various histologic layers (superficial mucosa, deep mucosa, submucosa, muscularis propria, and serosa) (Figure 67.4-5). Advantages to the images in this view include the ability to compare similar images in orientation with computed tomographic (CT) cross-sectional imaging. Recent developments of this technology have included the addition of Doppler technology to detect blood flow. The smallest radial array endoscope has a 12.7 mm outer diameter (GF-UM130, Olympus America Inc., Melville, NY, USA). The disadvantages of this modality are the inability to view and guide a needle biopsy device and the inability

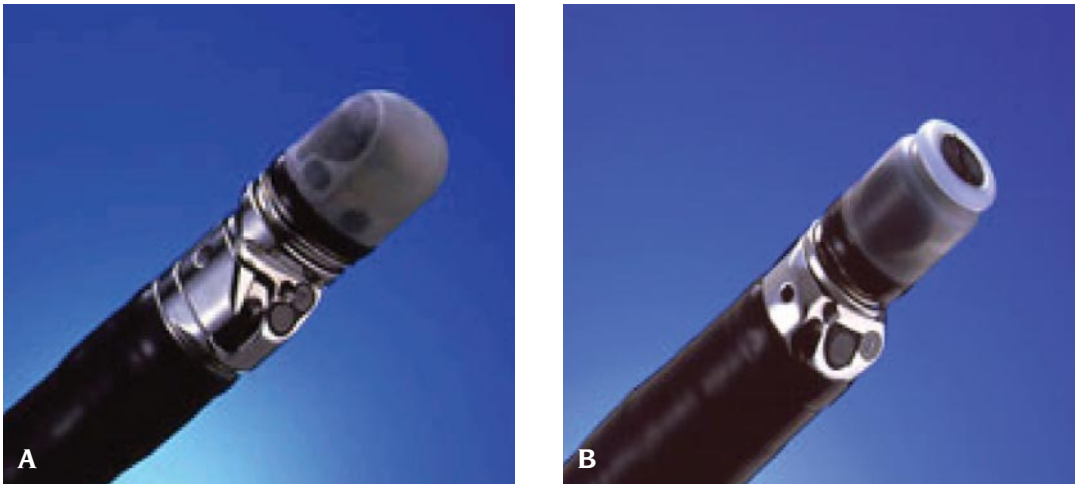

FIGURE 67.4-1 *A*, Radial ultrasound endoscope (GF-UM30P). *B*, Radial ultrasound endoscope (GF-UM130). Courtesy of Olympus Corporation (Tokyo, Japan).

to use the endoscope in small, young patients because of its large outer diameter.

The linear array echoendoscope provides a field of view in a configuration parallel to the endoscope (Figure 67.4-6). This instrument was initially developed for use with needle biopsy devices. The depth of the needle can be viewed when obtaining fluid or tissue. Along with the ability to use needle biopsy devices, the linear array echoendoscope can also facilitate use of Doppler imaging of blood vessels. A disadvantage to this type of EUS is its "forward oblique" view. For endoscopists familiar with side-viewing endoscopes, this may not be problematic, but for the average endoscopist, it can be disorienting. Another disadvantage similar to the radial array endoscope is its large outer diameter. The smallest linear array endoscope has an outer diameter of 12.1 mm (Pentax EG-3620U, Pentax Precision Instrument Corporation, Orangeburg, NY, USA).

Catheter-based ultrasound probes consist of a small-diameter transducer within a catheter sheath that can be introduced through a standard endoscope that has at least a 2.8 mm channel diameter. Catheter-based ultrasound probes using a variety of frequencies are available (5, 7.5, 12, 20, and 30 MHz). Typically, these probes are introduced into water-filled gut lumens to generate images. Probes are also available with a balloon sheath that can be filled with water to improve the image quality. Again, the disadvantage for the small pediatric patient is the need to use an endoscope that has at least a 2.8 mm channel diameter.

INDICATIONS

Because EUS is a fairly new modality and is just receiving acceptance in the adult patient population, use in the pediatric population is slow but steady. In the adult population, accepted indications for use include differential diagnosis of submucosal lesions, gastrointestinal malignancy staging, evaluation of the biliary tree, diagnosis of cystic or solid pancreatic masses, and FNA.[2] Recent case reports and retrospective publications with inclusion of some pediatric patients up to age 18 years have revealed some newer investigational indications for use of EUS in the pediatric population.

ESOPHAGUS

EUS has been used to differentiate eosinophilic esophagitis with normal controls.[3,4] Although histopathology is the gold standard method of diagnosis for this entity, findings

FIGURE 67.4-2 Linear array endoscope (EG3630-U). Courtesy of Pentax Precision Instrument Corporation (Orangeburg, NY, USA).

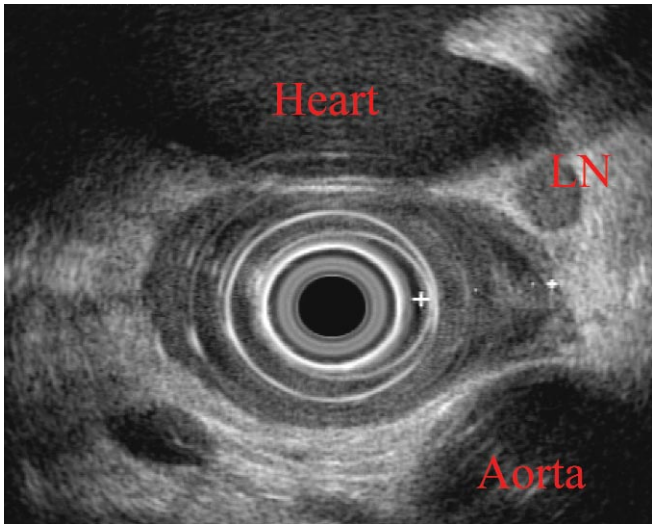

FIGURE 67.4-4 Esophageal wall layers and surrounding structures. LN = lymph node. Courtesy of J. Farrell, MD.

of esophageal wall thickening with significant expansion of the esophageal wall were noted in the subjects with eosinophilic esophagitis versus controls. Similar findings of esophageal wall thickening have been seen in subjects with gastroesophageal reflux disease[5,6]; thus, EUS only complements endoscopy and histology for the diagnosis of reflux esophagitis. Because EUS was used as an adjuvant for diagnosis of eosinophilic esophagitis and gives similar findings in patients with gastroesophageal reflux disease, this modality may be more useful as a follow-up tool in patients who are being treated for their eosinophilic esophagitis as opposed to a primary diagnostic tool.

The use of EUS in patients with congenital esophageal stenosis (CES) has been successful in a few reports for determination of the optimal treatment approach.[7–9] There are three histopathologic types of CES: tracheobronchial remnants, membranous diaphragm, and fibromuscular hypertrophy. The type of CES must be determined before deciding on dilatation versus surgical resection. Dilatation of tracheobronchial remnants carries a higher risk of perforation and a poor success rate, with the eventual necessity of surgical resection. EUS is able to visualize cartilage associated with tracheobronchial remnants and thereby eliminates attempts at dilatation.

Many studies have used EUS in the clinical setting of portal hypertension. A specific study was undertaken to determine if variceal wall thickness correlates with the risk of variceal bleeding.[10] Using these data, along with variceal pressures, wall tension was determined to estimate the risk of bleeding. However, the researchers were unable to provide similar findings in patients with multiple varices.

An established indication for use of EUS in adults is staging of esophageal cancers and the diagnosis of mediastinal lympadenopathy. Pediatric patients may have other etiologies for mediastinal lymphadenopathy, including infectious or granulomatous disease (eg, sarcoidosis). EUS was shown to assist in the diagnosis of histoplasmosis among patients with symptoms of dysphagia and a midesophageal submucosal mass.[11] Savides and colleagues also tried to determine the cost-effectiveness of EUS versus CT scan of the chest.[11] In their institution, the cost was comparable, but the advantage of EUS was the availability to obtain tissue via FNA. They also found that EUS provided greater resolution of periesophageal lesions and a greater sensitivity of calcified lymph nodes. The real benefit of the role of EUS-guided FNA in the evaluation of pediatric mediastinal processes may be in the avoidance of more invasive and costly diagnostic procedures (eg, mediastinoscopy and thoracoscopy).

EUS has also been used for post-treatment assessment of patients with achalasia.[12] Patients with achalasia who were treated with dilation versus botulinum toxin injection underwent EUS to assess esophageal wall damage post-treatment. Transient esophageal mucosa-submucosa diameter was increased postdilation but not post–botulinum toxin injection. Also of note, the thickening normalized within 24 hours of the procedure.

Stomach

Dieulafoy lesion can occasionally be seen in the pediatric patient population. Fockens and colleagues used EUS to determine the location of this abnormal, large submucosal vessel.[13] On finding such a vessel, they performed sclerotherapy. Unfortunately, they used a rotating sector scanner that did not have Doppler capability, and with the perpendicular scanning view, needle-guided injections were difficult. Use of the linear array would most likely alleviate this problem.

Foregut duplications are a rare abnormality, but generally two-thirds are found within the first year of life. An investigational indication for EUS is defining the relationship of these duplications to their intraluminal tract.[14] Because EUS can differentiate between cystic and solid structures and is in greater proximity to the lesion, it can be a reliable tool to diagnose this entity. Also, endosonographic aspiration of the cyst can be performed to identify cells consistent with duplication. The wall layers can be identified in duplications to match the gastrointestinal tract (Figure 67.4-7).

Pancreas/Biliary Tree

There are a significant number of established indications for EUS use in adults in the pancreas and biliary tract. In children, reports of EUS use include diagnosis of solid pseudopapillary tumors of the pancreas (Figure 67.4-8),[15] blunt pancreatic trauma,[16] drainage of pancreatic pseudocysts (Figure 67.4-9),[17] preoperative localization of insulinomas and gastrinomas,[18] and as a screening tool prior to sphincterotomy for acute biliary pancreatitis.[19,20]

EUS-guided FNA has also been used in children for the diagnosis of solid pseudopapillary tumors of the pancreas.[15] Owing to the malignant potential of the tumor, radical resection is the mainstay of treatment in adults. The investigators postulated that surgeons reluctant to perform radical resection in children when the diagnosis is in question might be reassured by a definitive diagnosis with the assistance of EUS. EUS may also be the best modality to obtain the FNA because of the location of the mass.

Pancreatic trauma can occasionally be seen in the pediatric population. EUS has been compared with CT for diagnosis and follow-up of pancreatic trauma.[16] Several advantages were established, including mobility of the EUS equipment, lack of radiation, ability to do multiple serial examinations, and no requirement of contrast material with sensitivity equal to that of CT. Disadvantages include increased time consumption for the EUS examination and diagnosis dependent on operator expertise.

Drainage of pancreatic pseudocysts with the use of conventional endoscopy has been reported since 1981.[21] EUS-guided drainage was first described in 1996.[22] EUS plays an important role in the evaluation of pancreatic pseudocysts prior to endoscopic drainage. More recently, an EUS-guided one-step drainage procedure was used in three patients, including one pediatric patient.[17] A curved linear

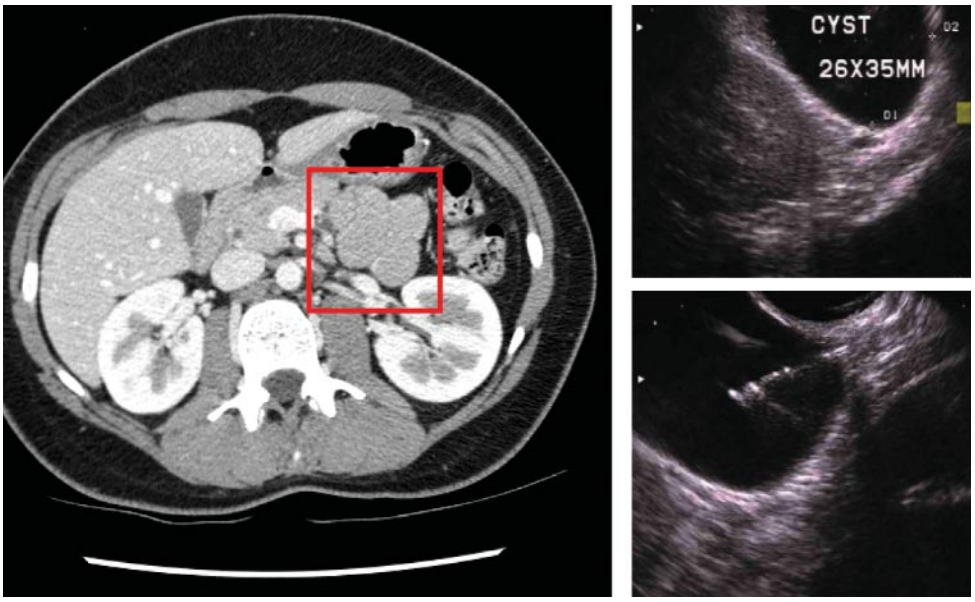

FIGURE 67.4-7 Gastric duplication cyst (computed tomographic scan and endoscopic ultrasonographic images with fine-needle aspiration). Courtesy of J. Farrell, MD.

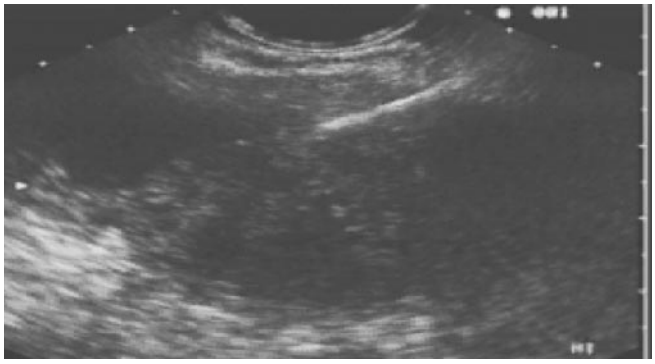

FIGURE 67.4-8 Endoscopic ultrasonography–guided fine-needle aspiration of a pancreatic mass. Courtesy of J. Farrell, MD.

array EUS with a 22-gauge needle and a 7 French drainage tube were used in this procedure. Although there were a small number of patients in this report, EUS-guided one-step drainage, with its ability to identify and avoid intramural vasculature, may be an advantageous procedure over a radiologic or a surgical approach.

EUS was compared with somatostatin receptor scintigraphy (SRS), transabdominal ultrasonography, CT, and magnetic resonance imaging (MRI) for the preoperative localization of insulinomas and gastrinomas.[18] The authors found that EUS and SRS had comparable sensitivity and significantly greater sensitivity for localization of gastrinomas than ultrasonography, CT, or MRI. EUS was the most sensitive modality for localization of insulinomas than all of the others.

Endoscopic sphincterotomy is beneficial for patients with biliary pancreatitis, but it can have serious complications. The use of EUS for prescreening patients prior to sphincterotomy can reduce the complications by avoiding unnecessary cannulation of the papilla.[19]

Colon

Established indications in adults for using EUS in the lower gastrointestinal tract are primarily for staging of rectal cancer, but EUS investigational use in children has included evaluation of the rectal venous system in patients with portal hypertension,[23,24] differential diagnosis in suspected cases of inflammatory bowel disease,[25,26] and EUS evaluation of perirectal and perianal complications of Crohn disease.[27,28]

Yachha and colleagues were able to use EUS to compare children with extrahepatic portal venous obstruction and controls to determine the size, number, and location of varices.[23] They determined that EUS was able to detect the presence of rectal varices better than endoscopy. They also suggested that EUS may be useful in differentiating between portal rectopathy and inflammatory colitis.

An attempt to use EUS for differentiating Crohn disease and ulcerative colitis has been inconclusive.[27] Many studies have tried to compare wall thickness and discrimination between mucosal and transmural inflammation. No consistent conclusions are seen among these studies. However, EUS has been used to correctly identify perirectal and perianal complications of Crohn disease better than fistulacontrast studies and CT.[28]

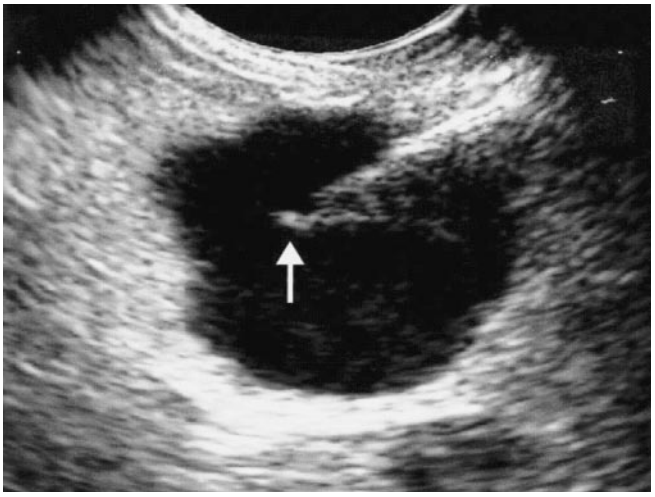

FIGURE 67.4-9 Endoscopic ultrasonography–guided fine-needle aspiration of a pancreatic cyst (*arrow*, tip of needle).

CONCLUSIONS

EUS, including EUS-guided FNA, is a new modality that has many established indications in the adult patient population. Its pediatric indications have increased somewhat since its inception, but owing to the lack of awareness among general physicians, it may be underused. As clinical indications increase, training in this technique will also need to increase.

5. Endoscopic Retrograde Cholangiopancreatography

Claude Liguory, MD
Jean-François Mougenot, MD
Gustavo Andrade de Paulo, MD, MSc

> Tell me and I forget. Teach me and I remember. Involve me and I learn.
>
> —Benjamin Franklin (1706–1790)

Over the past 30 years, endoscopic retrograde cholangiopancreatography (ERCP) has become an integral element in the diagnostic and therapeutic tools of the gastroenterologist. It has grown from a limited procedure, performed by a few, to a mainstream modality for the diagnosis and treatment of a wide variety of benign and malignant hepatobiliary and pancreatic disorders. Since the report of the first successful cannulation of the ampulla of Vater by McCune and colleagues in 1968,[1] the role of ERCP for diagnosing and treating these diseases has evolved, providing patients with a minimally invasive method to treat problems that previously required open surgery.

ERCP is currently used for the management of bile duct stones; benign and malignant biliary obstruction; benign and malignant pancreatic neoplasms and diseases of the major and minor papilla; acute and chronic pancreatitis; bile duct injuries; pancreatic duct disruption and pseudocysts; pain syndromes considered to be of pancreatic, biliary, or sphincter of Oddi origin; certain congenital and acquired hepatic conditions affecting the biliary tract; and bleeding or infection suspected of being of hepatic, biliary, or pancreatic origin.[2–4]

Although ERCP has been widely applied in adult patients for a long time, only recently has it become an accepted modality in pediatrics. The limited use of this technique in children might be caused by multiple factors, including (1) a relatively low incidence of pancreatic and biliary diseases in childhood and a low index of clinical suspicion; (2) limited availability of pediatric instruments; (3) a lack of expertise among pediatric gastroenterologists to perform ERCP; (4) reluctance of adult gastroenterologists to study small children; (5) the impression that ERCP in children is technically more difficult to accomplish; (6) difficulty in the effective evaluation of a therapeutic result; and (7) a lack of well-defined indications and safety of ERCP in children.[5–7]

Since the first report of a successful ERCP in a 3.5-month-old child in 1976,[8] the field of pediatric ERCP has expanded dramatically, driven by the growing subspecialty of pediatric gastroenterology, refinements in design, and worldwide distribution of small-diameter duodenoscopes.[9,10]

TECHNICAL CONSIDERATIONS

ERCP is a relatively complex combined endoscopic or radiographic procedure that requires multiple skilled personnel. Our goal is to provide state-of-the-art patient care, and success depends on the combined efforts of members from the departments of surgery, medicine, pediatrics, and radiology. Hence, one weak link in this multidisciplinary venture might limit success.[11–13]

Preprocedure Preparation

According to the Standards of Practice Committee from the American Society for Gastrointestinal Endoscopy (ASGE), "preparation for endoscopy in pediatric age patients requires attention to physiologic issues as well as emotional and psychosocial issues in both the patient and the parent or guardian."[12] The anticipation of potentially painful or noxious procedures provokes intense anxiety in children. Parental anxiety is heightened by protective feelings, wanting to shield the child against harm and unnecessary discomfort. Much of this anxiety may be relieved by providing optimal age-appropriate information and counseling to the patients and parents, with a detailed description of all aspects of the procedure.[9,12] With psychological preparation, children are less anxious and more cooperative during the procedure, requiring less sedation.[14]

Dietary Restrictions

Dietary restrictions are necessary to minimize the risks of pulmonary aspiration of gastric contents. In pediatric patients presumed to have normal gastric emptying, the fasting interval before endoscopy should be a minimum of 2 hours for clear liquids. Guidelines for fasting after ingestion of milk and solids are diverse and related to age. Fasting from milk or solids should be for 4 hours in infants under 5 months, 6 hours in those 6 to 36 months, and 8 hours in those over 36 months of age.[12,15]

Informed Consent

Written informed consent must be obtained from the appropriately designated parent or guardian after careful explanation of the risks and benefits of the entire procedure. Adolescents might be offered the option to review and sign the consent form to acknowledge their active participation in the process.[9]

Sedation

Premedication is not routinely used for pediatric endoscopy.[16] When necessary, oral or rectal administration of benzodiazepines might be used prior to intravenous sedation or anesthesia, improving the ease of separation from parents and of intravenous insertion.[12]

Most ERCPs are performed with the benefit of conscious sedation, deep sedation, or general anesthesia, although some experts give no sedation to selected patients.[17] The proper approach to sedation remains a major controversy among pediatric endoscopists.[9,18]

The relatively large diameter of standard duodenoscopes (eg, 11–12 mm) may cause discomfort and compress the soft-walled trachea in young children. The prone position during ERCP also compromises chest and lung excursion and may result in hypoventilation and hypoxia in a sedated child. With these considerations in mind, general anesthesia with endotracheal intubation might be appropriate for some children. Insufficient outcome data exist to make firm recommendations about the comparative adequacy, safety, and cost of sedation and general anesthesia in children undergoing ERCP (Table 67.5-1).[19]

An individual trained in pediatric monitoring and at least basic pediatric life support should be present in addition to the endoscopist for the entire duration of the procedure. Pulse oximetry and hemodynamic monitoring should be routinely used.[12]

Equipment

Fluoroscopic equipment should be suitable for children of all ages, minimizing radiation exposure.

In neonates and infants younger than 12 months, ERCP is performed with a pediatric duodenoscope, which has an insertion tube diameter of 7.5 mm, a channel of 2 mm, and an elevator (Olympus PJF–160 – Olympus, Hamburg, Germany). This endoscope, which is also preferred for children less than 2 years of age, accepts cannulas and other accessories that are 5 French or smaller. A standard diagnostic duodenoscope (insertion tube diameter approximately 11–12 mm) with a 3.2 mm operating channel may be used in most children older than 2 to 3 years. Therapeutic large-diameter (> 13 mm) endoscopes with a 4.2 mm channel are infrequently required to place 10 French stents in larger adolescents.[5,19]

Antimicrobial Prophylaxis

The frequency of bacteremia associated with upper or lower gastrointestinal endoscopy with or without biopsy is low, ranging from about 2 to 5%.[20,21] In immunocompetent children, clinically relevant bacteremia is very infrequent following routine endoscopic procedures.[22] The reported risk of bacteremia with ERCP (5–6%) is similar to that for upper and lower endoscopy unless an obstructed biliary ductal system is present.[20]

Infections associated with gastrointestinal endoscopic procedures are rare, including those performed in children.[22] In a meta-analysis of antibiotic prophylaxis in ERCP, Harris and colleagues concluded that antibiotic prophylaxis prior to ERCP may reduce the incidence of bacteremia, but this has little clinical relevance. Prophylaxis does not substantially reduce the incidence of sepsis or cholangitis; thus, the routine use of antibiotic prophylaxis cannot be recommended.[23]

The American Heart Association and the ASGE have developed criteria for the use of prophylactic antibiotics for endoscopic procedures based on the associated risk of developing endocarditis. ERCP in the absence of ductal obstruction is considered to be of low risk, and routine antibiotic prophylaxis is not recommended. Evaluation should be performed on a case by case basis.[20,24,25] For endoscopic procedures associated with increased rates of transient bacteremia (ERCP with known or suspected bile duct obstruction), prophylaxis is recommended for patients at "high risk" for the development of infective endocarditis (eg, prosthetic heart valves, a previous history of endocarditis, complex cyanotic congenital heart disease, and surgically constructed systemic-pulmonary shunts). No prophylaxis is recommended for patients with those cardiac lesions and conditions at no increased risk for infective endocarditis over the general population (eg, previous coronary artery bypass, graft surgery, cardiac pacemakers and implanted defibrillators, mitral valve prolapse or previous rheumatic fever without valvular dysfunction or regurgitation). There are insufficient data to recommend routine prophylaxis for patients with cardiac lesions or conditions at intermediate risk for the development of infective endocarditis (eg, most congenital cardiac malformations, rheumatic and other acquired valvular dysfunction, even after valvular surgery, hypertrophic cardiomyopathy, and mitral valve prolapse with valvular regurgitation). The endoscopist may consider prophylaxis on a case by case basis.[24,25]

Snyder and Bratton surveyed 14 academic pediatric centers in the United States and Canada to determine the current practices of these groups with regard to antimicrobial prophylaxis in ERCP. In patients with cardiac disease at high risk for endocarditis, all centers used prophylaxis. In patients with a moderate risk, 64% of the centers used prophylaxis.[20]

The Working Party for the British Society of Gastroenterology Endoscopy Committee recommends antibiotic prophylaxis for all patients undergoing ERCP with evidence of biliary stasis or pancreatic pseudocyst. Oral ciprofloxacin or parenteral gentamicin (or parenteral quinolone, cephalosporin, or ureidopenicillin) is recommended.[26] There are no pediatric data to guide antibiotic prophylaxis for ERCP.[5,20]

Procedure Length

The time for total examination (from introduction of duodenoscope to withdrawal of the instrument) varies considerably according to expertise and the difficulty of the

examination. The duration of a diagnostic examination ranges from 2 minutes to 1 hour.[17,27] In most series, the mean time is between 10 and 30 minutes.[6,17,28,29] For therapeutic ERCPs, it is difficult to define the "normal" mean time, considering the myriad of interventions available. In one study, the average time for ERCP, including both diagnostic and therapeutic studies, was 58 minutes.[12]

DIAGNOSTIC AND THERAPEUTIC INDICATIONS

Indications for diagnostic and therapeutic ERCP in pediatrics (see Table 67.5-1) are, for the most part, similar to those established for the adult population. However, the relative frequency of each indication differs because children are much more prone to congenital abnormalities and trauma than malignancy.

Diagnostic ERCP in the Era of Magnetic Resonance Cholangiopancreatography

Over the last two decades, several new diagnostic modalities have been developed and refined, such as ultrasonography (transabdominal and endoscopic), computed tomography (CT) (single and multislice helical), magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP), CT-virtual cholangiography, and laparoscopic surgery with intraoperative cholangiography. These techniques have proven useful in the diagnosis and staging of pancreatic and hepatobiliary diseases and may obviate the need for diagnostic ERCP in some cases.

MRCP is a noninvasive test for imaging the biliary and pancreatic ducts, which provides high-quality images without administration of exogenous contrast material or use of ionizing radiation.[30–36]

MRI relies on radiofrequency pulse-induced excitation of protons within a magnetic field to generate an image. Conventional MRI uses a combination of T_1- and T_2-weighted sequences to image abdominal organs (eg, liver, pancreas biliary tract, and duodenum). MRCP relies on heavily T_2-weighted sequences because fluid-containing structures have a much longer T_2 than solid tissue. Thus, stationary fluid in the biliary and pancreatic ducts serves as an intrinsic contrast medium, resulting in images similar to those obtained through ERCP.[30] Intraluminal filling defects and the nature of ductal stenoses and/or dilatation can be readily demonstrated. With current magnetic resonance scanners, images are acquired in a few seconds, virtually eliminating image degradation from motion artefacts. The entire biliary tract can be imaged in a single breath-hold of 20 seconds or less with high spatial resolution so that structures such as fourth-order intrahepatic bile ducts and small stones are detected.[35] No special preparation is required, although fasting for 2 to 4 hours is recommended to reduce gastric and duodenal fluids.[31]

Different MRCP pulse sequences have been used: steady-state free precession, two-dimensional and three-dimensional fast spin echo techniques, rapid acquisition with relaxation enhancement (RARE), and half-Fourier RARE. MRCP image sequencing differs from center to center because of rapidly evolving technology, equipment and software differences, and radiologist preferences and expertise. Currently, most centers are not equipped to perform state-of-the-art MRCP images.[30]

MRCP is a useful noninvasive alternative to diagnostic ERCP, especially when ERCP study is difficult or technically inadequate (eg, Billroth II surgical bypass, biliary-enteric anastomoses, periampullary diverticula, duodenal obstruction). It can also be used for planning surgical, endoscopic, and radiologic interventions.

The accuracy of MRCP in comparison with ERCP is very high. Adequate images can be obtained in 95 to 98% of patients.[37–39]

Currently, a limitation of MRCP is that its resolution is inferior to that of ERCP. Although MRCP detects stones as small as 2 mm, the spatial resolution of MRCP is not sufficient to detect small stones and crystals in a consistent fashion. It may not be able to detect small ampullary or distal bile duct tumors either.[35]

Absolute contraindications include the presence of a cardiac pacemaker, cerebral aneurysm clips, ocular or cochlear implants, and ocular foreign bodies. Relative contraindications include the presence of a cardiac prosthetic valve, neurostimulators, and metal prostheses. Claustrophobia accounts for 1 to 4% of failed or inadequate studies.[30,40]

In pediatrics, MRCP has been used to diagnose biliary atresia (BA) and other congenital or acquired pancreaticobiliary disorders (eg, choledochal cysts).[41–43] However, further studies are needed to support routine use of MRCP in pediatrics.[31]

Defining Normal Duct Size in Pediatrics

The size of a normal common bile duct (CBD) was measured in children between 7 and 16 years and varies from 2.1 to 4.9 mm, just below the entry of the cystic duct. The diameter of the pancreatic duct in the head ranges from 1.4 to 2.1 mm, and in the body from 1.1 to 1.9 mm (all measures are corrected for radiographic magnification).[29]

BILIARY INDICATIONS FOR ERCP

Indications for ERCP in children are listed in Table 67.5-2. Investigation of neonatal cholestasis is unique to pediatrics, although the role of ERCP remains controversial.[5,19] Structural causes of neonatal cholestasis include BA, choledochal cysts, choledocholithiasis, intrahepatic bile duct paucity or hypoplasia, neonatal sclerosing cholangitis, and congenital bile duct stricture.[19]

In children older than 1 year and adolescents with biliary disorders, the most frequent indications are obstructive jaundice, known or suspected choledocholithiasis, abnormal liver enzymes in children with inflammatory bowel diseases, abnormal biliary findings in abdominal ultrasonography, and therapeutic ERCP.[5]

Biliary Atresia

In a child with neonatal cholestasis, symptoms and signs of BA overlap those of idiopathic neonatal hepatitis and other rare causes of cholestasis.[17,44] Early identification

TABLE 67.5-2 BILIARY INDICATIONS FOR ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

DIAGNOSTIC	THERAPEUTIC
Investigation of neonatal cholestasis	Sphincterotomy
Biliary atresia	Sphincteroplasty (balloon dilation)
Choledochal cyst	Stone extraction
Choledocholithiasis	Stricture dilation
Biliary obstruction owing to parasitic infestation	Stent placement
Dilated intrahepatic bile duct	Nasobiliary drainage
Benign and malignant biliary strictures	
Primary sclerosing cholangitis	
Biliary obstruction or leaks after liver transplant	
Preoperative and postoperative evaluation (laparoscopic cholecystectomy)	
Bile plug syndrome	
Abnormal findings in other examinations	
Manometric evaluation of the sphincter of Oddi	

of BA before 8 weeks of age may be associated with better surgical results (Kasai procedure) and improved clinical outcome.[17,27,44]

BA is a localized, progressive obliteration of the extrahepatic and hilar bile ducts that uniquely presents in the first months of life. The disease occurs in approximately 1 in 8,000 to 1 in 15,000 live births, with a 1.4:1 female-to-male predominance. It accounts for 30% of all cases of cholestasis in young infants. If untreated, it leads to progressive fibrosis and, ultimately, cirrhosis and death.[44,45]

No single test or combination of tests is consistently reliable in differentiating BA from other forms of cholestasis.[27] Imaging techniques such as ultrasonography and hepatobiliary scan are useful procedures but are often inconclusive. The sensitivity and specificity of scintigraphy, with concomitant administration of phenobarbital, are about 95% and 93%, respectively. However, failure of excretion may be seen in neonatal hepatitis as well. Currently, the most reliable test, aside from exploratory laparotomy, is percutaneous liver biopsy (up to 93% accuracy).[44] However, the histologic features of giant cell transformation and bile duct proliferation can be seen in both neonatal hepatitis and early stages of BA.[17]

Duodenal intubation has been reported to exclude BA if bilirubin or bile is found in the fluid. However, 10% of infants in whom bile is not found will not have BA.[17]

The combination of several tests may improve the accuracy of the diagnosis. Discriminant analysis using clinical criteria, scintigraphic excretion scan, and liver biopsy permit accurate diagnosis of either BA or neonatal hepatitis in 80 to 94% of young infants.[17] Thus, 10 to 20% of infants might need surgical exploration to establish a diagnosis. For these children, ERCP may be of diagnostic value.[5,17,27,28,44]

ERCP is the procedure of choice for investigation of structural abnormalities or obstructive lesions of the extrahepatic bile ducts and gallbladder when the intrahepatic ducts are not dilated.[28] Three types of anatomic findings have been described in patients with BA[5,17]:

- Type 1: no visualization of the biliary tree. This is observed in about 35% of the cases. No bile is seen in the duodenum. A normal pancreatogram is obtained.
- Type 2: visualization of the distal CBD and gallbladder without visualization of the main hepatic or intrahepatic ducts (35% of the cases). No bile is seen in the duodenum, and a narrow and irregular distal CBD might be present. The pancreatic duct is normal.
- Type 3: type 3a includes visualization of the gallbladder and the complete CBD with biliary lakes at the porta hepatis; in type 3b, both hepatic ducts are seen with biliary lakes. It is present in 30% of cases. Bile can be seen in the duodenum. The pancreatic duct is normal, and a narrow distal CBD is present.

When the biliary tree is partially visualized (types 2 and 3), the diagnosis of BA is made and confirmed by surgery. When the biliary tree is not opacified and only the pancreatic duct is seen (type 1), the diagnosis is suspected, and exploratory laparotomy is indicated.

It is important to emphasize that absence of CBD opacification alone, despite several maneuvers to opacify the biliary tree, does not establish atresia.[16,27] In most situations, clinical, biochemical, and liver biopsy findings in conjunction with filling of the pancreatic duct without CBD opacification and absence of bile in the duodenum may be sufficient to establish the diagnosis of BA prior to surgical intervention.[16] Of the 310 infants with neonatal cholestasis reported in the literature and reviewed by Guelrud, the diagnosis by ERCP was incorrect in only 5 (1.6%) patients.[5]

MRCP has been used in neonates and infants for the diagnosis of BA, and the results are promising.[40] However, further studies are required.[30,43]

Choledochal Cysts

Choledochal cysts are uncommon anomalies of the bile ducts, with probable congenital origin, associated with anomalous pancreaticobiliary junction in 80 to 90% of cases.[46] The incidence is higher among Japanese, being rare in Western countries, where its prevalence is estimated in 1 in 100,000 to 1 in 150,000 newborns.[47] The female-to-male predominance is 3 to 4:1. These cysts are usually found during infancy or childhood (80% of patients are younger than 10 years of age),[48] although, in some series, 30% are found in adults or among the elderly.[49,50]

The most common classification accepted nowadays was proposed by Todani and colleagues,[51] expanding the original classification of Alonso-Lej and colleagues[52] by including intrahepatic cysts and redividing the extrahepatic disease:

- Type I cysts are present in 80 to 90% of cases and are further classified according to the shape of the affected segment. A type IA cyst involves cystic dilation of the CBD, with marked dilation of part of or the entire extrahepatic biliary tree. The gallbladder commonly arises from the cyst, and the intrahepatic biliary tree is normal. Type IB cyst involves focal, segmental dilation of the CBD, usually of the most distal part of the duct. A normal segment of CBD is present between the cyst and the cystic duct. Type IC cyst involves fusiform dilation of the CBD, along with diffuse, cylindrical dilation of the common hepatic duct. The gallbladder arises from the dilated CBD, and the intrahepatic biliary system is not dilated.
- Type II cysts are present in 2% of cases and are considered true choledochal diverticula.
- Type III cyst, found in 1.5 to 5% of the patients, is a choledochocele that involves only the intraduodenal portion of the CBD. Characteristically, the papilla appears as a hemispherical cystic structure protruding into the duodenal lumen. The terminal end of the CBD is blunt and bulbous, unlike the normal tapered appearance. The cystic structure enlarges further during injection of contrast material into the distal CBD. A rounded, cystic structure filled with contrast material is noted when patients are upright.[53]
- Type IV cysts are subclassified in two groups. Type IVA cyst involves dilation of the intra- and extrahepatic bile ducts and is present in up to 20% of patients. Cholangiography shows gross cystic dilation of the extrahepatic biliary tree, with extension of the cystic dilation into the intrahepatic biliary tree. The intrahepatic dilation may affect multiple segments and be smooth and fusiform or irregular. Type IVB cysts also involve dilation of multiple segments but are confined to the extrahepatic bile duct. They are much less common than type IVA cysts. Cholangiography shows multiple segmental dilation of the CBD. The intrahepatic biliary tree is normal.
- Type V cyst (Caroli disease) involves dilation of one or several segments of the intrahepatic bile duct.[51,54]

The origin and formation of choledochal cysts have been a matter of considerable investigation and debate.[55]

The classic triad of choledochal cyst is characterized by abdominal pain, jaundice, and abdominal mass. Unusual presentations include rupture of the choledochal cyst with bile peritonitis, pancreatitis, and bleeding esophageal varices owing to biliary cirrhosis.[56] Intermittent fever, vomiting, elevation in serum transaminases and amylase, abdominal pain, and jaundice might be related to bouts of cholangitis and pancreatitis.[57]

Many complications have been associated with choledochal cysts, including cholelithiasis, choledocholithiasis, cystolithiasis, pancreatitis, intrahepatic abscesses, biliary cirrhosis, portal hypertension, and biliary carcinoma.[46]

Malignancy related to choledochal cysts is more frequent with advancing age, being reported in 23 to 40% of the cases.[58,59] These rates are extremely high if compared with biliary carcinoma in the general population (0.003–0.004%).[60] The development of cancer seems to be related to bile stasis and prolonged contact with the epithelium. It might be related to pancreatic juice reflux to the biliary tree, leading to chronic irritation and metaplasia. Most cases are detected in advanced stages, with poor prognosis. Although cyst excision eliminates the potential site for neoplasia, it does not exclude the possibility of developing cancer in the intrahepatic ducts. Long-term follow-up is always mandatory.[61]

Abdominal ultrasonography and CT are important in detecting cystic masses in close relation to the pancreatic head and hepatic hilum. CT is more accurate in depicting intrahepatic bile ducts and the distal parts of the CBD. When the cyst is round and markedly dilated, with no evidence of intrahepatic ductal dilation, its biliary origin is difficult to determine. Cystic lesions such as mesenteric, omental, ovarian, renal, adrenal, and hepatic cysts; gastrointestinal duplication; hydronephrotic kidneys; and pancreatic pseudocysts are the main differential diagnoses when a huge choledochal cyst lacks intrahepatic involvement at CT.[54] Hepatobiliary scintigraphy using technetium 99m is useful in this setting.

ERCP is the most sensitive method to define the biliary system anatomy and depict anomalous pancreaticobiliary junction and biliary malignancies.[59,62] It is invasive and operator dependent, requiring a meticulous technique. In this setting, it has been associated with a particularly high risk of pancreatitis, probably related to the fact that, in the presence of a common channel, cyst opacification often requires repetitive injections of the pancreatic duct.[62,63]

Virtual cholangiography using CT with two- or three-dimensional visualization of the biliary tract has also been used in the diagnosis of choledochal cysts. Spinzi and colleagues emphasized its advantages in depicting the entire biliary system and the capability of showing mucosal lesions.[60] However, the need for contrast administration and adequate hepatic metabolism (absorption and excretion) limits its application.

MRCP is a noninvasive method capable of examining the entire biliary tree and the pancreatic duct in two or three dimensions. The development of fast acquisition techniques for MRCP has reduced acquisition time to a few seconds and made possible the performance of dynamic studies after secretin stimulation.[63] MRCP can identify the anomalous pancreaticobiliary junction in up to 82% of the cases. It also shows good correlation with ERCP with regard to choledochal cysts and anomalous pancreaticobiliary junction diagnoses.[63–65] MRCP has established value in the diagnosis of choledocholithiasis and biliary obstruction. However, small stones and gallbladder lesions (carcinoma and mucosal hyperplasia) often associated with anomalous pancreaticobiliary junction are difficult to demonstrate.[65] Endoscopic ultrasonography can be useful in this situation.[66]

Percutaneous drainage of choledochal cysts has been reported and is supposed to help in the decompression of the biliary tree, making the surgical approach easier.[46] Dilation of the sphincter of Oddi through ERCP has also been reported, relieving symptoms.[67] The ease of stent placement provides an alternative to urgent surgery in this group of sick children.[12] However, owing to the high potential of complications, including malignant degeneration, the treatment of choice is always surgery. According to the case, a choledochojejunal anastomosis can be performed, although cyst excision and Roux-en-Y hepaticojejunostomy are preferred.[49,54]

In type III cysts (choledochocele), the incidence of cholangiocarcinoma does not appear to be as high as for type I and IV cysts. Currently, in more than 50 cases of type III cysts, no cases of cholangiocarcinoma have been reported. Thus, resection of a type III cyst may not be mandatory for control of future cancer risk. Type III cysts have been effectively treated with transduodenal sphincterotomy or sphincteroplasty. The goal of therapy is to establish effective drainage of the CBD and pancreatic duct.[45,53,68]

Choledocholithiasis

In infants and children, choledocholithiasis rarely occurs.[69–71] Perforation of the extrahepatic biliary tract with resulting biliary ascites is the more common presentation of CBD stones in infants.[69]

Although the sensitivity of abdominal ultrasonography for cholelithiasis is in excess of 95%, reported sensitivities for choledocholithiasis range from 18 to 74%. No pediatric data are available. Sensitivities of conventional CT scan range from 76 to 90%.[35]

Early studies of MRCP in choledocholithiasis noted sensitivities ranging from 81 to 92% and specificities ranging from 91 to 100%. Recent works using state-of-the-art techniques yield sensitivities of 90 to 100%, specificities of 92 to 100%, and positive predictive values of 93 to 100%. Negative predictive values range from 96 to 100%.[34] Based on these results, MRCP is being used with increasing frequency as a screening examination for the detection and exclusion of CBD stones, especially in patients with a low or moderate probability of having stones. The limitations of MRCP are as follows: (1) inferior resolution to that of ERCP; although MRCP detects stones as small as 2 mm, the spatial resolution of MRCP is not sufficient to detect small stones and crystals in a consistent fashion; (2) impacted calculi (not surrounded by bile); (3) patients with metal clips, pneumobilia, and hemobilia; (4) the latest advances are not uniformly available worldwide; (5) a lack of therapeutic options.[2,30,31,35]

ERCP is very sensitive in detecting CBD stones, although, occasionally, small stones may be missed.[2] However, with the introduction of MRCP, the focus of ERCP has shifted in many institutions from its use both as a diagnostic and therapeutic tool to its use primarily as a therapeutic procedure.[35]

Many reports in the pediatric literature confirm the ability of ERCP to treat CBD stones.[12,70–74] A variety of techniques are used, including endoscopic sphincterotomy (ES), balloon dilation of the papilla (sphincteroplasty), balloon or basket removal, and stent and nasobiliary drain placement (Figure 67.5-1).[12]

ES is a well-established procedure in adult patients with choledocholithiasis. In children, it was first reported in 1982[29] and has been performed in infants as young as 5 months old.[73,75,76] Because the long-term consequences of ES in children are unknown, endoscopic balloon dilation of the sphincter of Oddi seems to be an attractive technique.[12,73] Evidence that sphincter function returns after balloon dilation may prove to be a major advantage, particularly in a younger age group. Further evidence is required to confirm that this is the case. There must be some concern about whether balloon dilation is justifiable in patients with stones more than 8 to 10 mm in diameter because lithotripsy then seems inevitable.[77]

Biliary microlithiasis causing pancreatitis in a 14-year-old boy has also been reported.[78]

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is an inflammatory disease of the biliary tract of uncertain etiology, occurring with a prevalence of 1 to 6 in 100,000.[32] It is characterized by recurrent fever, abdominal pain, and jaundice resulting from fibrosing and inflammatory obstruction of the biliary tree.[79] At presentation, about 70% of patients report slowly progressive symptoms, such as a gradual onset of fatigue and pruritus.[32]

The diagnosis of PSC is based on a combination of the clinical features, cholestatic biochemical profile, and histologic and radiographic abnormalities.

ERCP provides an accurate and sensitive method of diagnosing PSC. The typical cholangiographic features include diffuse multifocal annular strictures, intervening segments of normal or slightly ectatic ducts, diverticular outpouchings, and short band-like strictures involving the intrahepatic and/or extrahepatic biliary tree. Pruning of the peripheral biliary tree and irregularities of the duct walls may be found.[5,32,79]

Recently, MRCP has been evaluated in patients with PSC, with high sensitivity (85%) and specificity (99%) for the diagnosis of PSC.[32]

With regard to therapy, patients with major ductal strictures are candidates for endoscopic treatment with ES and balloon dilation to relieve the obstruction and delay the progression to cirrhosis.[5,80]

Cholangiopathy Associated with HIV Infection

Although pancreatic, hepatic, and biliary complications of human immunodeficiency virus (HIV) infection are well recognized in adults,[81–84] there have been few studies in children. Findings include cytomegalovirus infection, Kaposi sarcoma, giant cell transformation, granulomatous hepatitis, steatosis, portal inflammation, and cholestasis. Sclerosing cholangitis has been reported in children with immune deficiencies other than acquired immune deficiency syndrome (AIDS) and in HIV patients. Pancreatitis has been associated with infections with cytomegalovirus,

Cryptosporidium, *Pneumocystis*, and *Mycobacterium avium-intracellulare*.[85] ERCP can be safely performed on children with HIV infection. ERCP findings can direct treatment; it can also be used as a therapeutic procedure.[85]

Parasitic Infestation

Ascaris lumbricoides is the most common helminth in the human gastrointestinal tract. It is estimated that more than 1 billion people in the world are infected, and the prevalence is inversely related to the level of sanitation, personal hygiene, and agricultural development.[86,87] Children are predominantly affected. Most cases have a benign course and respond well to treatment.

Most intestinal *Ascaris* infections are asymptomatic or mildly symptomatic, but classic biliary symptoms occur if the large-sized *Ascaris* worm migrates into the bile duct. Patients may present with typical biliary colic, acute cholangitis, acalculous cholecystitis, hepatic abscess, or acute pancreatitis. Biliary colic or pancreatitis is often related to a worm impacted at the ampulla.[87]

The treatment should start with conservative measures, including hydration, analgesics, antispasmodics, and antihelminthic therapy. For patients unresponsive to these, ERCP may be performed.

ERCP plays an important role both in the diagnosis of the infestation in the biliary and pancreatic ducts (serpigi-

nous images causing filling defects) and in the treatment of this disease, removing the worms and permitting the decompression of the duct, with or without sphincterotomy. Rapid improvement of patients with pancreatic ascariasis after endoscopic removal is reported.[86, 88–90]

Duodenal Duplication Cyst

Duplication cysts of the gastrointestinal tract are rare congenital anomalies that occur predominantly in males. Duodenal duplications represent only 4 to 12% of all intestinal duplications.[91,92]

Severe vomiting, relapsing pancreatitis, bowel obstruction (mimicking hypertrophic pyloric stenosis), and pain during the first 2 to 4 years of life are possible early presenting symptoms. They rarely present with gastrointestinal bleeding owing to ulceration produced by acid-secreting ectopic gastric mucosa.

Real-time ultrasonography is useful in determining a duodenal duplication cyst. A peristaltic wave is shown passing through the cystic structure.[91] ERCP provides accurate information about the exact location, size, and communication to the biliary and pancreatic tract, which is necessary for guiding the therapeutic endoscopic intervention.[92]

Duodenal duplication cysts cannot be differentiated from a choledochocele by endoscopy. However, the histologic features of a duodenal duplication cyst are quite distinct. These include the presence of a muscular lining with or without ectopic gastric or pancreatic tissue.[53]

In the past, these patients have been managed surgically.[91] In recent years, a few reports of endoscopic drainage have been published with symptomatic improvement.[91,92]

Biliary Tract Complications after Liver Transplant

Biliary tract complications are common after orthotopic liver transplant, occurring in 13 to 35% of individuals.[93–95] Bile leaks and anastomotic strictures are the most common complications.

Leaks can occur with both duct-to-duct anastomoses and Roux-en-Y choledochojejunostomy. These can be divided into cystic duct leaks, incidental intrahepatic injury, T-tube tract leaks, and anastomotic leaks.[93]

Endoscopic treatment for bile leaks includes biliary stent placement with sphincterotomy, biliary stent placement alone, nasobiliary tube placement with sphincterotomy, and sphincterotomy alone. Excellent results are reported (up to 100% of fistula closure) after endoscopic treatment.[94]

Anastomotic strictures or stenosis can occur after choledochocholedochostomy or Roux-en-Y choledochojejunostomy and are thought to be caused by faulty surgical technique.[94] In some patients, a transient narrowing at a duct-to-duct connection appears within the first 30 to 60 days. This type of stenosis is usually caused by postoperative edema and inflammation and responds very well to balloon dilation and temporary stent placement.[93] The second type of stricture appears later, usually after 3 months. Although the narrowing responds well to initial dilation, the response is short-lived, and the relapse is predictable.[93] Dilation can be performed with either graduated bougies or balloons. In all instances, a balloon larger than one of the limbs of the anastomosis should never be used. In practice, balloons between 4 and 8 mm are used. The use of a stent is quite important because it prevents edema or intramural hemorrhage, which can obstruct the anastomosis. Hence, a stent prevents any leakage of bile from the anastomosis in the event of a microscopic perforation or disruption.[93] Stents must be exchanged periodically (usually every 3–4 months) for long periods (until stricture resolution occurs). The response to endoscopic treatment is usually very good.[94]

Another type of stricture is the nonanastomotic stricture (donor duct). The causes of these strictures are less clear and are associated with occlusion of the hepatic artery, prolonged cold ischemia, rejection, and ABO blood group incompatibility.[94] By comparison with anastomotic strictures, the success rate for nonsurgical management of nonanastomotic strictures is low (58% in one series).[94]

Unexplained Abdominal Pain

Abdominal pain is a frequent cause of disability and the most common reason that a patient will seek consultation with a gastroenterologist. The perception of pain is purely subjective and is heavily influenced by psychosocial aspects. For the gastroenterologist, the differential diagnosis of abdominal pain is a common but challenging clinical problem.[96] Whereas the diagnosis of pancreatic or biliary disease in patients with "classic" clinical features is usually straightforward, patients with the sole symptom of abdominal pain might represent a "Pandora's box."

Many of these patients undergo a battery of tests, including ERCP.[97] However, the role of ERCP in patients with pain and absence of obvious obstructive disorders of the pancreatic and bile duct is less clear.[98]

In pediatrics, ERCP has been used in many patients with unexplained abdominal pain (see Table 67.5-1). However, the role of ERCP in these patients is disappointing. This is probably due to the fact that most children with unexplained pain are suffering from a functional disorder in which ERCP is clearly unlikely to demonstrate any organic problem. In such children, if investigation is really envisaged, MRCP may be a more appropriate test.[6,7,72,99,100]

PANCREATIC INDICATIONS

Pancreatic indications for diagnostic and therapeutic ERCP are listed in Table 67.5-3.

Acute Pancreatitis

In adults, the two most common causes of acute pancreatitis are alcohol and gallstones. Both situations are rare in children. Other causes include drugs, infectious agents, hypertriglyceridemia, trauma, biliary tract anomalies, and pancreatic ductal obstruction.[101,102]

In patients who present with the typical findings of acute pancreatitis (elevated pancreatic enzymes, abdominal pain), ERCP has no role except when the diagnosis of acute biliary pancreatitis with concomitant cholangitis is suspected (presence of fever and abnormal liver chemistries). In most noncomplicated cases, noninvasive

TABLE 67.5-3 PANCREATIC INDICATIONS FOR ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

DIAGNOSTIC
Unexplained persistent acute pancreatitis
Recurrent pancreatitis
Congenital disorders
Biliary anomalies (choledochal cyst or anomalous pancreaticobiliary union)
Pancreatic anomalies (pancreas divisum, annular pancreas, short pancreas, pancreatocele)
Duodenal anomalies (duodenal or gastric duplication cysts, duodenal diverticulum)
Cystic fibrosis
Hyperlipidemia/hypercalcemia
Acquired disorders
Parasitic infestation (*Ascaris*)
Sphincter of Oddi dysfunction
Pancreatic trauma
Medications
Chronic pancreatitis
Pancreatic mass
Preoperative evaluation
THERAPEUTIC
Pancreatic sphincterotomy
Dilation of pancreatic stricture
Stone removal
Stent placement
Pseudocyst drainage
Nasopancreatic drainage

imaging studies such as abdominal ultrasonography and CT can define the extent of the disease, diagnose and quantify necrosis, and determine whether pseudocysts are present. MRCP is also a promising test.[2]

In patients with severe biliary pancreatitis, trials comparing early ERCP versus delayed ERCP show a benefit of early intervention, at least in a subset of patients.[2,103]

Indications for ERCP in acute biliary pancreatitis should be as follows[103]:

- Before cholecystectomy: in the presence of concomitant cholangitis, obstructive jaundice, or severe disease or in patients who suffer an in-hospital exacerbation
- After cholecystectomy: in patients with unsuccessful laparoscopic or open CBD exploration or patients with smoldering disease (± sphincter dysfunction or ductal disruption)

Anecdotal reports of therapeutic ERCP in acute biliary pancreatitis in children have been published.[104] However, no consistent data exist on the role of ERCP in acute pancreatitis in children.

Recurrent Pancreatitis

Recurrent pancreatitis is characterized by episodes of acute pancreatitis, manifested by unexplained recurrent bouts of abdominal pain, with intervening asymptomatic intervals of varying duration. It is rarely recognized in children because the index of clinical suspicion is low.[105] Diagnosis is often missed for several months or years. Patients are symptomatically treated during an acute attack and discharged.

Recurrent pancreatitis can be divided into two groups, depending on whether the cause is nonobstructive or obstructive.[105] Nonobstructive causes include hereditary factors, cystic fibrosis, hyperlipidemia, trauma, medication, and hypercalcemia. Obstructive causes include choledochal cysts, pancreas divisum, duodenal diverticulum, duodenal duplication, parasitic infestation, and anomalous pancreaticobiliary junction.

MRCP is a promising, noninvasive method of identifying and ruling out structural abnormalities as a cause of acute pancreatitis in children with early-stage pancreatitis.[106] However, currently, it is ERCP that offers the definition of the CBD and pancreatic ductal system that is necessary to make decisions in the management of these children. Whatever the underlying cause of pancreatitis, the possibility that there may be an anatomic abnormality amenable to endoscopic therapy or surgery should always be considered.[102,105,107] ERCP has been found useful in the identification of treatable causes in 40 to 75% of children with recurrent pancreatitis.[5]

Endoscopic therapy in recurrent pancreatitis includes standard biliary sphincterotomy, dual sphincterotomy of the pancreatic duct sphincter and the CBD sphincter, minor papilla sphincterotomy, pancreatic stone extraction, pancreatic endoprosthesis insertion, cystogastrostomy or cystoduodenostomy (Figure 67.5-2).

Pancreas Divisum. Pancreas divisum is a congenital anomaly caused by failure of fusion of the dorsal and ventral endodermal buds during gestation. Each duct drains via its own separate orifice, the major papilla of Vater for the ventral duct of Wirsung, and the minor accessory papilla for the dorsal duct of Santorini.[108] It is the most common congenital variant of pancreatic ductal anatomy and has been found in approximately 5 to 14% of autopsy series and 0.3 to 8% of ERCP studies.[105,108,109] However, when patients with unexplained recurrent pancreatitis are studied, the incidence is 25%.[105]

The exact prevalence of pancreas divisum in children is unknown. In 272 cases of successful ERCP performed in children, pancreas divisum was found in 9 (3.3%).[108] In children with recurrent pancreatitis, the incidence ranges between 7 and 22%.[105] The clinical significance of pancreas divisum is controversial. For many authors, it is related to recurrent pancreatitis, arguing that the minor papilla could be too small to allow adequate drainage.[108,110,111] However, others have considered it to be a coincidental finding by reviewing large series of ERCP.[112]

The treatment of pancreas divisum used to be surgical (minor papilla sphincterotomy). In recent years, endoscopic therapy has been directed to decompress the dorsal duct by insertion of endoprosthesis, dilation of the minor papilla, or sphincterotomy of the minor papilla with or without stent insertion. Overall, improvement is seen in 70 to 90% of the cases.[110,113–116]

Guelrud and colleagues treated three children with pancreas divisum by ES of the minor papilla. In one, a pancreatic stent was placed for 2 weeks. Two were asymptomatic during follow-up of 10 to 17 months, and one had

recurrent episodes of abdominal pain without enzyme elevation. Similar results were seen in three other patients treated surgically in the same series.[105]

Other Congenital Anomalies. Annular pancreas, short pancreas, cystic dilation of the pancreatic duct (pancreatocele), duodenal or gastric duplication, and duodenal diverticulum have been reported to be associated with recurrent pancreatitis. ERCP might be useful in the diagnostic evaluation of these entities, especially when less invasive tests, such as CT and MRCP, are inconclusive.[106]

Anomalous Pancreaticobiliary Junction. Anomalous pancreaticobiliary junction is a congenital malformation defined as a communication of the CBD with the pancreatic duct to form a long common channel outside the duodenal wall and therefore not under the influence of the sphincter of Oddi. During an ERCP, anomalous pancreaticobiliary junction is considered to be present when the common channel measures more than 15 mm or when its extraduodenal portion is more than 6 mm long.[117,118] This anomaly has been implicated as a cause of choledochal cyst, bile duct and gallbladder carcinoma, and recurrent pancreatitis.[117]

According to the classification of Kimura and colleagues,[119] there are two types of anomalous pancreaticobiliary junction:

- Type BP: when the common bile duct appears to join the pancreatic duct
- Type PB: when the pancreatic duct appears to join the CBD

Guelrud and colleagues have proposed a third type, the "long Y," in which there is only a long common channel without CBD dilation.[118] It seems that recurrent pancreatitis is more directly associated with the PB type than the BP type.[118]

One case of balloon dilation as an alternative to surgical biliodigestive anastomosis in a child with a long common channel, choledochal cyst, and multiple biliary stenoses has been reported.[120]

Sphincter of Oddi Dysfunction. Sphincter of Oddi dysfunction is an abnormality in the contractility of this sphincter. It is a benign, noncalculous obstruction to flow of bile or pancreatic juice through the pancreaticobiliary junction. Its pathogenesis is unknown.[98,121]

Sphincter of Oddi dysfunction may be manifested clinically by pancreaticobiliary pain, pancreatitis, or cholestasis. The pain is usually epigastric or in the right upper quadrant, may be disabling, and lasts for 30 minutes to several hours. It may radiate to the back or shoulder and be accompanied by nausea and vomiting. Although typically observed in middle-aged women, it may occur in pediatric or adult patients of any age.[98] It can involve abnormalities of the biliary sphincter, pancreatic sphincter, or both. Three types of suspected biliary SOD are reported:

- Biliary type I: patients with biliary-type pain, abnormal aspartate aminotransferase or alkaline phosphatase (> 2× normal documented on two or more occasions), delayed drainage of ERCP contrast from the biliary tree (> 45 minutes), and dilated CBD (> 12 mm in diameter). The frequency of abnormal manometry ranges between 75% and 95%, and the probability of pain relief by sphincterotomy is between 90% and 95%. Although manometry may be useful in documenting sphincter of Oddi dysfunction, it is not an essential diagnostic study before endoscopic or surgical sphincter ablation.

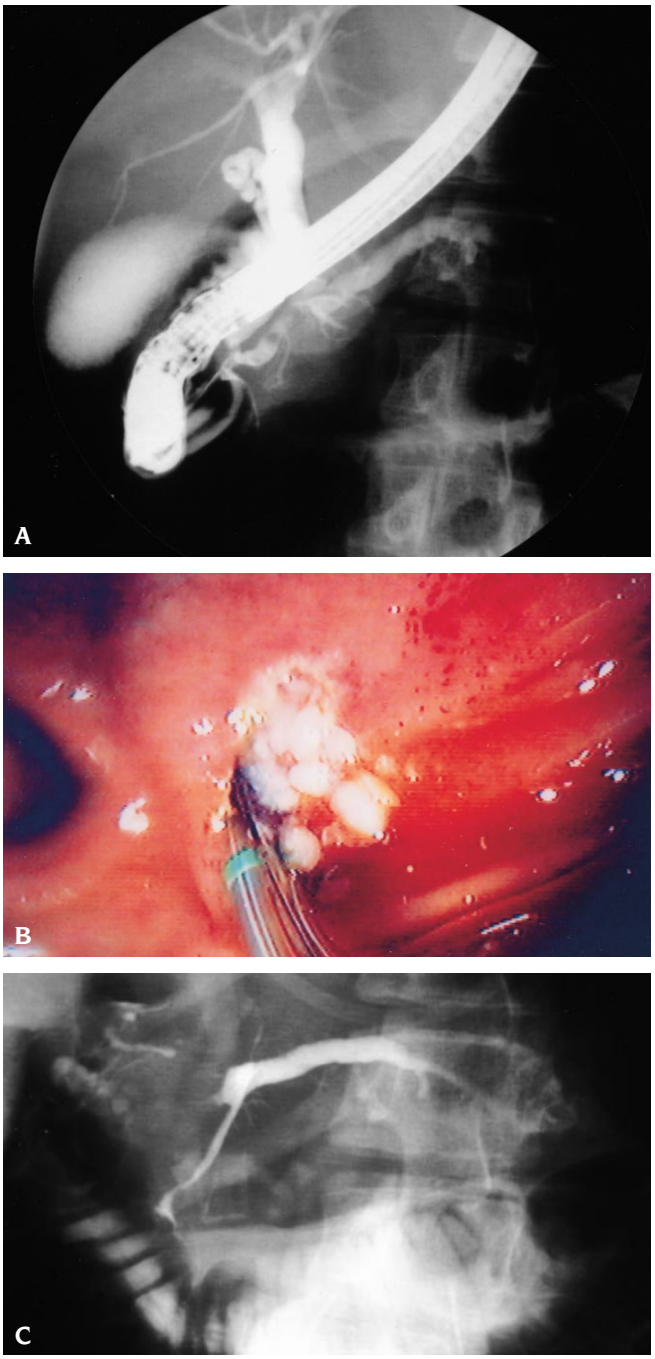

FIGURE 67.5-2 Recurrent pancreatitis. *A*, Recurrent pancreatitis in a 11-year-old girl. Endoscopic retrograde cholangiopancreatography showed a dilated main pancreatic duct with multiple filling defects owing to proteinaceous plugs. The common bile duct was also dilated. *B*, Stones were extracted after pancreatic duct sphincterotomy. *C*, Postoperative opacification showed a Wirsung duct clear of stone.

- Biliary type II: patients with biliary-type pain but only one or two of the above criteria. Manometry is abnormal in 55 to 65% of patients. If manometry is abnormal, about 85% of patients will experience pain relief by sphincterotomy. If manometry is normal, only 35% will benefit from sphincterotomy.
- Biliary Type III: patients with only biliary-type pain and no other abnormality. Manometry is abnormal in 25 to 60% of patients. If abnormal, 55 to 65% will improve with sphincterotomy. If manometry is normal, less than 10% will improve after sphincterotomy.

Manometry is the only available method to measure sphincter of Oddi motor activity directly.[98] ERCP has been used to perform sphincter of Oddi manometry in adults and children with suspected SOD. Because of the difficulties involved in performing manometry on healthy children, values obtained for adults are used as normal for children. Basal sphincter pressure is considered abnormal if it is greater than 35 mm Hg.[117] However, given that there are no normal control data in children, minimal published experience, and inherent technical difficulties with the test, no recommendation can be made regarding the clinical application or reliability of this test in children.[19]

Pediatric patients, like adults, can have pancreatitis secondary to sphincter of Oddi dysfunction. In general, they do not respond as well to endoscopic treatment, for which the complication rate tends to be higher than that for adults.[122]

Chronic Pancreatitis

Chronic pancreatitis is a chronic inflammatory condition characterized by fibrosis, destruction of exocrine tissue, and, eventually, destruction of exocrine and endocrine tissue. Both parenchymal and ductular tissue may be involved. Fibrosis may be accentuated in focal areas, causing sphincter of Oddi or main duct strictures, or it may be diffuse throughout the gland, including small ducts. Three subgroups of chronic pancreatitis are delineated[123–126]:

1. Chronic calcified pancreatitis. This is the largest subgroup, and it is characterized by sporadic parenchymal fibrosis associated with intraductal protein plugs, intraductal stones, and ductal injury.
2. Chronic obstructive pancreatitis. This results from obstruction of the main pancreatic duct and is characterized by uniform ductal dilatation and atrophy, with eventual replacement of acinar cells by fibrous tissue.
3. Chronic inflammatory pancreatitis. This subgroup is characterized by fibrosis, mononuclear cell infiltration, and atrophy. It is associated with autoimmune diseases such as Sjögren syndrome and PSC of the liver.

New etiologies for chronic pancreatitis have been recently defined: autoimmune pancreatitis, eosinophilic pancreatitis, genetic pancreatitis (mutation in the trypsinogen cationic gene responsible for familial pancreatitis, with autosomal dominant inheritance, or recessive mutations in the *SPINKI* gene [serine protease inhibitor Kazal type 1] or in the *CFTR* gene [cystic fibrosis transmembrane conductance regulator], observed with high frequencies in patients with "idiopathic" pancreatitis). Before performing invasive tests such as ERCP, searching for these entities is mandatory if the first bout of pancreatitis occurs before the age of 20 years.[127,128]

Abdominal pain is the most serious clinical problem in chronic pancreatitis and the most common indication for surgery. In an exacerbation of acute inflammation, the characteristics of pain are similar to those experienced during prior episodes of acute pancreatitis. Some patients have evidence of chronic pancreatitis, including intraductal calcification, ductal dilatation, and pseudocyst in the absence of pain.

The later stages of chronic pancreatitis are characterized by spontaneous remission of abdominal pain and the appearance of signs of full-blown insufficiency of both the exocrine and endocrine pancreas. Before the disease reaches this stage, treatment is aimed at producing stable remission of painful symptoms (that respond poorly to medical treatment), prevention of complications (cystic lesions, stenosis of the main bile duct), and halting or slowing the progression of the disease. These objectives are particularly important when the disease appears early in life because it can interfere with the psychophysical development of the child. In a growing child, suspension of oral feedings prescribed during acute attacks or refusal to eat owing to fear of pain can have effects that are much more serious than in adults.[129]

In the treatment of chronic pancreatitis, endoscopy can be proposed in certain circumstances. Endoscopic treatment is useful in treating local complications such as pancreatic pseudocysts and biliary strictures. Endotherapy is also effective in treating postsurgical complications such as pancreatic leakage after pancreaticojejunostomy. However, the main indication is to control painful chronic pancreatitis resistant to medical treatment or recurrent attacks of acute pancreatitis, which frequently appear in the course of chronic pancreatitis. This goal can be achieved by endoscopic drainage procedures in cases of outflow obstruction caused by pancreatic ductal stones, strictures of the main pancreatic duct, or a compressing pseudocyst, all resulting in upstream dilation. These drainage procedures include pancreatic sphincterotomy, stone extraction, balloon dilation of strictures, usually followed by stent insertion, and pseudocyst drainage.[130,131] Most endoscopic studies have concluded that pain diminishes in a majority of patients after endoscopic therapy, particularly in those patients with a dominant duct stricture and upstream dilation.[124,126]

Because of the experience gained in adults and a greater understanding of the mechanisms underlying the pain experienced by children, endoscopic approaches are now being used to treat pediatric patients as well.[129,132] The pain experienced by children with chronic idiopathic pancreatitis appears to be more commonly caused by the transient occlusion of the sphincter of Oddi by protein plugs. In these cases, the most effective approach to restore the flow within the duct is to reduce the resistance to the passage of these plugs by sphincterotomy.[129]

In a study involving 22 children with pancreatitis (6 acute, 6 recurrent, and 10 chronic) treated endoscopi-

cally, Hsu and colleagues observed significant improvement in all 6 outcome parameters analyzed, especially improvement in the frequency and severity of pain, a decrease in health care encounters (emergency department visit, clinic visit, and hospital admission), and improvement in general conditions.[122] In an early stage, patients without diffuse ductal changes in the pancreatogram had the most significant clinical improvement.

Pseudocysts

Pancreatic pseudocysts are nonepithelium-lined fluid collections that result from transient or persistent pancreatic duct disruption. They are common consequences of acute and chronic pancreatitis. Most of the pseudocysts resolve spontaneously. In the setting of chronic pancreatitis, symptomatic pseudocysts are commonly seen in association with pancreatic stones and strictures. Symptomatic, large (> 4 cm), or persistent (beyond 6 weeks) pseudocysts are unlikely to resolve and are at risk of complications. There has been increased interest in nonoperative management of pseudocysts.[5,19,124]

Pseudocysts that connect with the main pancreatic duct and are accessible to guidewire passage and those that abut the stomach or duodenum are addressed by transductal or transmural pseudocyst entry and stent placement.[124]

In adults, successful endoscopic treatment with pseudocyst resolution has been reported in about 80 to 90% of cases within 1 to 2 months. A 15% recurrence rate has been reported. Complication rates are approximately 20%, with a 1% mortality, indicating that this is one of the more dangerous endoscopic therapies.[5,124] Pediatric experience is limited to a few case reports and insufficient to comment on either the efficacy or safety of this procedure in children.[7,19,105,132]

Pancreatic Trauma

Injuries to the pancreas from blunt abdominal trauma in children are rare. Most are minor and are best treated conservatively. The mainstay for treatment of major ductal injuries has been prompt surgical resection.

Diagnostic imaging modalities are the key to the accurate classification of these injuries and planning appropriate treatment. CT has been the major imaging modality in blunt abdominal trauma for children, but it has shortcomings in the diagnosis of pancreatic ductal injury. MRCP is a promising test in these patients.[133]

ERCP has been shown recently to be superior to CT in the diagnosis of pancreatic trauma, allowing the possibility of stent placement (Figure 67.5-3).[134] In reported pediatric cases, clinical improvement is rapid, with complete resolution of clinical and biochemical pancreatitis, resumption of a normal diet, and discharge from hospital.[135]

CONTRAINDICATIONS

Contraindications to ERCP include unstable cardiovascular, pulmonary, or neurologic conditions or suspected bowel perforation. Esophageal stricture is a relative contraindication. Coagulopathies should be corrected before ERCP whenever possible, especially if a therapeutic procedure is envisaged. Aspirin, nonsteroidal anti-inflammatory drugs, and medications that interfere with platelet function should be avoided before and immediately after the procedure.[19]

COMPLICATIONS

ERCP has evolved from a diagnostic test into a primarily therapeutic procedure for a variety of biliary and pancreatic disorders. Many short-term complications are associated with the examination, mainly pancreatitis, hemorrhage, perforation, cholangitis, and cholecystitis, and are related to the anesthesia. Short-term complications are reported to occur after 5 to 10% of ERCPs with or without sphincterotomy (see Table 67.5-1).[136,137]

In children, the major risks and complications of ERCP are the same as in adults. The relative risk for these complications in children is not well established because of the small number of patients in pediatric series.[19]

In a large pediatric ERCP series, the overall complication rate was 11.6%. Pancreatitis occurred in 3.3% (see Table 67.5-1).[7] Hemorrhage and perforation have rarely been reported after ERCP in children.[28,72,138] Rates are likely to be similar to those reported in adults: 0.7 to 2% for hemorrhage and 0.3 to 0.6% for perforation.[139,140] In Guelrud's experience with 184 neonates and young infants, minor complication without clinical significance occurred in 24 (13%) patients. In 220 ERCPs in children older than 1 year, this author observed 1.8% of complications in diagnostic examinations and 10.7% in therapeutic ERCPs.[5]

The long-term complications of ES or use of stents in pediatric patients are unknown.[19]

COMPETENCE IN PEDIATRIC ERCP

Endoscopic competence is difficult to define and almost impossible to quantitate. Strictly defined, "competence" is the ability to carry out a set of tasks or a role adequately or effectively.[141] Competency in diagnostic and therapeutic endoscopy implies a demonstration of appropriate clinical judgment in patient selection and adequate cognitive and technical skills to complete a procedure safely and successfully. Deep knowledge of appropriate indications and contraindications, potential risks, and benefits is also mandatory. The endoscopist must be prepared to manage or to enlist the help of others to manage complications or adverse outcomes expeditiously in an appropriate medical facility.[142]

According to the ASGE, endoscopic competence includes objectives that trained endoscopists will be able to[143]

- Recommend endoscopic procedures based on findings of a personal consultation and in consideration of specific indications, contraindications, and diagnostic or therapeutic alternatives
- Perform specific procedures safely, completely, and expeditiously
- Correctly interpret most endoscopic findings and undertake endoscopic interventions when indicated

- Integrate endoscopic findings or therapy into patient management plans
- Understand risk factors and recognize and manage complications
- Recognize personal and procedural limits and know when to request help

Competency in pediatric endoscopy requires a specialized knowledge of gastrointestinal diseases affecting children. Such knowledge is conventionally gained through formal training in pediatric gastroenterology. However, other physicians experienced in the care of children or adults with gastrointestinal disease may

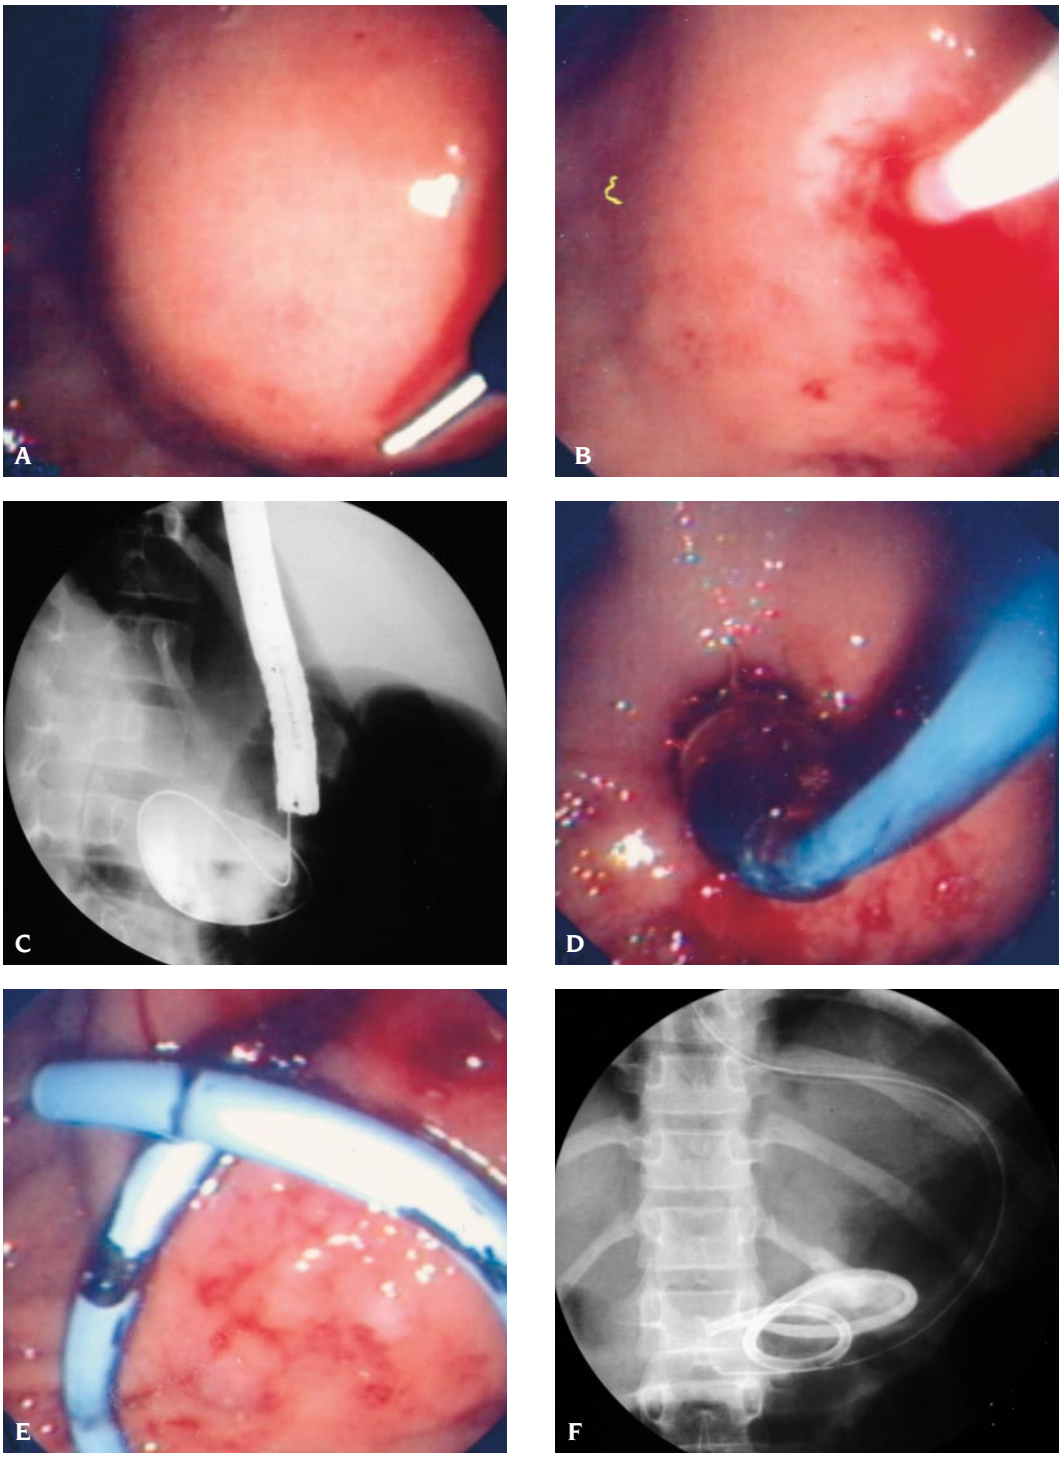

FIGURE 67.5-3 Pancreatic trauma. *A*, Traumatic pseudocyst with obvious bulging into the gastric lumen. *B*, Diathermic needle puncture of the gastric wall toward the cyst's center. *C*, Opacification of the cystic cavity and guidewire placement. *D*, Balloon dilation of the cystic opening. *E*, Insertion of a pigtail stent to maintain the patency of the cystogastrostomy. *F*, Pigtail stent allowing communication between the cystic cavity and the stomach.

acquire suitable cognitive skills to achieve competence in pediatric endoscopy.[142]

CONCLUSIONS

ERCP is a safe and valuable diagnostic and therapeutic procedure in children with presumptive pancreaticobiliary disease. Considerable experience with this endoscopic procedure is a prerequisite before undertaking cannulation in this young age group. It is anticipated that ERCP and its associated endoscopic therapy will find increasing use in the pediatric population, not only for diagnosis and preoperative delineation of the pancreaticobiliary tract but, in many instances, as a substitute for traditional operative therapy.[144] The performance of endoscopy in children assumes an adequate knowledge and understanding of pediatrics. To provide appropriate care for each child, a team approach is often required, including the pediatrician or pediatric gastroenterologist, the surgeon, and the adult endoscopist.[7,12,76]

CHAPTER 68

LIVER BIOPSY INTERPRETATION

A. S. Knisely, MD

Diagnosis in a liver biopsy specimen resembles diagnosis in a patient. The specimen, or the patient, is interrogated using a standard set of questions, or histochemical techniques. An inventory is made of the findings, or the responses, that differ from expected norms. Both the histopathologist and the clinician conclude their data-taking with a synthesis, an attempt to identify a diagnosis that accounts for any abnormalities recognized. Both the clinician and the histopathologist continue their inquiries when they believe that a better diagnosis is yet to be achieved.

Two points are particularly important in interpreting liver biopsy findings. First, the histopathologist must not work in isolation. Help from clinical colleagues is essential if the histopathologist is best to serve the patient. Second, the histopathologist must not lose information. For that as well, teamwork is essential.

This chapter outlines how to ensure, between the clinician and the histopathologist, that information is not lost as a liver biopsy specimen is obtained and processed. It lists a set of studies likely to permit a first-line diagnosis, while permitting referral, if necessary, of biopsy material in consultation, and gives examples of how each study can prove useful. The question of when biopsy is in order is raised. The chapter ends by discussing several clinical settings frequently encountered in pediatric patients in which biopsy may prove useful, as well as what biopsy may find. It does not pretend, however, to match the comprehensive accounts of liver biopsy interpretation[1] and the pathology of the liver[2] available elsewhere, to which the reader is referred.

MATTERS TO BE SETTLED BEFORE THE BIOPSY PROCEDURE

Much more can now be won from a sample of liver tissue than only morphologic data. For many, even most, purposes, formalin fixation is adequate. But genetic or proteomic information specific to the liver, such as how genomic deoxyribonucleic acid (DNA) is processed into messenger ribonucleic acid (RNA) and beyond, is lost when liver is not snap-frozen immediately on biopsy.

Formalin-fixed liver can be used only for routine microscopy and for a limited range of immunohistochemical and in situ hybridization studies. Snap-frozen liver can be used for quantitative analysis of constituents, microbiologic evaluation, molecular diagnosis, transmission electron microscopy (after thawing in proper fixative), or specialized immunohistochemical studies. It can also be used for all of the studies possible with routinely formalin-fixed liver (again, after thawing in proper fixative). A 2 cm core biopsy specimen provides ample tissue for routine processing and for freezing.

In all but rare settings, liver biopsy is an elective procedure. Referral units that specialize in liver disease routinely ensure that a Dewar flask of liquid nitrogen is brought to the bedside, the ultrasonography suite, or the operating room to receive and to snap-freeze a sample of liver as soon as it is obtained. The tissue can be placed in an embedding compound within a mold, placed inside a vial or capsule, or (perhaps giving easiest access) laid on a labeled piece of aluminum foil, which is then folded to yield a packet. For reasons presented above, immediate snap-freezing of liver tissue must be regarded as the standard of optimal care.

Pediatric gastroenterology and hepatology services have recently extended outside predominantly academic hospitals as specialty trainees take up careers in the wider community. Appropriate support from histopathology services (snap-freezing; storage and shipment at –80°C) should be in place before pediatric liver biopsy is undertaken. If liver biopsy is contemplated where snap-freezing is not available, the possible need for rebiopsy, with attendant risk, must be balanced against any inconvenience of patient transfer to a venue where liver biopsy tissue can be correctly preserved.

HANDLING THE BIOPSY CORE

A biopsy specimen intended for routine histopathologic study should be immersed in formalin as soon as it is obtained. Contact with saline solution or wicking away of fluids into a towel or gauze produces a variety of artifacts and alters immunohistochemical reactivity. Tissue should be processed in mesh cassettes rather than on biopsy sponges, which distort anatomic relationships.

Biopsy specimens often are presented to the histopathologist as “ribbons,” with large numbers of sections closely packed on a single slide. Liver biopsy specimens should be handled differently, with a ribbon divided into individual, serial sections, each mounted on the proper sequentially numbered slide. Even after trimming the block, 12 pairs of such sections at 4 μ or 5 μ extend only some 200 μ into the biopsy core (1,000 μ thick

before fixation and dehydration), conserving tissue against future work. At the Institute of Liver Studies, our practice is that alternate pairs are held on slides as unstained sections, early and late pairs are stained with hematoxylin and eosin (HE), and pairs in the bracketed interval are stained with diastase and periodic acid–Schiff (DPAS) technique, for iron, with orcein, and for reticulin. Abnormalities can be tracked through the core; lesions such as granulomata can be further evaluated where they occur, and with unstained sections on hand, a delay in additional studies is minimal.

Regulators in different venues require retention of glass slides and tissue blocks for different times. The pediatric gastroenterologist or hepatologist working in a facility with care of adults as its primary concern may wish to ensure that pediatric materials are held longer than the minimum time prescribed or even indefinitely.

THE NORMAL LIVER: A REFRESHER

Blood enters the liver at its hilum, through the portal vein and hepatic artery. It passes from portal tracts (Figure 68-1A) along the sinusoids within the lobule into centrilobular venules (Figure 68-1B) and leaves the liver for the inferior vena cava via the hepatic veins. The line of junction and demarcation between portal tract and lobule is known as the limiting plate. Hepatocytes extract various substances from the plasma that bathes their sides and bases. They return others to it; blood passing over hepatocytes is sequentially modified from the portal tract to the centrilobular venule.

Hepatocytes are disposed between sinusoids in cords one cell thick. Their dimensions are similar throughout the lobule. Although they exhibit zonal differences in function, on light microscopy they tend to look alike. They are

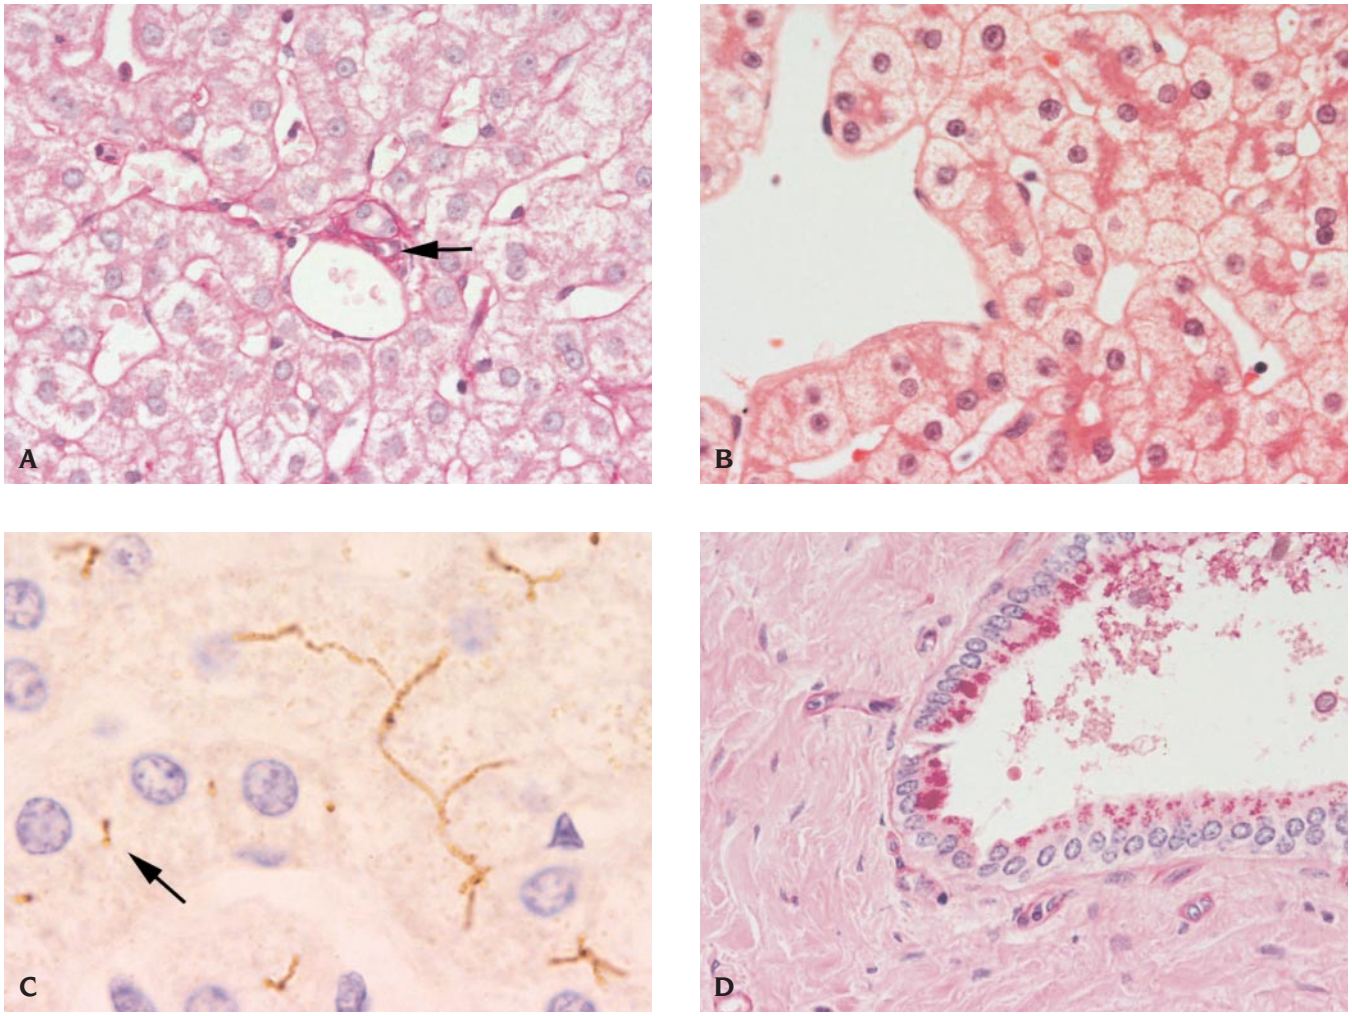

FIGURE 68-1 *A*, An interlobular portal tract, with a large, thin-walled portal venule containing a few erythrocytes; a bile duct circumscribed by basement membrane and lined by cholangiocytes (two nuclei are visible); and a small, thick-walled arteriole (*arrow*). Normal liver. Diastase and periodic acid–Schiff technique with hematoxylin counterstain (DPAS); ×400 original magnification. *B*, A centrilobular venule, with sinusoids and hepatocyte cords of the adjacent lobule. Some of the cords are two cells thick. Lysosomes, whose contents tend to mark with eosin, are clustered at the hepatocytes' canalicular poles. Normal liver (hematoxylin and eosin; ×400 original magnification). *C*, Canaliculi in transverse (*arrow*) and longitudinal section. A hepatocyte may contribute to several canaliculi, as shown. Normal liver. Hematoxylin and antibody against canalicular multispecific organic anion transporter (immunoperoxidase technique); ×1,000 original magnification. *D*, Droplets of mucin are found within columnar cholangiocytes of a septal bile duct, and scant mucus is seen in the ductal lumen. Normal liver (DPAS; ×400 original magnification).

cuboidal or polygonal and uniform in size. They have one or two nuclei, which are generally round in profile and may contain a chromocenter. Hepatocytes may be euploid or polyploid. Their cytoplasm is finely granular and uniform, although pigment may be seen at the aspect most remote from the sinusoid, the canalicular pole.

Portions of two or three hepatocytes may meet at the canaliculus, which is separated by tight junctions from the basolateral aspects of the hepatocytes that form it (Figure 68-1C). An individual hepatocyte participates in forming several canaliculi. Hepatocytes secrete various substances across the canalicular membrane into the bile. This travels from canaliculi into interlobular bile ducts, then into trabecular or septal bile ducts, and finally into segmental or lobar ducts, moving into the hilum in the direction opposite to that taken by the blood. The cholangiocytes of interlobular bile ducts are cuboidal and serous (see Figure 68-1A). Those of larger bile ducts are columnar and mucinous (Figure 68-1D). Large ducts toward the hilum also gradually acquire a mural secretory gland apparatus. Bile passing down canaliculi and ducts is sequentially modified in its transit, and bile at its exit from the liver is a very different fluid from bile within the canaliculus.

Endothelial cells with one set of characteristics line vessels within portal tracts and centrilobular venules. Those that line the sinusoids have different characteristics; they are discontinuous or fenestrated, allowing hepatocytes direct access to plasma. Within the sinusoids are the macrophages known as Kupffer cells. Nerves accompany vessels into the hilum; they enter the lobule in the space of Disse, which lies between sinusoidal basement membrane and hepatocellular basolateral membrane. This space also contains stellate cells, which are contractile and fibrogenic and which store vitamin A. Small numbers of leukocytes, principally small lymphocytes and macrophages, are normally found in portal tracts.

Liver biopsy relies on the axiom that parenchymal disease uniformly involves lobules throughout the liver. This is not true, but as an approximation, it is true enough to be useful. One should bear in mind, however, that neither percutaneous nor transvenous liver biopsy will routinely sample central or hilar structures. Processes that affect them must be studied by specifically directed biopsy.

WHAT ROUTINELY STAINED SECTIONS WILL AND WILL NOT SHOW

Nucleic Acids and Proteins within Nucleus and Cytoplasm: HE

The purple-blue dye, hematoxylin, binds with electronegative substances (ie, nucleic acids or carbonates and phosphates found in mineralized tissues). It marks the DNA of nuclei and the RNA of rough endoplasmic reticulum. The orange-red dye, eosin, binds with electropositive substances (proteins). It marks much of the cytoplasm of most cells, as well as the bulk of interstitial or intercellular material. Shifts in degrees of eosinophilia or hematoxylinophilia signal various metabolic changes (eg, the move from purple-red to orange-red, associated with loss of RNA, that indicates both maturation in erythrocytes and cell death in hepatocytes). HE-stained sections are the mainstay of histopathologic diagnosis.

Glycosylated Substances: DPAS

Diastase digestion removes complex sugars from tissue sections; glycoproteins remain. The aldehyde moieties in these, after oxidation with periodic acid, take up the fuchsin chromophore in Schiff reagent and become magenta. Proteins not coupled with sugars are marked only very palely. DPAS-stained sections, with a hematoxylin (nuclear) counterstain, demonstrate cell outlines and basement membranes excellently. These stand out all the more because the hemoglobin of erythrocytes, which sometimes can obscure tissue details, effectively does not mark. Collections of glycoprotein within cytoplasm (mucin [see Figure 68-1D], the phagocytosed material within Kupffer cells, secondary lysosomes in hepatocytes, and some, but not all, materials accumulated in storage disorders [Figure 68-2A]) also stand out. DPAS staining is valuable in identifying residua of some structures; basement membranes of bile ducts can persist after cholangiocytes are gone. It also permits screening for fungal forms, whose cell walls take the stain.

Iron: Prussian Blue Reaction

Acid pretreatment converts iron complexed as ferritin (or, after partial digestion within lysosomes, as hemosiderin) to its ferric form, which reacts with potassium ferrocyanide to yield bright, crisp Prussian blue. A counterstain such as nuclear fast red is often used to make it easier to identify where in the tissue stainable iron lies (Figure 68-2B). To demonstrate iron may have prognostic implications, as in hepatitis C virus infection, or permit diagnosis of a metabolic disorder, as in hemochromatosis. Because hepatocytes and Kupffer cells or macrophages may contain granular brown material other than hemosiderin (Dubin-Johnson pigment, lipofuscin, malarial pigment), to demonstrate that particular deposits do not contain iron also can be useful.

Materials Rich in Sulfhydryls: Orcein

The purple-black dyestuff, orcein, originally extracted from lichen, complexes with sulfhydryl groups. These abound in elastin (Figure 68-3A), in the surface antigen of hepatitis B virus (Figure 68-3, B and C), and in metallothioneins (see Figure 68-3A). Synthesis of metallothioneins is induced by cytosolic accumulation of several transition metals; the most clinically important is copper. Subclinical cholestasis, without hyperbilirubinemia, is associated with impaired excretion of copper into bile. Metallothioneins bind copper and sequester it within the cytosol. Over time, they accumulate in partly degenerated form in secondary lysosomes—"cuprisomes."[3] These are particularly prominent in periportal hepatocytes. Orcein staining highlights vessels by picking out elastic tissue within their walls. It shows (when elastic tissue is present) that a scar has matured.[4] By demonstrating copper-associated protein,

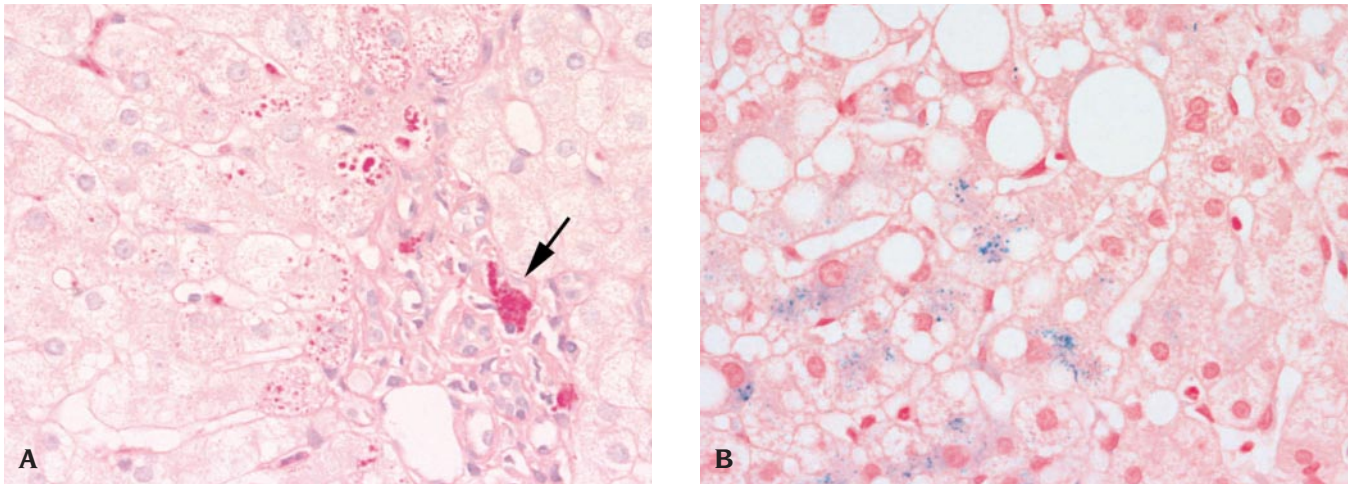

FIGURE 68-2 *A*, Granules and globules of the glycoprotein α_1-antitrypsin have accumulated within cytoplasm of periportal hepatocytes. Portal tract macrophages (*arrow*) contain lipofuscin pigment; the two substances stain alike. α_1-Antitrypsin storage disorder (diastase and periodic acid–Schiff; ×400 original magnification). *B*, Finely granular dark reaction product marks hemosiderin, principally within lysosomes (note a tendency toward pericanalicular accumulation). The large and small optically clear vacuoles represent the lacunae left after elution of neutral lipid during specimen processing (Perls' Prussian blue and nuclear fast red technique; ×400 original magnification).

orcein staining can support an impression, garnered from HE-stained sections, that a cholangiopathy is present even when bilirubinostasis is not apparent, or that cholestasis is likely of long standing.

Type III Collagen: Reticulin

Abnormalities in the architecture of the liver, including the sometimes subtle changes of shrinkage or swelling of hepatocytes associated with perturbed vascular supply, are easily assessed in sections stained for basement membrane collagen ("reticulin," in which collagen type III predominates[5,6]) using a silver impregnation technique. Parenchymal loss with stromal collapse is marked by apposition of reticulin fibers (Figure 68-4A). Hyperplasia of hepatocytes (broadened hepatocyte cords that are two cells rather than one cell thick) is marked by splaying apart of reticulin fibers (Figure 68-4B). Hepatocellular malignancy is marked by a deficiency of reticulin fibers. The fibrosis owing to inflammation or injury is generally accompanied by an increase in reticulin within the fibrous tissue. Assessment of the extent of fibrosis is an important aspect of biopsy diagnosis.

Substances Lost in Processing

The formaldehyde in formalin (an aqueous solution of formaldehyde) stabilizes tissues, as a fixative, by cross-linking them. Formaldehyde cross-links proteins and nucleic acids more efficiently than it cross-links neutral lipids or simple sugars. As a liver biopsy specimen moves from formalin through alcohol into xylene and on to paraffin, the tissue is brought into contact with polar and nonpolar solvents. Most stains are applied in aqueous solution, so to permit staining, sections mounted on slides are again passed through xylene and then through alcohol into water. Once sections are stained, because coverslips are secured with adhesives dissolved in nonpolar media, the sections are exposed to alcohol and then again to xylene. Water, alcohol, and xylene leach many small molecules, such as sugars or bilirubin, and neutral lipid from the tissue (see Figures 68-2B and 68-5, A and B). These then cannot be stained, and statements that they ever were present rely on inference.

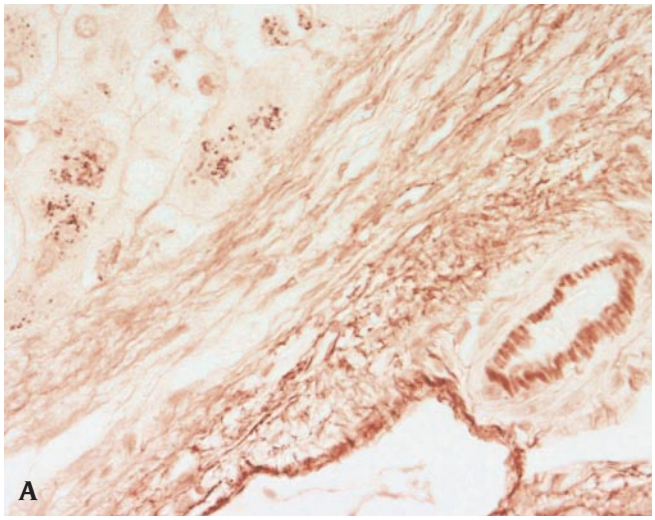
If such substances must be specifically demonstrated, fixation in absolute alcohol or other selected substances rather than in formalin can lessen tissue exposure to polar solvents and can partly conserve small molecules through subsequent handling. Postfixation in osmium tetroxide (osmication) after initial exposure to formalin can cross-link and stabilize neutral lipid against elution, permitting routine processing into paraffin thereafter. Osmication affords histologic detail superior to that available in sections of frozen tissue (from which lipid is not lost) that are stained with oil red O or Sudan black.

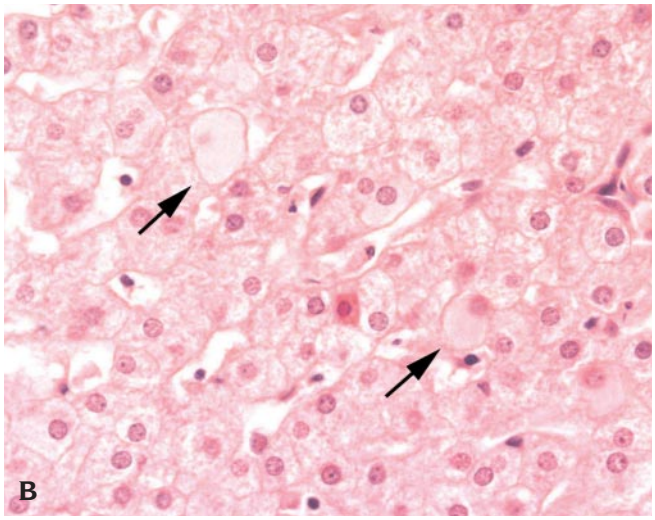
PITFALLS OF ONTOGENY

Postnatal patterns of hepatocellular and bile duct growth in prematurely born infants may differ from those in infants born at term.[7] Standards for the former are not well defined. Caution in interpreting biopsy findings is in order.

The liver is the principal site of fetal hematopoiesis, which can persist into the first postnatal weeks. Foci of erythropoiesis in the lobule and of granulopoiesis in portal tracts should not be confused with inflammation in biopsy specimens from neonates.

Copper-associated protein is normally present in the first several tiers of periportal hepatocytes of infants born at term; it may persist for several weeks or months. The same is true for hemosiderin, which may extend into midzonal or even centrilobular hepatocytes. To see either, which would mark disease in older children, can be disregarded in early infancy.





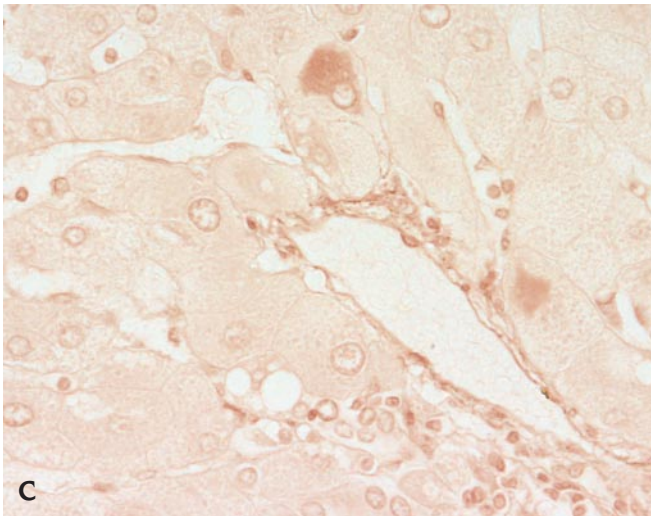


FIGURE 68-3 *A*, Granular dark material, upper left, within hepatocytes represents copper-associated protein. The corrugated, dense elastic lamina of a portal tract artery and individual elastic fibrils within looser portal tract connective tissue also mark. Familial intrahepatic cholestasis 1 at hepatectomy (orcein; ×400 original magnification). *B*, Most hepatocytes have finely granular, eosinophilic cytoplasm; that of several hepatocytes is uniformly pale (*arrows*), resembling frosted glass. A shrunken, densely eosinophilic hepatocyte at the center is undergoing cell death. Chronic hepatitis B virus infection (hematoxylin and eosin; ×400 original magnification). *C*, The cytoplasm of "ground-glass" hepatocytes like those in *B* marks when the change is due to accumulation of hepatitis B surface antigen. Chronic hepatitis B virus infection (orcein; ×400 original magnification).

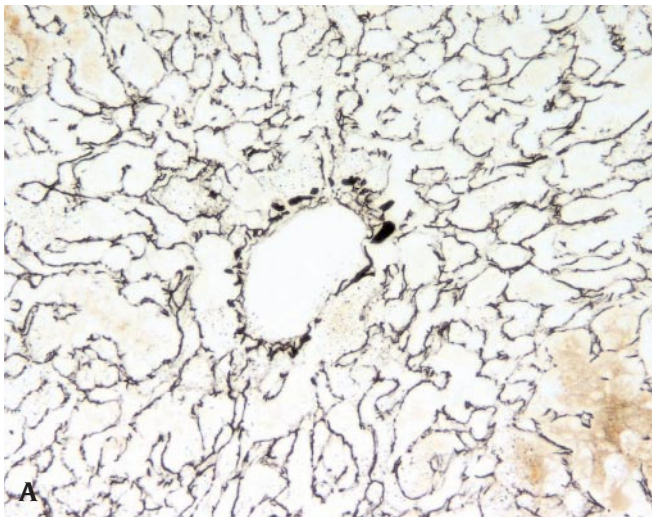

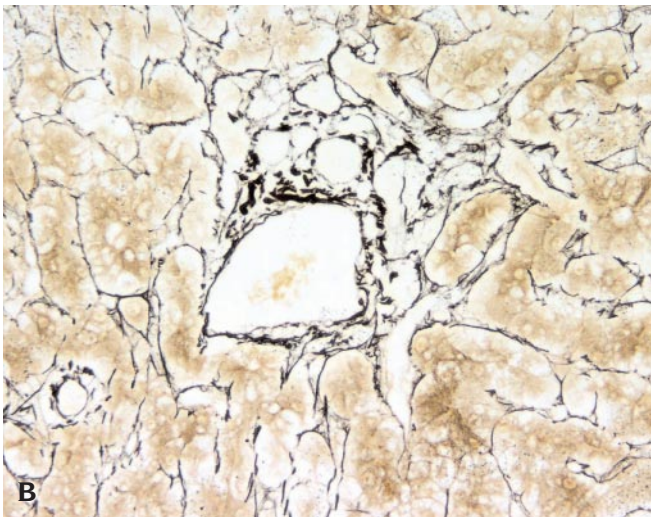

FIGURE 68-4 *A*, Silver impregnation marks reticulin fibers brown-black and defines sinusoidal margins at junctions with hepatocyte cords. They are relatively closely apposed around this centrilobular venule (reticulin; ×400 original magnification). *B*, Same patient as in *A*; acetaminophen (paracetamol) overdose with zonal hepatocyte loss. Hepatocyte cords are wider, and reticulin fibers lie farther apart, in this periportal zone than in centrilobular liver (compare with *A*). Loss of hepatocytes (*A*) and regenerative hyperplasia of hepatocytes (*B*) underlie the differences (reticulin; ×400 original magnification).

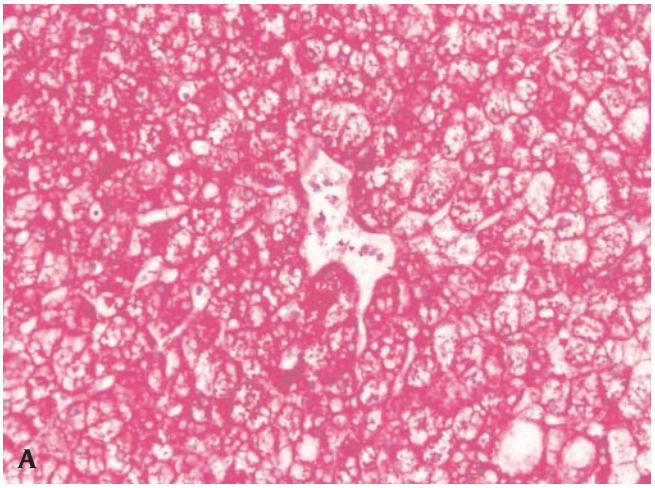

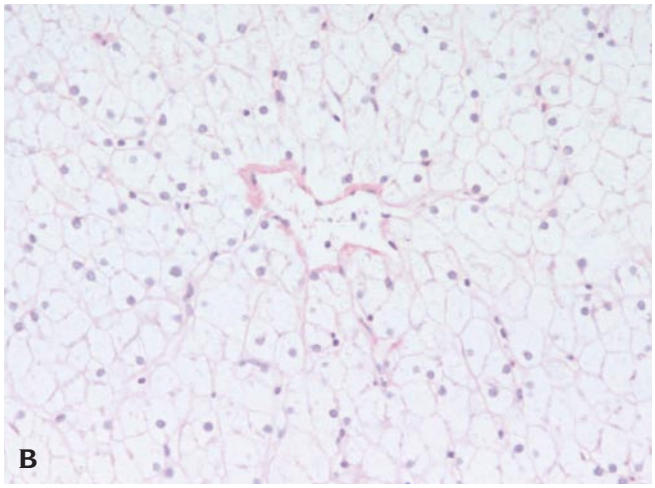

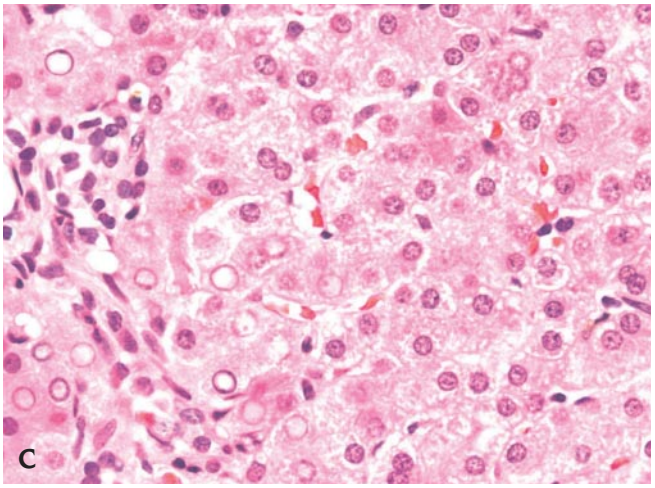

FIGURE 68-5 *A*, Accumulated glycogen within hepatocyte cytoplasm can be demonstrated histochemically. Glycogen storage disease, type I (periodic acid–Schiff technique with hematoxylin counterstain; ×200 original magnification). *B*, Diastase pretreatment of sections eliminates glycogen and, with it, histochemical reactivity (same patient as in *A*). Hepatocellular enlargement is apparent. Glycogen storage disease, type I (diastase and periodic acid–Schiff; ×200 original magnification). *C*, No particular significance inheres in slight enlargement of nuclei, with displacement of chromatin to the periphery by accumulated glycogen, as seen here in periportal hepatocytes (hematoxylin and eosin; ×400 original magnification).

Hepatocyte cords are normally two cells broad in the first several years of childhood. Only at age 4 or 5 years and thereafter should this finding be considered pathologic. In adults, optically clear nuclei in which glycogen has displaced chromatin may signal diabetes. They occur in children without metabolic abnormality (Figure 68-5C).

WHEN IS LIVER BIOPSY IN ORDER?

Leaving aside masses within the liver, most of which continue to require direct examination of tissue for definitive diagnosis, advances in microbiology, clinical biochemistry, clinical immunology, imaging studies, and molecular genetics have made the morphologic study of the liver less and less necessary. This is as it should be; liver biopsy is invasive and carries a small but real risk to the patient.

Specialized metabolic or molecular analysis techniques may be accessible, however, at several centers worldwide at most, with no guarantee that clinically useful results ever will be supplied. Even routinely conducted assays may be seldom done, with uncomfortable delays in receiving results. The techniques used in biopsy diagnosis, in contrast, are very widely employed, with (possibly nondefinitive) results available in only a few hours. Historical experience with evaluation of disease in liver biopsy materials also is extensive.

In addition, even if noninvasive studies strongly suggest a particular diagnosis, how badly a particular disease has damaged the liver often can be determined only at biopsy. This information can be useful in assessing prognosis or, with follow-up biopsy, in evaluating response to therapy.

Biopsy is thus generally used at present to aid in selecting among a small number of likely diagnoses and to guide further work, to corroborate a provisional diagnosis already arrived at on clinical grounds, and to determine the extent of the disease or, over time, the progress of the disease. Satisfactory interpretation often depends on understanding what questions a particular biopsy is hoped to answer.

FREQUENTLY ENCOUNTERED CLINICAL SETTINGS

Conjugated Hyperbilirubinemia in Infancy

Inflammation of the extrahepatic biliary tract with perinatal onset may lead to fibrosis that occludes or obliterates the lumen of the common bile duct (extrahepatic biliary atresia [EHBA]). This process may involve the gallbladder. EHBA is manifest as conjugated hyperbilirubinemia with elevated serum concentrations of γ-glutamyl transpeptidase (GGT) activity (high-GGT cholestasis). EHBA can be palliated by hepatic portoenterostomy. The results of such

surgery are better the earlier it is performed. When imaging study results (failure to identify a normal gallbladder on ultrasonography; in some centers, failure to opacify the biliary tract on percutaneous or endoscopic cholangiography) are ambiguous, the histopathologist thus may be asked to identify changes in the liver that suggest distal biliary tract obstruction.

These changes include edema of portal tracts, fibrosis of portal tracts, an increase in the number of bile duct profiles seen, and the presence of bile plugs in the lumina of principal bile ducts, that is, of bile ducts within portal tracts rather than of recruited ductules at portal tract margins (Figure 68-6). The cholangiocytes of bile duct epithelium are irregularly arrayed, and intraepithelial leukocytes may be found, but this is the nonspecific case in any cholangiopathy. Granulocytes may be seen in portal tracts, but this also is nonspecific and may reflect not inflammation but the postnatal persistence of hematopoiesis. The lobular changes of "neonatal hepatitis" (edema of hepatocytes, with giant cell change and intrahepatocytic bile pigment; rosetting of hepatocytes around dilated canalicular lumina that contain bile plugs; necrosis of occasional hepatocytes; and clusters of hematopoietic elements, usually erythroid [Figure 68-7, A and B]) may be minimal or quite pronounced. Their extent cannot be used definitively to exclude EHBA: florid "neonatal hepatitis" and EHBA may coexist.[8]

High-GGT cholestasis can reflect, beside EHBA, syndromic and nonsyndromic paucity of interlobular bile ducts (PIB); α_1-antitrypsin (A1AT) storage disorder (A1ATSD); neonatal sclerosing cholangitis (NSC); mutation in *ABCB4*, which encodes multiple drug resistance 3 (MDR3), a "flippase" that shifts phospholipid from inner leaflet to outer leaflet of the canalicular membrane (MDR3 disease)[9]; and a long list of rarer entities, as well as infective disorders or defects in intermediary metabolism. These infective disorders or defects in intermediary metabolism are generally identified by microbiologic studies, serologic work, or screening of urine and serum for unusual substances. High-GGT cholestasis also can accompany the nonspecific and highly unsatisfactory diagnosis of "neonatal hepatitis" (see above). Intralobular cholestasis and steatosis tend to mark defects of intermediary metabolism, and the latter is not a feature of EHBA. "Neonatal hepatitis" lacks the portal tract changes of EHBA (see Figure 68-7B).

PIB, A1ATSD, NSC, and MDR3 disease may pass through a phase of bile duct proliferation, with evident injury to cholangiocytes. Features that reliably permit the diagnosis of NSC on histopathologic examination have not yet been identified. NSC must be considered a diagnosis made on cholangiography.[10] MDR3 disease also has no well-defined, specific histopathologic features. To demonstrate a lack of phospholipid in bile, or to identify mutation in *ABCB4*, is necessary for diagnosis.[9]

In only A1ATSD, however, do the degree of portal tract edema and the extent of bile duct proliferation, with bile plugging, sometimes mimic those found in EHBA. Fine granules of A1AT that mark in DPAS-stained sections may be seen in periportal hepatocytes of infants several months old. In infants approximately 6 to 10 weeks old, when the urgency in diagnosing features of distal biliary tract obstruction is greatest, bile pigment and secondary lysosomes, which physiologically contain hemosiderin and metallothioneins, are easily confused on DPAS staining with the minimal quantities of stored A1AT that may be present at that age in A1ATSD. An inconstant but useful feature of A1ATSD is steatosis of periportal hepatocytes.[11] Its presence can shift EHBA down the differential diagnosis rank table.

Issues of definition tend to confound discussions of PIB. The criteria for assigning the diagnosis depend classically on finding fewer than five bile duct profiles in six interlobular portal tracts.[12,13] These criteria, however, were

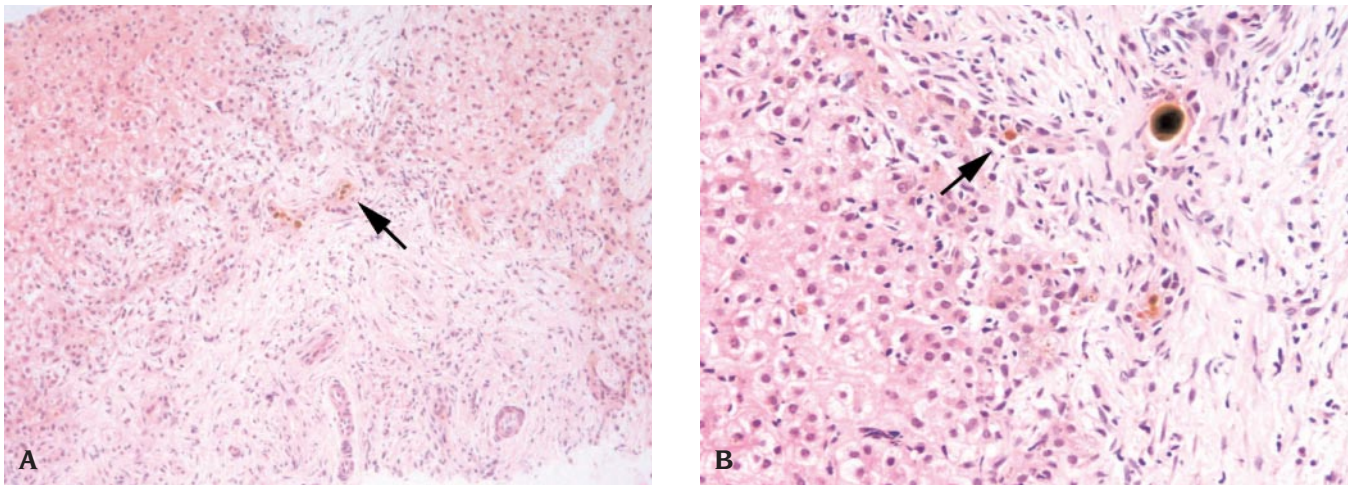

FIGURE 68-6 *A*, In distal biliary tract obstruction, a portal tract is expanded by loose, pale fibrous tissue, suggesting edema. Bile plugs are present in centrally located duct lumina (*arrow*). Extrahepatic biliary atresia (EHBA); biopsy at presentation (hematoxylin and eosin (HE); ×100 original magnification). *B*, Hepatocytes at the limiting plate have adopted a cholangiolar phenotype (the ductular reaction), and bile plugs are seen both in principal bile ducts and a newly recruited ductule (*arrow*). Hepatocyte disarray is generally slight in distal biliary tract obstruction, as seen here, but brisk giant cell change and necrosis also may be found. EHBA; biopsy at presentation (HE; ×200 original magnification).

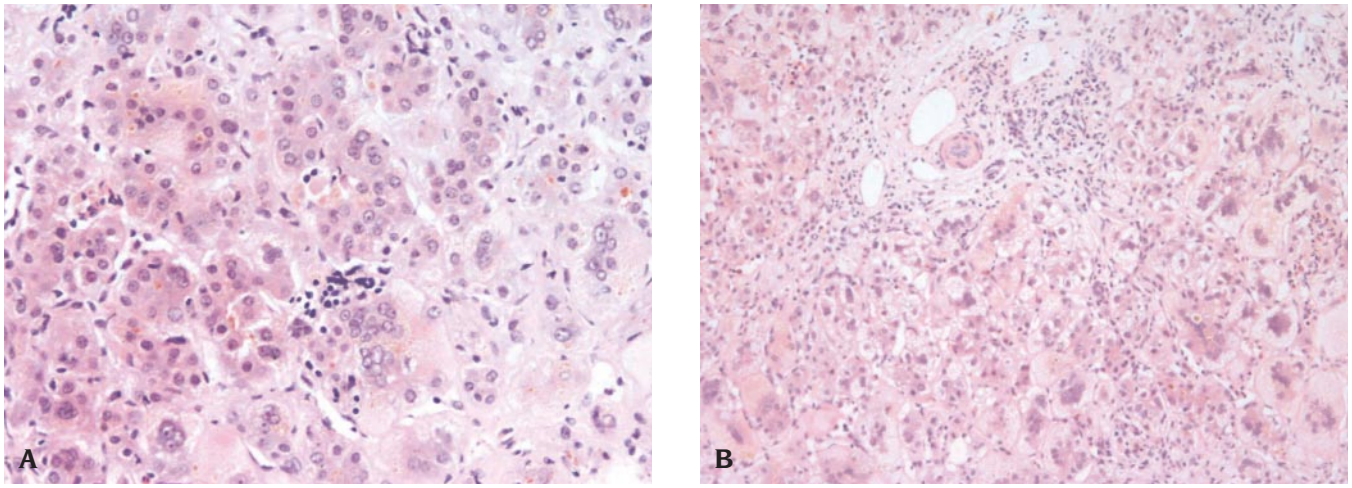

FIGURE 68-7 *A*, Typical "neonatal hepatitis" includes giant cell change and edema, with bile pigment in hepatocytes and canaliculi, as well as lobular hematopoiesis (*arrow*). Compare with *B*, in which such changes are lacking. Biopsy at presentation. Hematoxylin and eosin [HE]; ×200 original magnification. *B*, Portal tracts in usual "neonatal hepatitis" are compact, with, at most, slight ductular reaction. Cholestasis is restricted to the lobule. Compare with *A*, in which the portal tract is expanded and contains bile plugs. Biopsy at presentation (HE; ×100 original magnification).

set before the development of immunohistochemical techniques for marking bile ducts, so that strict use requires examination of HE- or DPAS-stained sections only. Finding six interlobular portal tracts seen in full cross-section can itself be difficult in slender, short needle biopsy specimens of liver. Inflammation or hematopoiesis that blurs structural detail makes identifying bile ducts harder. Personal experience suggests that immunostaining for bile duct cytokeratins often picks out bile ducts that cannot be discerned in routinely stained sections (Figure 68-8A).

Bile ducts identifiable only on immunostaining, however, generally are threadlike, with as few as one or two cholangiocytes seen (Figure 68-8B). They appear hypoplastic—a hypoplasia to be distinguished from hypoplasia of the intrahepatic biliary tree, as PIB is sometimes termed. This appearance is frequent in the setting of intralobular cholestasis, perhaps because stimuli to normal development are lacking when hepatocellular bile secretion lags. But hypoplasia of a bile duct is distinct from absence of a bile duct; hypoplastic ducts may grow and cholestasis resolve. To diagnose PIB, because of its potentially adverse prognosis, seems to require that even minute ducts be absent from more than one of six interlobular portal tracts. Whoever interprets the findings on microscopy when PIB is at issue would be prudent to specify in any report what criteria and techniques were used.

The distal biliary tract is not generally malformed in infants with either syndromic or nonsyndromic PIB. Larger bile ducts are not identifiably lacking. Peripheral larger bile ducts began as interlobular ducts and with growth were

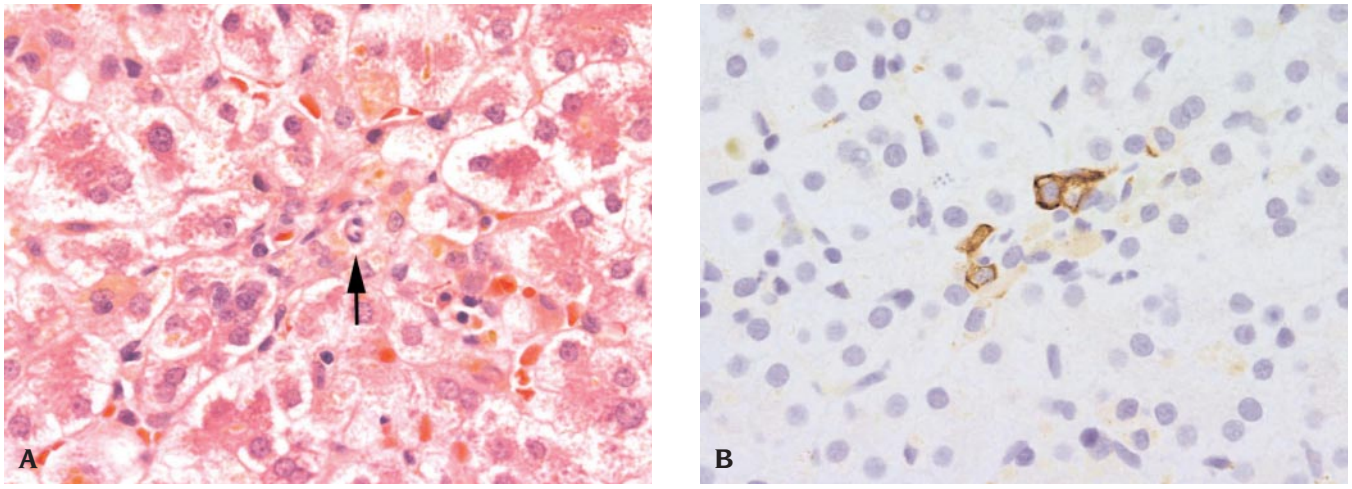

FIGURE 68-8 *A*, An interlobular portal tract in an infant with conjugated hyperbilirubinemia; compare with Figure 68-1A. An arrow indicates the hepatic arteriole. No bile duct can be discerned. Suspected paucity of interlobular bile ducts. Hematoxylin and eosin; ×400 original magnification. *B*, The same portal tract (compare with *A*), several micra distant, proves on immunohistochemical study to contain cells that express cytokeratin 19, which is usually found in cholangiocytes (hematoxylin and antibody against cytokeratin 19 [immunoperoxidase technique]; ×400 original magnification).

remodeled into trabecular or septal ducts. This suggests that bile duct morphogenesis in utero is unremarkable in such infants. Perinatal shifts in bile secretion, with alterations in bile composition,[14] may underlie perinatal development of a cholangiopathy. Septal and interlobular cholangiocytes differ in form (see Figure 68-1). Susceptibility to injury by more caustic bile may also differ between trabecular or septal ducts and interlobular ducts (the smallest, most recently formed, most peripheral ducts).

As mentioned, injured bile ducts may proliferate before they are lost. In EHBA, a vigorous increase in the number of bile ducts is initially the rule, but after several years, end-stage liver disease is characterized by bile duct disappearance.[15] This is generally ascribed to bile duct injury by bile. Such injury seems markedly accelerated in some instances of PIB. Of note is that newly laid down liver in early infancy is at the periphery of both the biliary tree and the liver itself and that newly formed interlobular ducts can be expected to predominate there. In addition, the right lobe of the infant liver grows more briskly after birth than does the left lobe.[16] Routine percutaneous biopsy is most likely to sample liver beneath the capsule in the right lobe, the youngest region. The pace of liver growth slows in later infancy, however (liver weight 75 g at term birth, 150 g at 3 months, 300 g at 1 year[17]). Follow-up biopsy, after duct loss has come to predominate over duct neogenesis, may be useful in assessing whether PIB is present. Histopathologic study cannot distinguish between syndromic PIB (associated with *JAG1* mutation[18]) and nonsyndromic PIB.

Some instances of conjugated hyperbilirubinemia in infancy are marked by a failure of GGT activity to rise. This may be due to severe hepatocellular injury, in which case, low GGT is nonspecific.[19] It may be due to any number of heritable disorders of synthesis of bile acids or their precursor molecules.[20–22] In such a setting, low GGT is likely due to an absence from bile of the bile acids that usually elute canalicular membrane GGT into bile, whence it can reflux into plasma. Finally, it may be due to one of several heritable disorders (arthrogryposis-renal dysfunction-cholestasis syndrome [ARC][23]; mutation in *ATP8B1*, which encodes familial intrahepatic cholestasis 1 [FIC1], a protein of undefined function[24]; or mutation in *ABCB11*, which encodes bile salt export protein [BSEP], the pump that transports bile salts from hepatocytes into bile).[25]

The etiology of ARC is not clear; it seems, however, that deficient expression of GGT at the canaliculus may underlie the failure of GGT activity to rise.[26] The same appears true for FIC1 disease.[27] With BSEP disease, although GGT is normally expressed, a lack of bile acids within bile—as with primary disorders of bile acid synthesis—may be responsible for failure to elute GGT and, accordingly, for the failure of GGT activity to rise.[27] The renal, neuromuscular, and skeletal manifestations of ARC permit its distinction from FIC1 disease and BSEP disease. FIC1 disease and BSEP disease, however, may be difficult to differentiate from one another. Changes of cholate stasis, with hepatocellular injury generally ascribed to retained bile acids, are usually less pronounced in FIC1 disease than in BSEP disease. The former tends to manifest as bland intracanalicular cholestasis (Figure 68-9A) and the latter as giant cell hepatitis (Figure 68-9B). Transmission electron microscopy in FIC1 disease tends to find loose, coarsely granular bile within canaliculi (Figure 68-9C), which is not usually the case in BSEP disease (Figure 68-9D).[28,29] Criteria for histopathologic diagnosis of these two recently distinguished disorders are under study.

Predominantly Hepatocellular Injury (Transaminitis) in Childhood

Damage to hepatocytes and damage to the biliary tract overlap, but two patterns of clinical biochemistry findings can be broadly defined. The first, which is more usual when damage to hepatocytes predominates, is characterized most prominently by elevations in serum concentrations of transaminase activities (the hepatitic pattern). The second, which is more usual when damage to the biliary tract predominates, is characterized most prominently by elevations in serum concentrations of bilirubin and of alkaline phosphatase and GGT activities (the cholestatic pattern). These two patterns also overlap: injury to hepatocytes induces cholestasis, and cholestasis leads to injury to hepatocytes.

On liver biopsy in patients whose clinical biochemistry test results fit the hepatitic pattern, increased numbers of leukocytes are found in portal tracts and in the lobule. Regardless of the speed of clinical onset of disease, whether slow (chronic) or abrupt (acute), most of the leukocytes are the mononuclear forms (lymphocytes, macrophages, and plasma cells) that, rather than granulocytes, characterize chronic inflammation elsewhere in the body. Acute hepatitis and chronic hepatitis are thus differentiated from one another by criteria other than the composition of the inflammatory infiltrate found.

In acute hepatitis, inflammation is predominantly within the lobule; in chronic hepatitis, it is within the portal tracts. Hepatocellular injury is more pronounced in acute hepatitis than in chronic hepatitis, with edema, necrosis of individual hepatocytes (Figure 68-10A), and both hepatocellular and canalicular cholestasis (Figure 68-10B). Macrophages enlarge and become more numerous; their cytoplasm contains ingested debris (see Figure 68-10B). Loss of hepatocytes may be associated with approximation of reticulin fibers to one another (stromal collapse, bridging) (Figure 68-10C). Acute hepatitis may be due to viral infection, toxin or drug ingestion, or autoimmune disease. It may resolve entirely, be so severe that liver transplant is necessary for survival, or evolve into a chronic hepatitis, with varying degrees of scarring and persistent inflammation.

In chronic hepatitis, the extent of inflammation and of injury to hepatocytes is assessed under the general heading of "necroinflammatory activity." Points considered are the distribution of inflammation and the extent of injury to hepatocytes. When inflammation is not restricted to the portal tracts but spills across the limiting plate into the lobule (Figure 68-11), interface hepatitis is present. The proportions of portal tracts involved by interface hepatitis, the extent of their circumference at which the limiting plate is blurred or effaced, and the depth and intensity to which

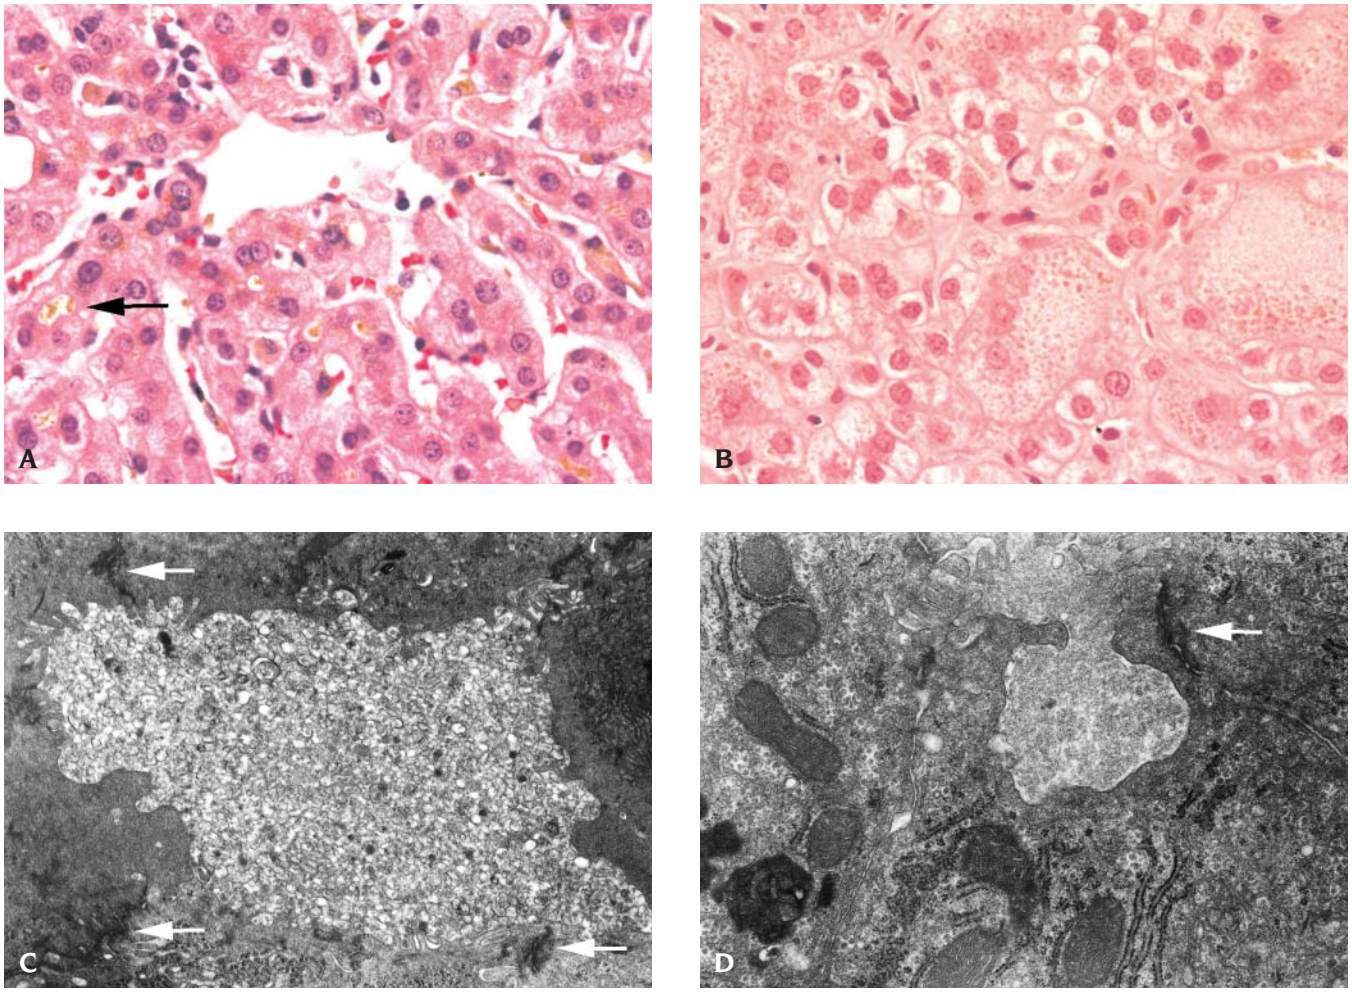

FIGURE 68-9 *A*, Small hepatocytes, varying only slightly in size, with compact cytoplasm border canaliculi containing bile plugs (*arrow*). Kupffer cells also contain bile pigment, but cholestasis within hepatocytes is not apparent. Familial intrahepatic cholestasis 1 (FIC1) disease (hematoxylin and eosin [HE]; ×400 original magnification). *B*, Giant cell change, with bile pigment in cytoplasm, is seen. Edema and variation in hepatocyte size are usual. Bile salt export protein (BSEP) disease (HE; ×400 original magnification). *C*, Circular profiles suggesting coarse granularity occupy the lumen of a canaliculus (tight junctions, *arrows*). FIC1 disease (osmium tetroxide, uranyl acetate, and lead citrate; ×16,500 original magnification). *D*, A canaliculus (tight junction, *arrow*) contains amorphous bile. Microvilli are lacking. BSEP disease (osmium tetroxide, uranyl acetate, and lead citrate; ×20,750 original magnification).

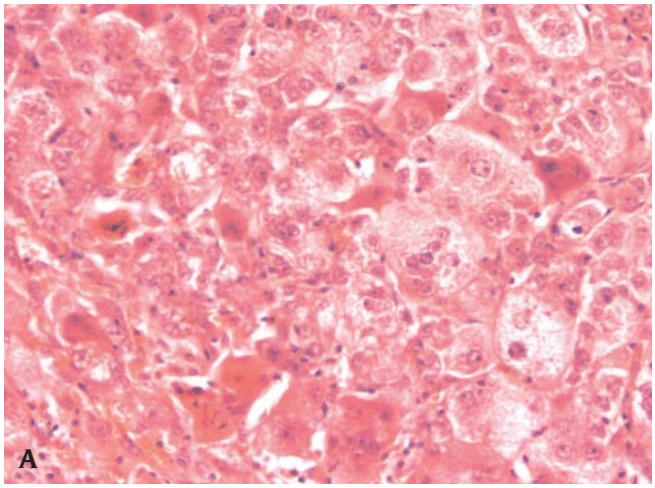
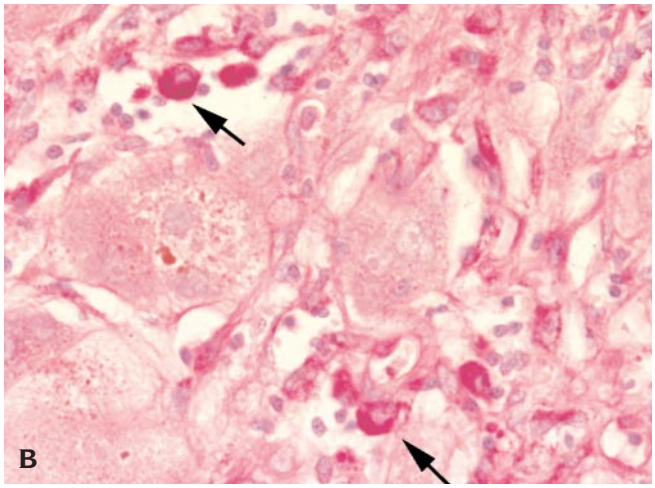
inflammation incurs into the lobule are evaluated. Changes in the appearance of hepatocytes, as listed for acute hepatitis (above), also are weighed. This assessment of injury at the moment of biopsy is called "grading." The damage to the liver caused by hepatitis is manifest as parenchymal loss, scarring, and parenchymal regeneration. If the insult to the liver is not eliminated, cirrhosis ensues. Evaluation of how far along the path to cirrhosis this damage has progressed is called "staging."

Several systems have been developed for numeric grading of the severity of chronic hepatitis and for staging associated scarring.[30–32] They are most useful when comparing instances of a particular disorder with one another and can be misleading when used too rigidly. Even the worst injury owing to hepatitis C virus infection, for example, falls short of what can be found in a florid autoimmune hepatitis. That, in turn, falls short of the devastation seen in non-A, non-B hepatitis with fulminant hepatic failure. Yet each of these varying degrees of necroinflammatory activity warrants designation as "severe"—of its kind.

This deficiency in across the board grading of necroinflammatory activity in chronic hepatitis has been expressly recognized for the changes seen in association with fatty change of hepatocytes (steatohepatitis), for which a specific grading system has been proposed.[33] It has been implicitly recognized in the lack of demand for numeric grading of necroinflammatory activity in neonatal hepatitis. Experience and access to clinical information that will help identify the etiology of a chronic hepatitis are needed for proper flexibility in choosing and applying a grading system for a particular biopsy specimen. Reliance on a numeric score alone is convenient, but the clinical practitioner should ensure, through discussions with colleagues in histopathology and, when possible, through review of findings on microscopy, that as little ambiguity as possible inheres in what, in the setting of a particular etiologic diagnosis, that score is meant to convey.

Morphologically defined chronic hepatitis has causes or associations that include viral infection, autoimmune





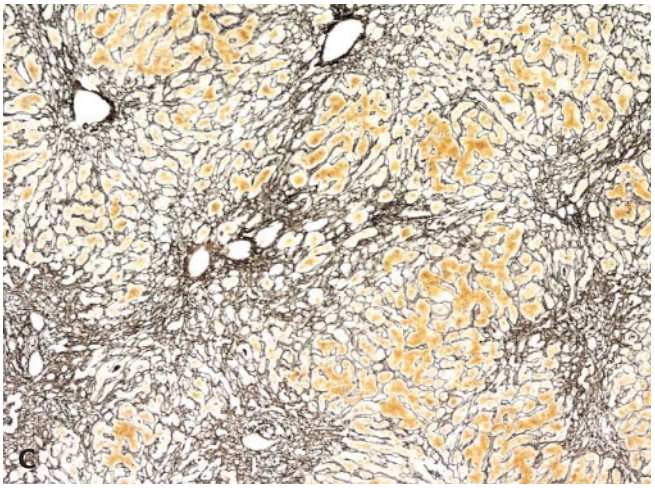


FIGURE 68-10 *A*, Edema, marked anisocytosis, and hepatocyte necrosis (with hypereosinophilia of cytoplasm and pyknosis of nuclei) are found in severe acute hepatitis owing to hepatitis B virus infection and requiring liver transplant for survival (hematoxylin and eosin; ×200 original magnification). *B*, Bile pigment is seen within edematous hepatocytes. Macrophages laden with ingested material (*arrows*) and lymphocytes lie among the hepatocytes. Acute hepatitis B virus infection; same patient as in *A* (diastase and periodic acid–Schiff; ×400 original magnification). *C*, Reticulin fibers are approximated to one another, without intervening hepatocytes, at many sites. The pattern is that of "bridging necrosis." Acute hepatitis B virus infection; same patient as in *A* (reticulin; ×40 original magnification).

disease, toxin exposure, Wilson disease, and fatty change. A wide variety of viruses can infect the liver, with hepatitis B virus and hepatitis C virus being the most frequently encountered at biopsy. Serologic and molecular-biologic studies generally provide diagnosis; as discussed above, biopsy is used to evaluate the extent of injury and for clues to prognosis. Hepatitis B virus infection may be manifest as "ground-glass" inclusions in hepatocyte cytoplasm (see Figure 68-3B); these mark on orcein staining (see Figure 68-3C). Hepatitis C virus infection is associated with expansion of portal tracts by lymphoid aggregates or even follicles, with germinal centers (Figure 68-12A), as well as with steatosis of hepatocytes (Figure 68-12B).

Autoimmune hepatitis is necessarily a serologically assigned diagnosis, but biopsy has a place in evaluating the severity and progression of disease.[34] Some features are more common in autoimmune hepatitis than in other forms of chronic hepatitis. These include plasma cell infiltrates that extend into the lobule (Figure 68-13A) and a tendency to centrilobular injury (Figure 68-13B). Toxin or drug ingestion may trigger an autoimmune hepatitis, and the histopathologic features of toxin- or drug-associated hepatitis overlap somewhat with those of autoimmune hepatitis. Prominence of neutrophils and eosinophils among inflammatory cells may suggest that injury is drug induced.

Wilson disease results from mutation in *ATP7B*, which encodes a hepatic copper-transporting enzyme.[35] It is effectively a pediatric disorder. Wilson disease may come to attention in the second decade with acute hepatic failure superimposed on cirrhosis or be identified earlier during the evaluation of transaminitis. In later stages of disease, copper-associated protein abounds within hepatocytes, but its distribution within the liver is patchy (Figure 68-14A). Cytosolic copper cannot readily be demonstrated histochemically. However, it may be present when cuprisomal copper is not, and to quantitate copper in liver tissue is still important in confirming a clinical diagnosis. Earlier stages are marked by steatosis of hepatocytes, a generally mild chronic hepatitis, and portal tract fibrosis, with relatively scant stainable copper (Figure 68-14B). Steatosis and hepatitis in a child thus should prompt evaluation for Wilson disease.

Steatohepatitis is characterized by steatosis of hepatocytes, portal tract fibrosis with perisinusoidal extension, centrilobular fibrosis, neutrophils within the lobule, hepatocyte ballooning with Mallory hyalin, activation of Kupffer cells, and lipogranulomata formed in response to rupture of fat-laden hepatocytes (Figure 68-15).[33] Not all of these need to be present before the diagnosis can be made. These changes are not distinguishable from those induced by ingestion of alcohol to excess. Steatohepatitis associated with obesity is increasingly reported in children.[36]

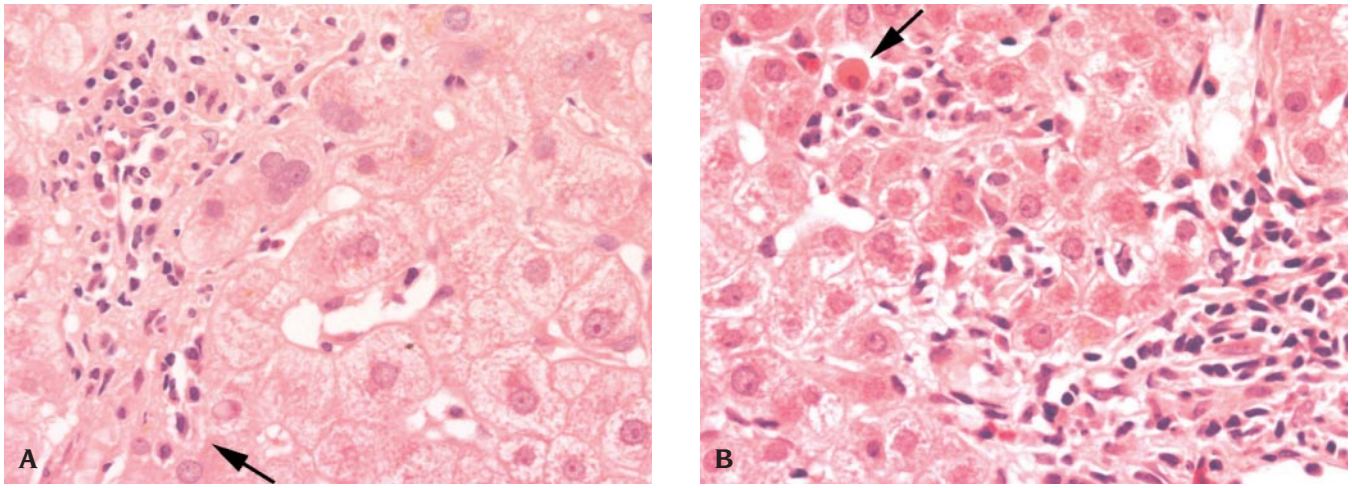

FIGURE 68-11 *A*, A portal tract contains an inflammatory infiltrate. It traverses and blurs the limiting plate, extending a short distance into the lobule. Mononuclear leukocytes are seen within hepatocytes (*arrow*). Hepatocellular anisocytosis is slight. Chronic hepatitis with mild activity; hepatitis C virus infection (hematoxylin and eosin [HE]; ×400 original magnification). *B*, A portal tract contains an inflammatory infiltrate. The present infiltrate extends more deeply into parenchyma and is more dense than that in *A*. It is associated with necrosis of a hepatocyte (*arrow*). Hepatocellular anisocytosis is pronounced. Chronic hepatitis with moderate activity; autoimmune hepatitis (HE; ×400 original magnification).

Predominantly Biliary Tract Injury (Cholestatic Pattern) in Childhood

The changes seen in distal biliary tract obstruction (extrahepatic cholestasis), in several heritable forms of intrahepatic cholestasis, and in hepatitis with secondary cholestasis are touched on above; the changes seen in sepsis are addressed below, with other post-transplant complications. Drugs, including both endogenous and exogenous hormones, can trigger intrahepatic cholestasis that both clinically and at biopsy resembles heritable cholestasis. Such acute-onset cholestasis and its pharmacogenetics are under study. Various spectra of susceptibility to drug-induced cholestasis, with implications for prophylaxis and treatment, may at some point be defined mutationally.

Damage to large and small bile ducts in childhood may itself be a heritable condition, as in NSC[37,38] and cirhin disease (North American Indian childhood cirrhosis).[39] It may be associated with neoplasia, as in Langerhans cell histiocytosis, or with immunodeficiency and its complications.[40] More frequently encountered are the changes seen in association with inflammatory bowel disease, which are generally called primary sclerosing cholangitis. These include an obliterative atrophy of septal or trabecular ducts, which are found rarely in needle biopsy specimens, and proliferative changes in interlobular bile ducts (Figure 68-16A) proximal to sites of large duct scarring. These changes may be associated with mixed or predominantly lymphocytic inflammation and with some degree of interface hepatitis. Frank cholestasis is not generally seen,

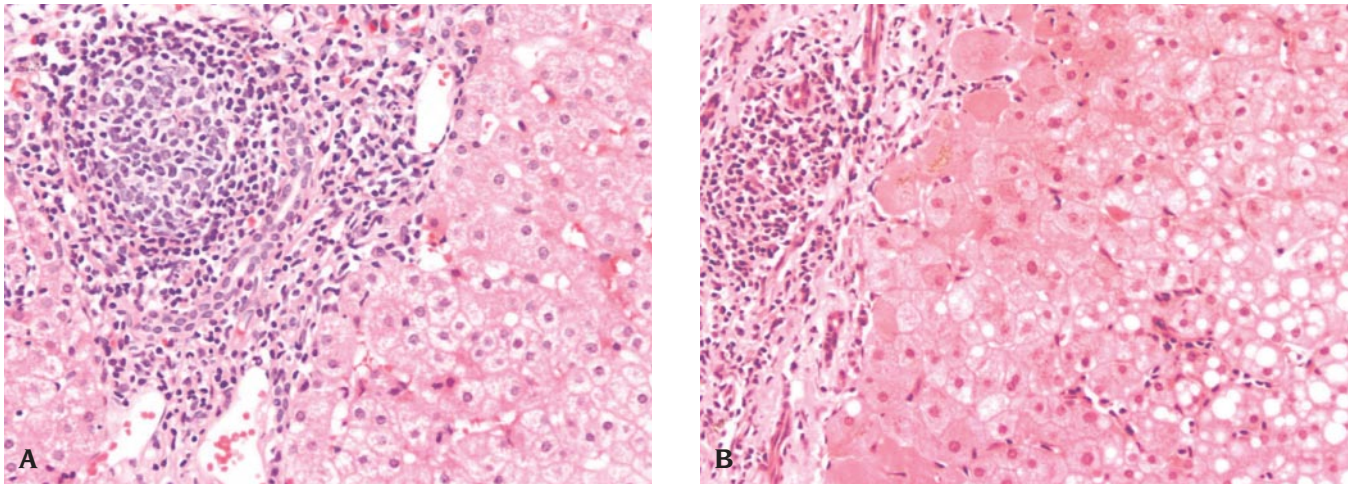

FIGURE 68-12 *A*, A germinal center lies within a portal tract. A bile duct appears draped along the germinal center's border; it is not the focus of inflammation. Slight interface activity is present. Hepatitis C virus infection (hematoxylin and eosin [HE]; ×200 original magnification). *B*, A portal tract contains a lymphoid aggregate. Slight interface activity and lobular inflammation are found. Macrovesicular steatosis of hepatocytes is seen. Hepatitis C virus infection (HE; ×200 original magnification).

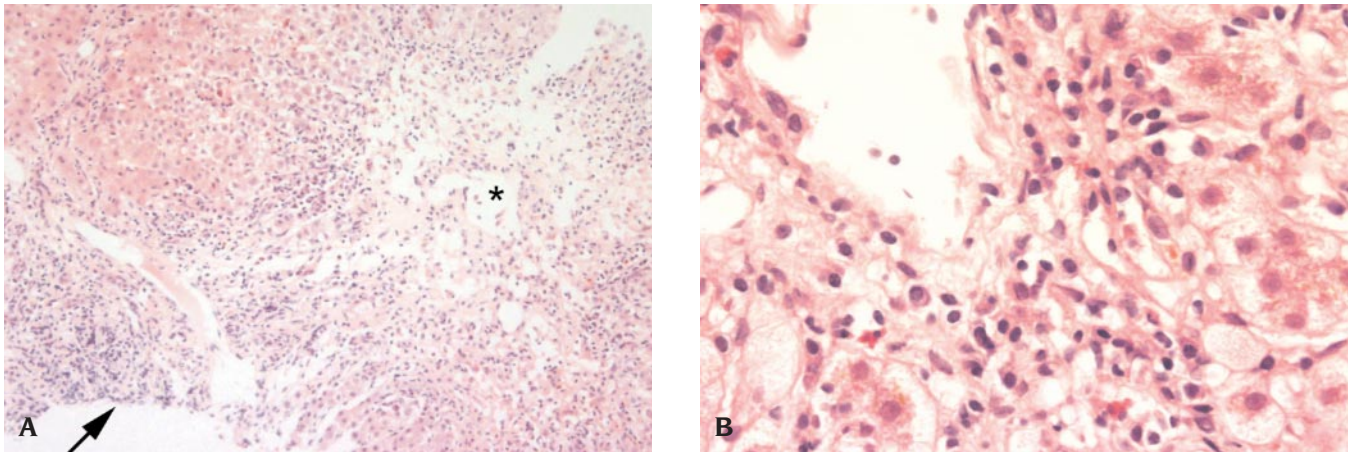

FIGURE 68-13 *A*, Brisk mononuclear leukocyte inflammation extends from the portal tract (*arrow*) to the central vein (*asterisk*), a pattern of injury leading to bridging necrosis and fibrosis. Autoimmune hepatitis (hematoxylin and eosin [HE]; ×100 original magnification). *B*, Plasma cells are conspicuous, with lymphocytes and scattered eosinophils, in a centrilobular infiltrate. Autoimmune hepatitis (HE; ×400 original magnification).

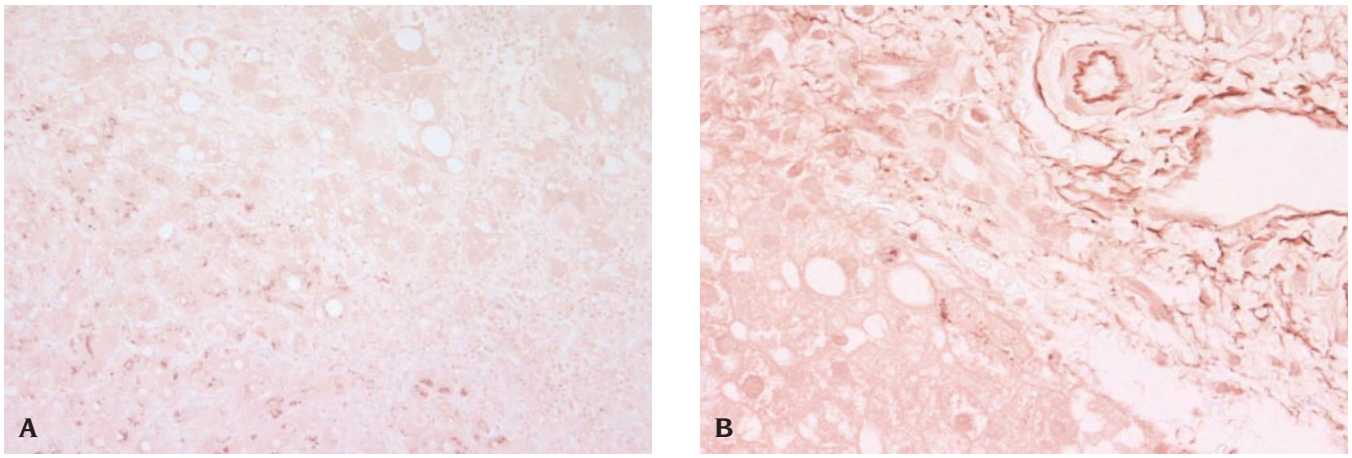

FIGURE 68-14 *A*, A nodule of hepatocytes (note the curved margin) contains substantial deposits of copper-associated protein; elsewhere in the section, none is demonstrated. Steatosis can be identified. Wilson disease at hepatectomy, age 14 years (orcein; ×100 original magnification). *B*, Small quantities of copper-associated protein are seen in hepatocytes at the limiting plate. Steatosis can be identified. Wilson disease at presentation, age 5 years (orcein; ×400 original magnification).

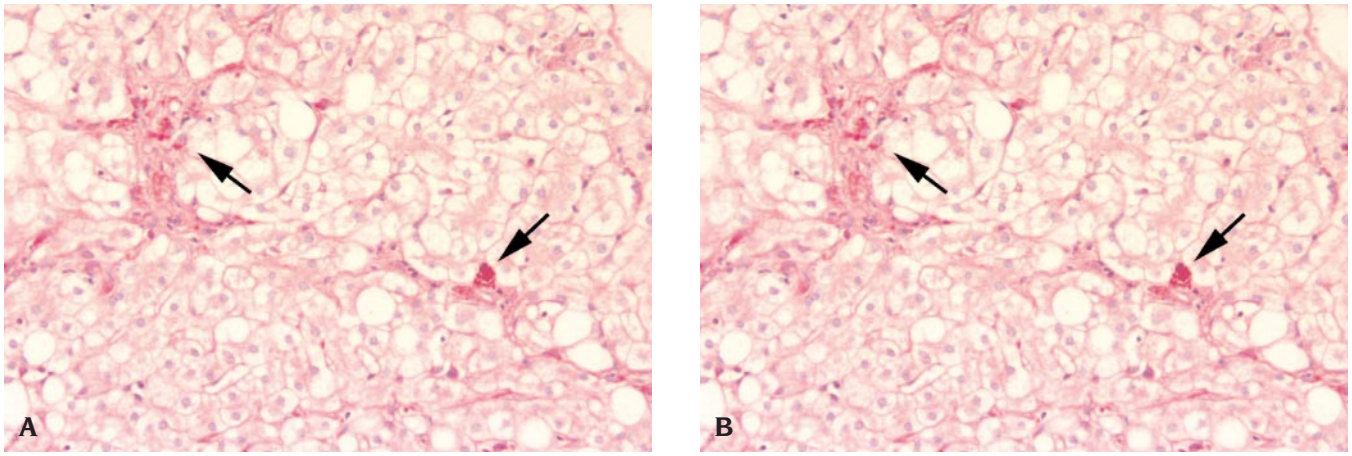

FIGURE 68-15 *A*, Nearly all hepatocytes exhibit steatosis. A small granuloma is present (*arrow*). Nonalcoholic steatohepatitis (hematoxylin and eosin; ×200 original magnification). *B*, "Turnover" pigment arising from necrosis of hepatocytes is seen in Kupffer cells and portal tract macrophages (*arrows*). Fine perisinusoidal fibrosis can be appreciated. Nonalcoholic steatohepatitis; same patient as in *A* (diastase and periodic acid–Schiff; ×200 original magnification).

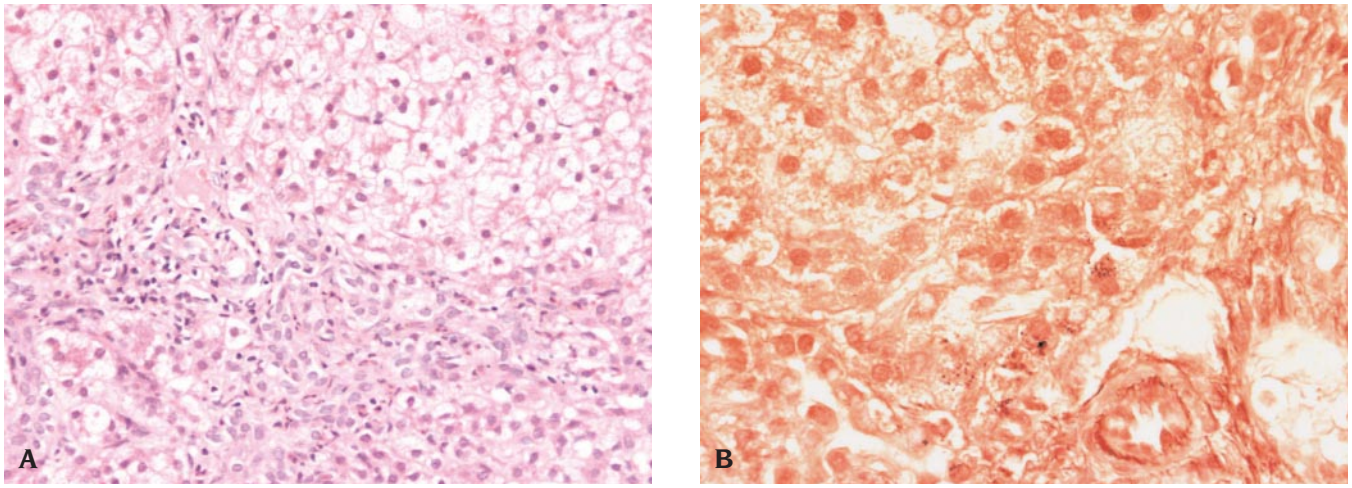

FIGURE 68-16 *A*, A portal tract is expanded by fibrosis and by increased numbers of bile duct profiles. Cholestasis is not seen. A scant acute and chronic pericholangitis is present. Cholangiopathy of inflammatory bowel disease (hematoxylin and eosin; ×200 original magnification). *B*, Copper-associated protein in small quantities is present in periportal hepatocytes. Cholangiopathy of inflammatory bowel disease; same patient as in *A* (orcein; ×400 original magnification).

although the hepatocellular edema of cholate stasis may be found. Copper-associated protein in periportal hepatocytes (Figure 68-16B) may mark the subclinical cholestasis of cholangiopathy and should be sought. If small duct cholangiopathy is found at biopsy and large duct cholangiopathy cannot be documented on imaging study, MDR3 disease[9] should be considered. Some patients in whom features of cholangiopathy clinically dominate features of hepatitis also have autoantibodies.[40,41] These may be considered instances of "overlap" or of an autoimmune sclerosing cholangitis. This diagnosis is made predominantly on serologic grounds.

Portal Hypertension

Some children without apparent metabolic disorder and without clinical biochemistry evidence of hepatic injury are noted to have stigmata of portal hypertension or hepatomegaly. Evaluation of portal hypertension constitutes an indication for liver biopsy. Two conditions identified from time to time in this setting are congenital hepatic fibrosis and portal vein thrombosis. In the former, portal tracts are expanded by fibrosis and contain increased numbers of bile ducts. The profiles and locations of bile ducts are unusual. They appear dilated and often lie at the limiting plate rather than within the collagenous stroma of the portal tract (Figure 68-17A). These changes suggest persistence of a stage in fetal liver development and are one manifestation of the ductal plate malformation.[42] Portal vein branches may appear hypoplastic. Extrahepatic and intrahepatic portal vein thrombosis (hepatoportal sclerosis) sometimes follows umbilical vein catheterization, but it may have no identifiable antecedent. Portal venules of unusually small caliber (Figure 68-17B) or parenchymal atrophy, particularly of centrilobular regions, may suggest that diagnosis.[43]

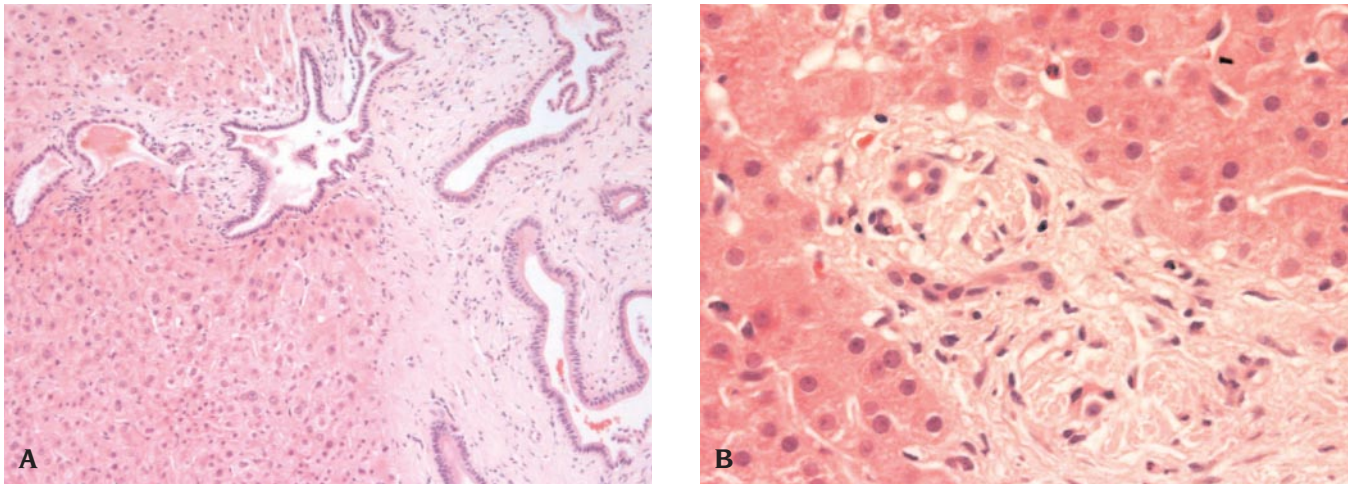

FIGURE 68-17 *A*, Dilated bile ducts in increased numbers are seen in and at the margins of a fibrotic portal tract. The profiles of the ducts are irregular. Congenital hepatic fibrosis (hematoxylin and eosin [HE]; ×100 original magnification). *B*, An interlobular portal tract lacks a portal venule of appropriate size (compare with Figure 68-1A) and exhibits slight fibrosis. History of portal vein thrombosis (HE; ×400 original magnification).

Post-Transplant Complications

Allograft livers are susceptible in adult and pediatric patients alike to rejection; to problems of vascular supply or drainage; to problems of biliary drainage; to infection, sometimes facilitated by immunosuppression; to involvement of the allograft by the original disorder; and to post-transplant de novo "autoimmune" hepatitis. Children who receive hepatic allografts are more likely to experience problems owing to technical aspects of surgery, to infection, and to de novo "autoimmune" hepatitis.

Rejection of allograft livers (leaving aside hyperacute rejection) takes two forms: acute and chronic. In acute rejection,[44] biopsy finds lymphocytic endotheliitis of portal and centrilobular venules, lymphocytic cholangitis, and portal tract inflammation, with lymphocytes and eosinophils (Figure 68-18A). Macrophages and neutrophils may be present as well. Centrilobular injury may extend into the parenchyma, with hepatocyte loss and hemorrhage. Intralobular cholestasis and hepatocellular edema often are seen (Figure 68-18B). Acute rejection is most frequently diagnosed on biopsy in the first weeks after liver transplant, but it can occur at any time if immunosuppression is withdrawn. Intercurrent viral infection may also precipitate acute rejection.[45] A consensus grading scheme for assessing the severity of acute rejection is available.[46] Its utility is probably greater in clinical trials than in day-to-day patient management.

Chronic rejection is characterized by loss of interlobular bile ducts and by a foam cell obliterative arteriopathy affecting larger vessels. Only bile duct injury can generally be assessed in needle biopsy specimens. Bile duct damage, with attenuation and disordered polarity of cholangiocytes (Figure 68-18C), precedes duct loss. A consensus staging scheme for assigning the diagnosis of chronic rejection is available.[47]

Global ischemic injury to the hepatic allograft may result in geographic-pattern infarction, with irregularly distributed regions of sparing and necrosis. Core needle biopsy thus cannot reliably assess the extent of injury. A late sequela of hepatic artery thrombosis can be incomplete biliary tract obstruction owing to scarring and stricture. The ductular reaction (recruitment of periportal hepatocytes to the small cholangiocyte phenotype) is found in both distal biliary tract stricture and acute rejection.[44,48] If edema of portal tracts and substantial numbers of neutrophils are particularly prominent, stricture should be considered.

Bacterial, fungal, and viral infections can damage the allograft liver. When sepsis is among the clinically considered reasons for allograft dysfunction (most commonly soon after transplant), bile plugs in the lumina of newly recruited cholangioles at the margin of the portal tract[49]

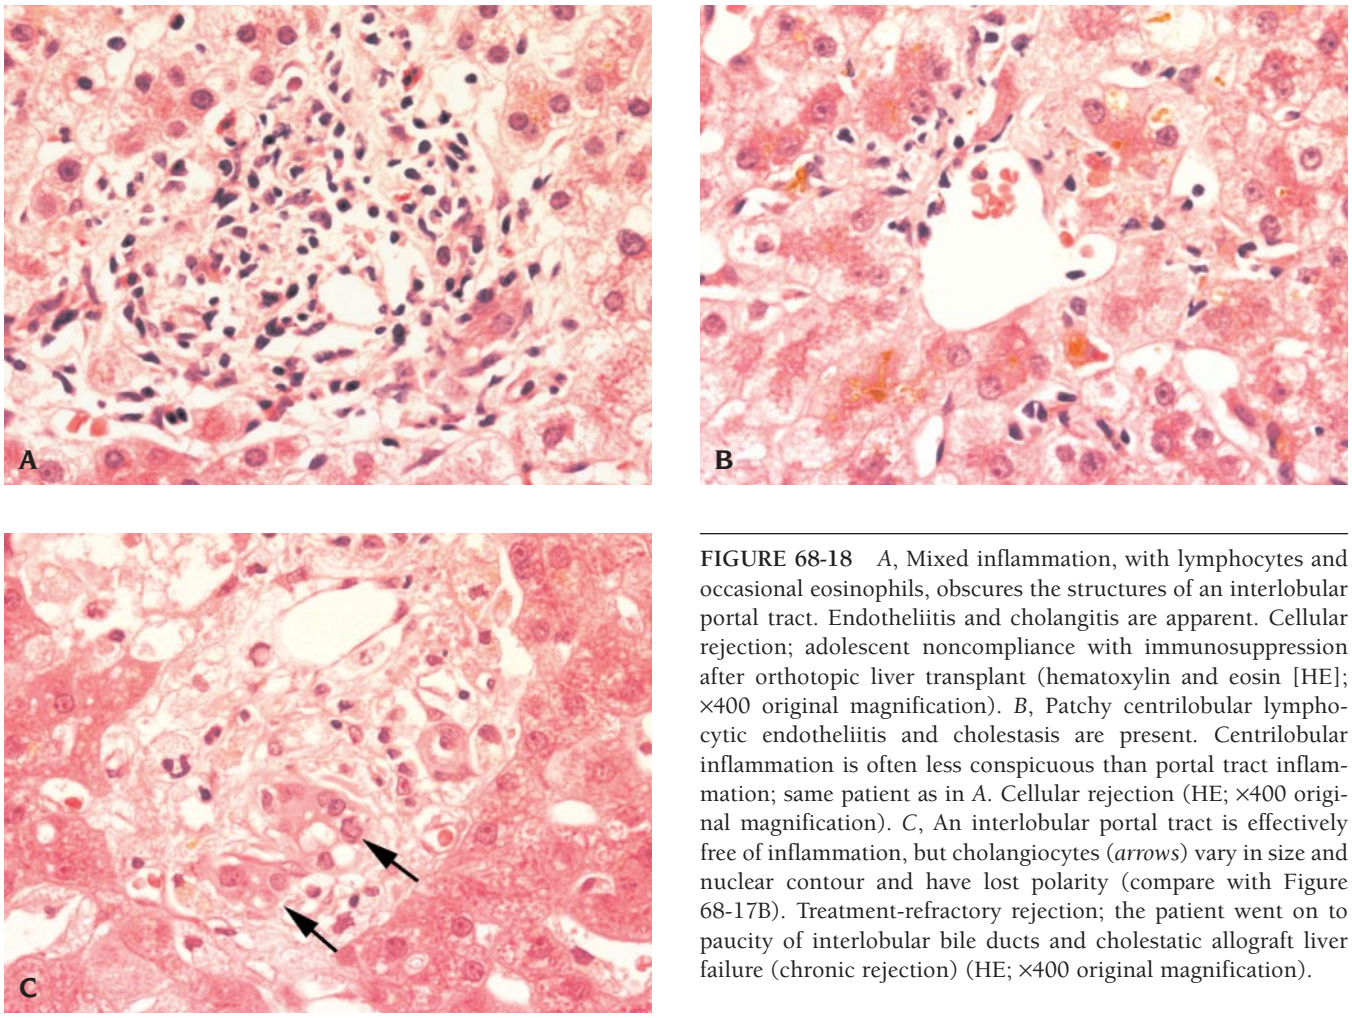

FIGURE 68-18 *A*, Mixed inflammation, with lymphocytes and occasional eosinophils, obscures the structures of an interlobular portal tract. Endotheliitis and cholangitis are apparent. Cellular rejection; adolescent noncompliance with immunosuppression after orthotopic liver transplant (hematoxylin and eosin [HE]; ×400 original magnification). *B*, Patchy centrilobular lymphocytic endotheliitis and cholestasis are present. Centrilobular inflammation is often less conspicuous than portal tract inflammation; same patient as in *A*. Cellular rejection (HE; ×400 original magnification). *C*, An interlobular portal tract is effectively free of inflammation, but cholangiocytes (*arrows*) vary in size and nuclear contour and have lost polarity (compare with Figure 68-17B). Treatment-refractory rejection; the patient went on to paucity of interlobular bile ducts and cholestatic allograft liver failure (chronic rejection) (HE; ×400 original magnification).

may support that diagnosis. Ascending cholangitis is an additional consideration, particularly when, as in EHBA, a limb of bowel has replaced the extrahepatic biliary tract. Fungal infection may complicate ischemic injury to the bile ducts, but it only very rarely involves the liver sampled by core needle biopsy.

Viral pathogens of particular note in pediatric liver transplant recipients include adenovirus, herpes simplex or varicella-zoster virus, cytomegalovirus, and Epstein-Barr virus. Adenovirus, herpes simplex, and varicella-zoster viruses produce pock-like foci of coagulative necrosis randomly distributed within the lobule; adenovirus can also directly involve the biliary tract.[50] Cytomegalovirus causes characteristic inclusions within endothelial cells, cholangiocytes, and hepatocytes, leading in the lobule to microabscess or microgranuloma formation. Epstein-Barr virus infection may lead to post-transplant lymphoproliferative disorder, more frequently so when primary infection occurs at the time of transplant or thereafter.[51] Immunosuppression predisposes the patient to development and progression of Epstein-Barr virus–associated disease. Post-transplant lymphoproliferative disorder may range from a mononucleosis-like syndrome to frank lymphoma. Features distinguishing the portal tract infiltrates of post-transplant lymphoproliferative disorder from those of acute cellular rejection include B-cell rather than T-cell predominance, immunoblastic or plasmacytoid features, and numerous—rather than occasional—cells containing Epstein-Barr virus sequences on in situ hybridization.[52,53]

Some patients who undergo liver transplant for disorders other than an autoimmune hepatitis develop allograft injury characterized by transaminitis, histopathologic findings more characteristic of autoimmune hepatitis than of either acute or chronic rejection, and circulating antinuclear or anti–smooth muscle antibodies. This pattern of disease, called de novo autoimmune hepatitis, appears more frequently in children than in adults and is not generally manifest soon after transplant.[54–56] To see a plasma cell component in an allograft liver biopsy specimen should prompt consideration of this diagnosis.

CHAPTER 69

INTESTINAL BIOPSY

Alan David Phillips, BA, PhD, FRCPCH
Virpi V. Smith, PhD

SMALL INTESTINAL BIOPSY

Small intestinal mucosal biopsy is a routine procedure in specialty centers in which considerable experience and expertise in the technique itself and in the interpretation of biopsy findings are available. Therefore, safety, minimal disturbance to the child, and reliable results are all appropriately combined. The occasional small intestinal biopsy performed by inexperienced hands may lead to a disturbed child and often yields inconclusive results.

The introduction of the techniques of proximal small intestinal mucosal biopsy to pediatric practice by Sakula and Shiner in 1957[1] was a major advance, and access to tissue samples in children has led to a burgeoning of knowledge of intestinal pathology. It has also led to a better understanding of how the intestine functions normally. Variations on the biopsy capsule format have been produced and include a smaller porthole size to provide safer tissue sampling in children and double portholes[2] to improve sampling of potentially patchy lesions.[3] It is dangerous to use the adult capsule in small children because the size of the tissue biopsy specimen may be too large and may occasionally lead to perforation. Use of the pediatric capsule is safe in the experience of most observers, although a small risk of complications still exists. However, the use of the suction biopsy capsule has been superseded in most centers by endoscopic grab biopsy, which can provide tissue samples of similar quality and size.[4,5] It is possible to combine the two techniques.[6] Endoscopic sampling gives multiple biopsy specimens of adequate quality from one region, and it is possible to use a narrow-bore endoscope to give access to patients of low weight (> 1.8 kg). In addition, endoscopy provides a surface view of the upper gastrointestinal (GI) tract, with the option to biopsy esophageal and gastric regions during the procedure, although it is usually performed under a general anesthetic. Suction biopsy, in contrast, is usually performed in a sedated patient and has no facility for a macroscopic view (thereby requiring screening to position the capsule before taking a sample). Both require sterilization after use, and suction biopsy provides a cheaper route to intestinal sampling. Historically, suction biopsies have been performed toward the duodenojejunal flexure. Small intestinal endoscopic biopsies may be performed more proximally, around the second part of the duodenum, although distal duodenal sampling is perfectly feasible, and it is important to be aware that morphologic features may not be identical in the two regions (eg, in villous height, degree of lamina propria cellularity).

Technique of Small Intestinal Biopsy

Suction Biopsy. The child should fast overnight, although small amounts of water may be given as required. Infants may have a 10 pm and sometimes a 2 am feeding if necessary. On the morning of the biopsy, the child is sedated. The Royal Free Hospital (London, UK) no longer performs suction biopsies, and all intestinal mucosal biopsies are taken via endoscopy. Historically, the following oral regimen for sedation was used: trimeprazine, chloral hydrate, and metoclopramide in an appropriate dose for age. If the child becomes highly restless or distressed during the procedure, intravenous diazepam may be given at a maximum dose of 0.5 mg/kg. This should be done only when there is no risk to the child because of heavy sedation and when resuscitation equipment is immediately available. Grossly enlarged tonsils and any compromise to the upper airways are clear contraindications to its use. Once the child is appropriately sedated, the capsule is passed. This is done in the small child by placing a tongue depressor in the mouth and placing the capsule at the back of the tongue. The depressor is withdrawn, the chin is held up, and the child swallows. The tubing is then gently advanced until the capsule is in the stomach. Resistance is often felt at the cardioesophageal junction. The child is then placed on his right side, and the capsule is further advanced. It should then fall toward the pylorus. The next step depends on whether a flexible or a more rigid tubing is being used and whether there is to be fluoroscopic screening (the preferred technique) or if progress is to be assessed by plain radiography of the abdomen. In addition, if a nonradiopaque tube is used, radiopaque material needs to be injected down the tubing before the position of the capsule can be checked radiologically. Using a flexible tubing and a plain radiograph of the abdomen is a time-consuming procedure, but it does have the virtue of providing an exact record (a radiograph) of the exact site of the biopsy. However, the more rapid technique of using a radiopaque relatively rigid tube and positioning the capsule under fluoroscopic control is preferred. Such a semi-

rigid catheter is the metal, braided angiocardiographic catheter, which successfully transmits torque. It is also helpful to inject some air into the stomach via the capsule. A practical advantage of this technique is its usual speed, which makes the procedure preferable from the child's point of view. Care should be taken to monitor the fluoroscopy time. This should not exceed 2 minutes and usually is far shorter.

Metoclopramide introduced into the tubing in the dose of 2.5 mg for infants younger than 2 years and 5 mg for those older than 2 years usually speeds the passage of the capsule when there is a holdup at the pylorus. Alternatively, cisapride (0.2–0.3 mg/kg) can be given as a single dose via the capsule tubing. Using either procedure, once the capsule is positioned in the fourth part of the duodenum, the duodenojejunal flexure, or the first loop of the jejunum, it is "fired" by suction with a 20 mL syringe and then withdrawn. Ideally, biopsy specimens should be taken from a constant standard site. To ensure that the tube is not blocked (if radiopaque material or metoclopramide syrup has been injected down the tube), it is helpful to inject 2 mL of water followed by 2 mL of air before firing the capsule.

Ideally, some duodenal juice should be obtained either by free drainage before the capsule is fired or at the time of firing. The juice should be examined immediately by light microscopic study, under phase-contrast or high-contrast conditions, for the presence of *Giardia lamblia* and should be sent for culture if bacterial overgrowth or infection (eg, enteropathogenic *Escherichia coli* [EPEC]) is considered a diagnostic possibility.

Endoscopic Biopsy. The majority of centers now perform the small bowel biopsy during upper GI endoscopy. This has led to increased awareness of coexistent gastric and esophageal pathology, such as reflux esophagitis in many infants with cow's milk–sensitive enteropathy (CMSE). Position statements on the role of endoscopy in the investigation of conditions such as esophagitis have been published by both the North American Society for Pediatric Gastroenterology and Nutrition (NASPGN)[7] and the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN)[8]; however, this chapter concerns only the role of endoscopic small intestinal biopsy in the diagnosis of enteropathy. When pediatric endoscopy was first performed, concerns were expressed about the quality of tissue obtained by endoscopic grab biopsy compared with capsule biopsy. This does not appear to be a problem with modern equipment, and several studies have confirmed that endoscopic biopsies are perfectly satisfactory for diagnostic purposes provided that tissue handling is performed correctly (see below).

The techniques of upper GI endoscopy are considered in detail in Chapter 67, "Gastrointestinal Endoscopy." As for capsule biopsy, it is appropriate to consider sedative premedication for the young child or an apprehensive older child. There has been recent discussion about the relative merits of deep intravenous sedation and general anesthesia in pediatric endoscopy.[9] Although some gastroenterologists use little or no sedation for their adult patients, this is not appropriate in pediatrics. The level of sedation achieved using intravenous benzodiazepines, together with narcotic analgesics such as pethidine, may overlap with general anesthesia, and it is mandatory that an appropriately qualified specialist has continuing responsibility for supervising the safety of the sedated patient throughout and after the procedure. Thus, in addition to continuous monitoring of oxygen saturation, there is an absolute requirement for functional resuscitation equipment and the ready availability of reversal agents such as naloxone and flumazenil. Some centers use a qualified anesthetist in this role, although in other centers, a member of the pediatric gastroenterology team assumes this responsibility. It is thus desirable for pediatric gastroenterologists in training to have undergone certified training in intubation and airway maintenance. Several countries now run registered courses in pediatric advanced lifesaving techniques.

The advent of video endoscopy, which has largely superseded the old fiberoptic instruments, has increased the potential diagnostic efficacy of endoscopy, and recognition of subtle lesions has been enhanced. It is thus easier to detect patchy small bowel lesions, such as CMSE. It is also possible, using very small-diameter "neonatal" endoscopes, to perform examinations in very small infants of less than 2 kg. There is an inevitable trade-off in terms of the quality of biopsy obtained if small biopsy forceps are used, and the choice of forceps is a matter of personal or departmental choice. Diagnostic ability is always enhanced by appropriate tissue handling (see below). Conversely, the largest samples may be rendered diagnostically uninformative by mishandling. Simply dropping a small intestinal biopsy into formalin runs the risk of causing a contraction of the longitudinal muscle layer, making subsequent orientation difficult. Although this may not affect diagnosis of celiac disease, it may make secure diagnosis of subtle enteropathy impossible.

Sample Handling. Once the capsule or endoscopic biopsy forceps has been withdrawn, the biopsy specimens should be rapidly removed from the capsule onto a gloved finger using a blunt seeker. The samples are opened out carefully so that the mucosal surface is facing downward (this can be checked using a dissecting microscope or hand lens if required). A piece of dry black card is then applied gently to the serosal surface for a few seconds, resulting in the sample adhering to the card. The card and sample, with the mucosal surface now facing upward, are placed into cold (4°C) normal saline. The black card optimizes the contrast of the specimen for study and photography. Under the dissecting microscope, the appearance of the mucosa can be assessed, but fixation must be prompt so that tissue autolysis is minimized. If using suction biopsy, it is not easy to repeat the procedure, so samples for which fixation with formalin is to be avoided, for example, electron microscopic study, disaccharidase assay, and immunohistochemical study, should be taken. Using endoscopy, it is a simple process to take additional grasp biopsy samples for any other requirements.

The specimens, still on the black card, are then placed in 10% phosphate-buffered formalin and processed for histologic examination. Routinely, 10 to 20 serial sections are cut, mounted on a single glass slide, and stained with hematoxylin and eosin (HE) and with periodic acid–Schiff (PAS) stain.

Hygiene Precautions. It is good practice when handling the biopsy capsule or endoscopic forceps after firing to wear surgical gloves. It is also advisable to wear safety spectacles or a visor to avoid face splashes with tissue and/or fluids. The endoscope is cleaned in 2% activated glutaraldehyde solution in an automatic, self-contained system. The biopsy capsule should be cleaned thoroughly after use and disinfected for at least 10 minutes in 0.5% chlorhexidine gluconate (weight per volume) in 70% alcohol, followed by a minimum of 1 hour in 2% activated glutaraldehyde solution, rinsed thoroughly in water, and allowed to dry. Great care should be taken when handling glutaraldehyde, and individual exposure must be kept to a minimum by using appropriate personal protection equipment and adequate ventilation.

Morphologic and Other Observations of Small Intestinal Biopsy Specimens

Dissecting Microscopy. The value of initial examination of biopsy samples with the dissecting microscope has been confirmed by many workers, both in adult medicine and pediatrics.[10,11] The following points illustrate the value of this method:

1. It facilitates the orientation of biopsy specimens to optimize histologic sectioning.
2. It allows a study to be made of the three-dimensional arrangements of mucosal architecture.
3. The entire biopsy specimen may be examined, which is particularly important in pediatrics because patchy mucosal lesions often occur (Figure 69-1).
4. Any gross artifactual damage can be recognized along with the adequacy, or otherwise, of the sample, so that a repeat biopsy can be considered while the patient remains sedated or anesthetized.
5. It allows rapid diagnosis of the presence or absence of a flat mucosa.
6. It allows parents to see the mucosa themselves (eg, a flat mucosa [Figure 69-2] and therefore reinforces the need for a gluten-free diet, particularly in postgluten challenges, when symptoms may not arise.
7. It offers the opportunity to take small samples of the specimen for other procedures (eg, electron microscopy, disaccharidase assay), although this is not necessary with endoscopy.

The drawbacks of the method are that if due care is not taken, fixation may be postponed, giving rise to the possibility of autolytic changes, and the severity of an abnormality other than a flat mucosa can be underestimated.

Some authors have considered that this method of examination adds little to histologic diagnosis and that its only value lies in the rapid recognition of a flat mucosa.[12] They instead advocate serial sectioning for histologic study of the whole biopsy specimen. However, such an approach is idealistic because it is not practical in most hospitals, whereas dissecting microscopic study is simple and straightforward and can easily be performed routinely.

In normal, healthy adults, the small intestinal mucosa is characterized principally by finger-like villi, with some leaf-like villi, but in children, the villi tend to be broader. The term "tongue-like" is used to describe such villi, and when they are extremely wide, the term "ridge-like" villi is used. The latter appearance is frequently seen in children in the first 5 years of life (Figure 69-3).[13] The appearance of leaf-like, tongue-like, or thin ridge-like villi on a proximal small

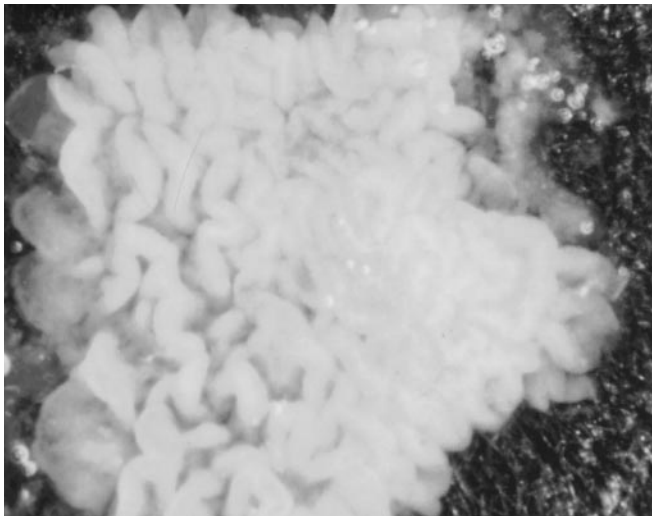

FIGURE 69-1 Dissecting microscopic study: patchy appearance showing ridgelike villi on the left side with low, closely packed ridges on the right (male infant, 13 months, postenteritis syndrome).

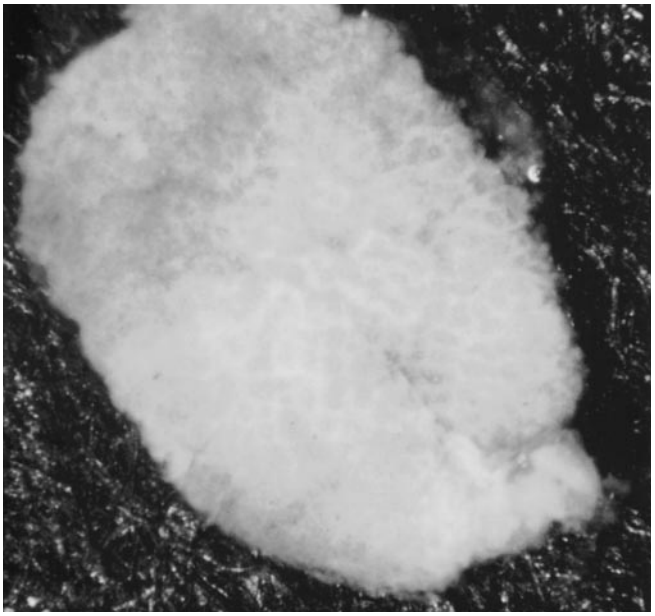

FIGURE 69-2 Dissecting microscopic study: flat mucosa showing visible crypt openings (female infant, 13 months, untreated celiac disease).

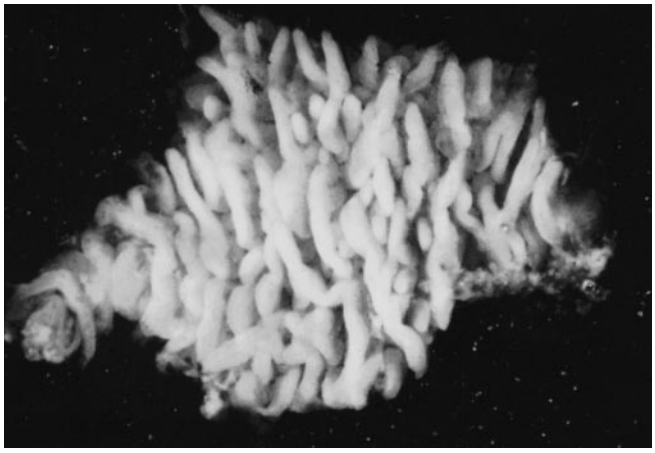

FIGURE 69-3 Dissecting microscopic study: normal appearance of tall, thin, ridgelike villi interspersed with leaflike villi (male infant, 5 months, intermittent diarrhea).

intestinal biopsy is accepted as a normal finding in children. Wright and others found that in childhood controls, the epithelial cell transit time in the crypts was 40% less than in adult controls, and the corrected mitotic index was 20% greater.[14] Thus, in early childhood, the mucosal surface area is reduced, and epithelial cell turnover is greater than in adults. The explanation for these observations is unknown. Because the changes are found in infants of 26 or more weeks gestation who have not been fed,[15] they cannot result from the ingestion of food and bacteria after birth. However, in utero ingestion of amniotic fluid or gastric acid secretions per se may play a role.

Abnormal appearances seen under the dissecting microscope are broadly grouped under two headings: a flat mucosa and a ridged or convoluted mucosa. In both types of mucosa, the normal villous architecture is lost. Mild villous shortening can be difficult to appreciate on dissecting microscopy. Patchy changes in architecture also can be seen with the dissecting microscope.[3]

Proximal intestinal isolated lymphoid follicles can be readily identified by dissecting microscopic study and are more frequent in children between 1 and 2 years old, being uncommon in children older than 6 years of age. Dilated lacteals also may be visible, but they are not indicative of lymphangiectasia in the absence of other clinical features. Endoscopy allows the clear visualization of ileal Peyer patches, which can therefore be selectively biopsied.[16]

Light Microscopy. *Terminology.* Small intestinal biopsy sections are routinely examined with the light microscope after the sections have been stained with HE. Current histologic terminology is unsatisfactory. The earliest reports divided pathologic small intestinal mucosa into subtotal and partial villous atrophy. The former category was characterized by a flat mucosa with thickening of the glandular layer beneath an atrophic epithelium, and the latter was characterized by a less abnormal mucosa. Some authors have further qualified partial villous atrophy with the terms "mild" and "severe." Others have used the term total villous atrophy to describe a flat mucosa. In fact, the mucosa described as either total or subtotal villous atrophy is not a truly atrophic mucosa in that it is not thinner than normal. Currently, most pathologists avoid the terms referred to above and use the term crypt hyperplastic villous atrophy to describe lesions in which villi are shortened and crypts are lengthened. This is the most frequently observed abnormality of the small intestinal mucosa (Figure 69-4). When villous height and crypt depth are approximately equal, this is termed a mild or minor abnormality (Figure 69-4B); a moderate abnormality involves crypt depth greater than villous height (Figure 69-4C), and a flat mucosa (Figure 69-4D) is a severe abnormality. Just as observed under the dissecting microscope, a patchy histologic abnormality may be seen (ie, a patchy enteropathy; Figure 69-5).[3]

It should be recognized that it is possible to find villous atrophy without marked crypt hyperplasia.[17] This may be referred to as crypt hypoplastic villous atrophy; however, crypt dimensions are normal. Thus, a more accurate description is crypt normoplastic villous atrophy. This produces a thin mucosa, and lesions of variable severity are seen (Figure 69-6). It is also possible to see villous hyperplasia with crypt hyperplasia.[18]

Parameters of Analysis. Many parameters of mucosal structure may be appreciated on light microscopic examination. However, classification of the appearance has mainly centered on villous height and crypt depth.

Histologic Normality. A clear idea of what is "normal" is required to evaluate the appearance of the small intestinal mucosa. This is not necessarily easy to determine in childhood because it is not ethical to perform biopsies on healthy children. However, observation of the morphologic features of biopsy specimens in the following situations expands the knowledge of the morphologic features of normal small intestinal mucosa: (1) biopsy specimens from children thought to have GI disease but whose specimens turn out to be normal, (2) control biopsy specimens from children on a gluten-free diet with celiac disease in remission, and (3) postmortem studies of the small intestine from children dying without evidence of GI disease (see Figure 69-4).

It is important to study other aspects of the mucosa along with villous height and crypt depth because these can give specific diagnoses. Aspects to be studied include the following:

- *Organisms*. Look for the presence of luminal, surface-attached, and intramucosal organisms (eg, *G. lamblia*, *Cryptosporidium*, enteropathogenic *E. coli,* and microsporidiosis).
- *Epithelial cells*. Assess the state of the epithelium, in particular the enterocyte, for cell height and degree of vacuolation. The latter finding can indicate abetalipoproteinemia and hypobetalipoproteinemia if extensive vacuolation of villous epithelium is seen in an otherwise normal mucosa. However, this should not be confused with the lesser degree of vacuolation seen in the enteropathies of celiac disease and the postenteritis syndrome. This is usually confined to the villous tip or

to a small number of surface exposed cells in severe enteropathies.[19] Crypt epithelium should be studied for the number of mitotic figures to give an indication of cell production, and the number of goblet cells should be assessed. In some cases of autoimmune enteropathy, a complete absence of goblet cells has been noted.[20] Paneth and endocrine cells also form part of the epithelium, but these are not useful for routine diagnostic purposes. Paneth cell dysplasia can be seen in conditions of increased epithelial cell turnover, and the number of endocrine cells is increased in celiac disease. This can be appreciated by studying histologic sections under fluorescence microscopy because these cells autofluoresce.

- *Intraepithelial cells*. Note the presence and number of migratory, intraepithelial cells, such as lymphocytes, eosinophils, neutrophils, and mast cells. Quantifying

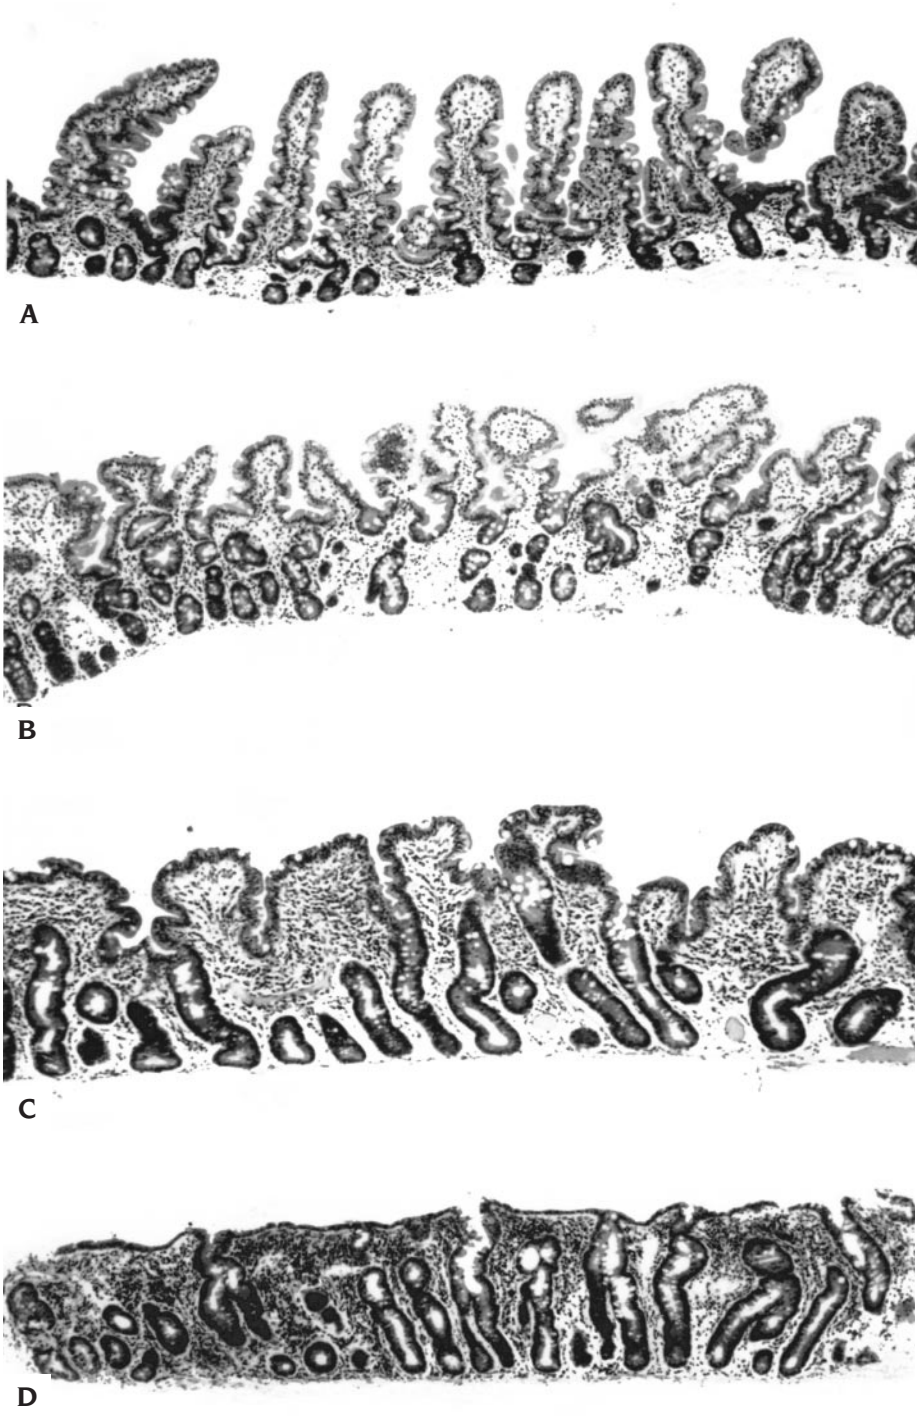

FIGURE 69-4 Light microscopic study: *A*, histologically normal small intestinal mucosa (female infant, 12 months, failure to thrive); *B*, minor enteropathy (female infant, 5 months, chronic diarrhea with failure to thrive); *C*, moderate enteropathy (boy, 6 years 9 months, celiac disease—postgluten challenge); *D*, severe enteropathy (girl, 6 years 10 months, untreated celiac disease) (hematoxylin and eosin; ×60 original magnification).

the density of lymphocytes within the small intestinal villus or surface epithelium (number of lymphocytes per 100 epithelial cells) is of value for routine diagnostic use.[21] Children with normal histologic features (controls) have a mean value of 23,[22] which is similar to that described in adults.[23] Raised counts of intraepithelial lymphocytes (IELs) are found in children and adults with celiac disease, adults with untreated dermatitis herpetiformis or tropical sprue, and some cases of children with unexplained failure to thrive,[21] giardiasis,[21] cryptosporidiosis,[24] or CMSE.[22] IEL counts return to the normal range in cases of celiac disease when the patient is placed on a gluten-free diet, and they become lower than normal in patients with CMSE on a milk-free diet.[22] The absolute number of IEL may not alter with changes in morphologic features[25]; however, IEL density is not directly related to mucosal surface area.[26] Intraepithelial eosinophils have been reported to be increased in CMSE,[17] and intraepithelial neutrophils are seen in inflammatory bowel disease[27] and in EPEC infections[27] but may also occasionally be noticed in active celiac disease.

- *Lamina propria cellularity*. Study the lamina propria for the degree and nature of cellular infiltrate and the appearance of lacteals. This is usually done subjectively, but more reports are making use of readily available computer-based image analysis systems that provide a means of objective analysis. Recognition of basic cell types can be performed on HE-stained sections, but it is important to use immunohistochemical techniques to investigate cell phenotype (eg, lymphocyte subclass; see below) and for secretion of specific cytokines. Mucosal mast cells are best studied using Carnoy solution as a fixative[28,29] and chloroacetoesterase reaction for staining so that they can be clearly seen,[30] although this has limited diagnostic usefulness. Using this technique, Sanderson and others have demonstrated that a higher mast cell density exists in the ileum than in the colon.[31]
- *PAS staining*. This allows the preservation of the brush border to be visualized and demonstrates mucus-

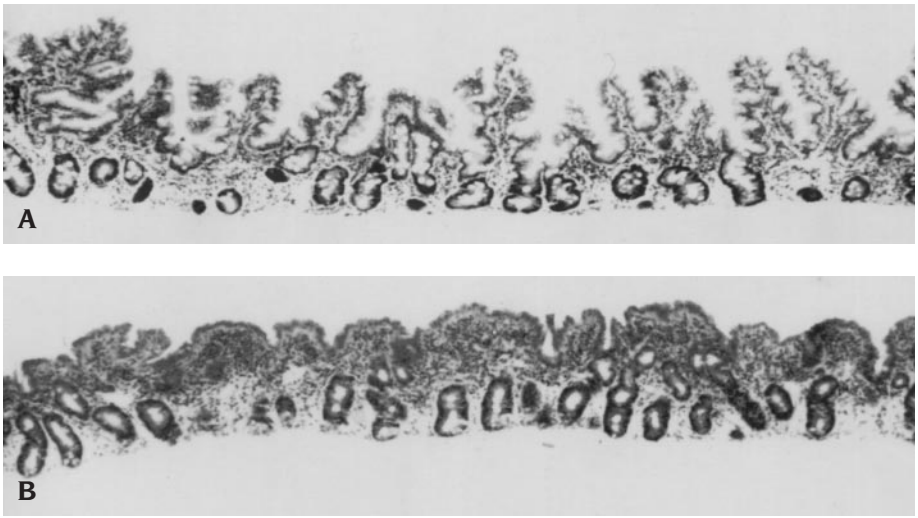

FIGURE 69-6 Light microscopic study: villous atrophy without marked crypt hyperplasia. *A,* Mild enteropathy (female infant, 1 year 7 months, cow's milk protein intolerance). *B,* Moderate enteropathy (male infant, 11 months, cow's milk protein intolerance) (hematoxylin and eosin; ×75 original magnification for both).

containing goblet cells. The presence of PAS-positive material in the apical cytoplasm of upper crypt and low villous epithelial cells indicates microvillous atrophy,[32] although this should not be confused with the granular epithelial staining seen in enteropathies, where it reflects an increased presence of lysosomal bodies. PAS-positive inspissated mucus in crypt lumina suggests cystic fibrosis.[33]

Electron Microscopy. Transmission electron microscopy and scanning electron microscopy have been used to study the morphologic characteristics of small intestinal biopsy tissue taken from children[34] and adults. It is important to consider whether electron microscopy will be of diagnostic value in advance of the biopsy so that glutaraldehyde fixation (2–3% glutaraldehyde in 0.1 M phosphate or cacodylate buffer is suitable) can be used to preserve the tissue samples and optimize interpretation. Ultrastructural studies are now routine in cases of protracted diarrhea. Disorders such as microvillous atrophy (Figure 69-7),[32] attaching and effacing *E. coli* (Figure 69-8),[35] and cryptosporidiosis (Figure 69-9)[24] are diagnostic possibilities. Small intestinal biopsy specimens from patients with acquired immune deficiency syndrome (AIDS) should also be studied by electron microscopic examination because many infectious agents are beyond the resolution of the light microscope (eg, microsporidiosis).

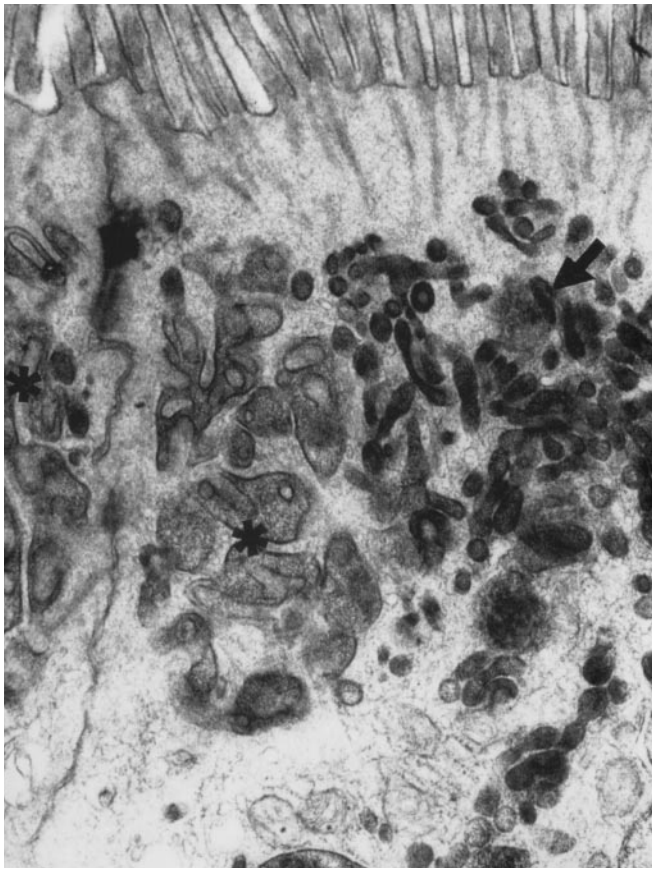

FIGURE 69-7 Electron microscopic study: microvillous atrophy (female infant, 14 months). Increased presence of secretory granules with membrane-bound inclusions containing microvillus-like projections (×40,000 original magnification).

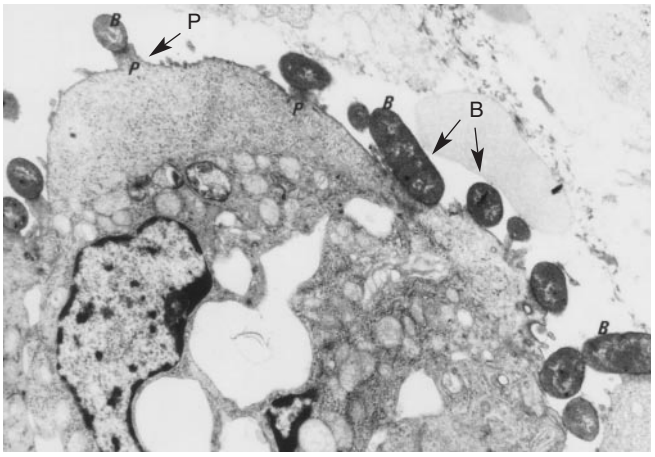

FIGURE 69-8 Electron microscopic study: enteropathogenic enteritis caused by *Escherichia coli* (male infant, 8 months). *E. coli* 0128 (B) attached to apical surface of epithelium in association with microvillous effacement and pedestal formation (P) (×18,000 original magnification).

Biochemistry. A mucosal sample should be taken and frozen for biochemical studies[36] in cases in which primary or secondary disaccharidase deficiencies are diagnostic possibilities. Although enzyme levels can be appreciated on histochemical study of frozen tissue sections[37] or on duodenal juice, the usual practice is to analyze tissue homogenates.[36,38] Breath tests can be used to indicate disaccharide malabsorption,[39] but this is not the same as disaccharidase deficiency. Other techniques are possible and may be required to diagnose rare disorders, such as the use of brush border membrane vesicles to diagnose defective sodium-proton transport.[40]

Immunohistochemistry. Conventional staining techniques give information about intestinal architecture and cellularity without shedding much light on the precise nature of the inflammatory response. All lymphocytes look similar on HE staining, and it is impossible to see whether

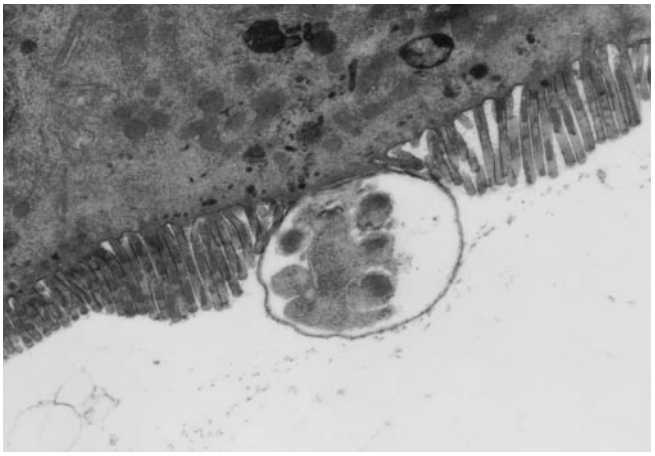

FIGURE 69-9 Electron microscopic study: cryptosporidiosis (male infant, 13 months). Cryptosporidial schizont adhering to the epithelial surface. Notice displacement of microvilli at site of attachment (×18,000 original magnification).

a lymphocyte infiltration represents oligoclonal expansion or a polyclonal response, whether an IEL has a particular T-cell receptor type,[41] or whether evidence exists of epithelial or endothelial inflammatory activation. Special techniques are required to understand disease mechanisms rather than simply describe appearances.

Immunohistochemical analysis may give highly important information in the diagnosis of enteropathy and study of disease mechanism. It is a relatively simple technique to perform, yet it is powerful because of the range of available antibodies that can give precise information on cell lineage, activation status, and functional protein expression. However, access to the full range of diagnostic markers requires the use of snap-frozen tissue because formalin fixation crosslinks tissue proteins and may alter tertiary structure enough to prevent antibody recognition. An important practical point is that any child with an unusual enteropathy should have biopsies snap-frozen at endoscopy in addition to those taken into formalin (ideally, a further biopsy should be taken into glutaraldehyde for possible electron microscopic studies). This is now accepted good practice for any infant with unexplained intractable diarrhea. The widespread use of endoscopic biopsy has removed the problems arising with capsule biopsy of balancing the need for proper histologic assessment and obtaining enough tissue for snap-freezing. Although immunohistochemistry may be considered a research tool for the majority of small bowel enteropathies, it is an important diagnostic aid for conditions such as autoimmune enteropathy, when activated mucosal lymphocytes may be seen in conjunction with class II major histocompatibility complex (MHC) expression (human leukocyte antigen [HLA]-DR) on the surface epithelium.[42] The detection of high numbers of T cells within the epithelium favors the diagnosis of celiac disease in a child with positive serology, even if the mucosa shows only subtle abnormalities otherwise.

Immunohistochemistry has been particularly useful in celiac disease, allowing the recognition of the primary role of lamina propria CD4 cells in the pathogenesis of this condition.[43,44] Immunohistochemical analysis may extend to the detection of secreted molecules such as cytokines, and most of the major immunoregulatory molecules can be demonstrated in this way.

Molecular Biology. Using molecular biologic techniques, it is possible to detect the presence of messenger ribonucleic acid (mRNA) for specific proteins. If whole biopsy specimens are homogenized, specific mRNA can be detected by Northern blotting or reverse transcriptase polymerase chain reaction. Such techniques allow detection and semiquantitative estimation of such small amounts of mRNA but do not allow localization within tissue. The technique is also dependent on expertise, and some centers have found difficulty in differentiating diseased tissue from controls because many cytokines are produced at low levels in healthy intestines and thus may be amplified to apparently similar levels. In contrast, it is possible to localize specific mRNA within individual cells using in situ hybridization, which is technically more difficult but which may also be combined on the same slide with tissue for immunohistochemical study. These techniques are still largely reserved for research, although detection of viral or bacterial pathogens such as cytomegalovirus or mycobacteria may be efficiently achieved.

In general, in situ hybridization requires the use of frozen tissue, although mRNA for some molecules may be detected in formalin-fixed tissue after proteolytic digestion to unmask ribonucleic acid sequences.[45] The use of in situ hybridization in studying intestinal function has been demonstrated best in animal work. The development of class II MHC molecules (required for antigen presentation to T lymphocytes) in mouse small intestinal epithelium was shown to be dependent on the introduction of a complex diet at weaning.[46] The expression of the Na-glucose cotransporter gene was maximal at the crypt-villus junction in rabbits, although the actual enzyme activity was greatest at the villus tip.[47]

The advent of laser capture microdissection now allows molecular biologic analysis of collections of individual cells so that transcriptional activity of discrete cell populations can be achieved.[48] Combined with knockout mouse technology, this has allowed functional genomic analysis of intestinal stem cells,[49] and these techniques promise important advances in understanding gut function.

Lymphocyte Isolation. In addition to the staining techniques available, it is possible to obtain individual inflammatory cells from whole biopsy samples. Epithelial cells and intraepithelial lymphocyte populations can be extracted initially by separation from the rest of the biopsy using ethylenediaminetetraacetic acid (EDTA). Lamina propria lymphocytes may then be obtained by digestion of the remaining tissue with collagenase. If necessary, the lymphocyte subpopulations may be separated further by density gradient centrifugation followed by magnetic bead extraction. Once separated, the inflammatory cells may be categorized on the basis of their surface markers by fluorescent-activated cell sorter analysis,[50] which may also be employed to demonstrate spontaneous cytokine secretion (Figure 69-10). Other techniques include measuring supernatant levels after the cells are stimulated and the use of the enzyme-linked immunospot.[51]

In Vitro Organ Culture Techniques. Although it is not possible to maintain the viability of biopsy tissue for any great length of time, individual explants (approximately 2 mm^2 pieces) will maintain morphologic features for 24 to 48 hours under appropriate culture conditions. Cultured small intestinal explants from celiac patients show improvement in morphologic features if cultured in the absence of gluten,[52] whereas the addition of gliadin fragments upregulates the expression of HLA-DR on epithelial cells in vitro.[53] Short-term culture (8 hours) is of particular value in experimental studies of microbial pathogenesis.[54]

Role of Small Intestinal Biopsy in Diagnosis

Currently a single, investigative, small intestinal biopsy has two main roles that are of value in making a diagnosis in clinical pediatrics. The first is to demonstrate the pres-

ence or absence of a proximal small intestinal enteropathy.[55] Enteropathy may be defined as an abnormality of the small intestinal mucosa that can be demonstrated with the light microscope. The second is to provide samples of small intestinal mucosa for other diagnostic purposes (eg, for disaccharidase assay).

Arranged small intestinal biopsies are sometimes required before a final diagnosis can be made. Such situations include organized dietary challenges with pre- and postchallenge biopsies (eg, in celiac disease or dietary loading), in which diagnostic features may be more easily distinguished (eg, lipoproteinemias, lymphangiectasia).

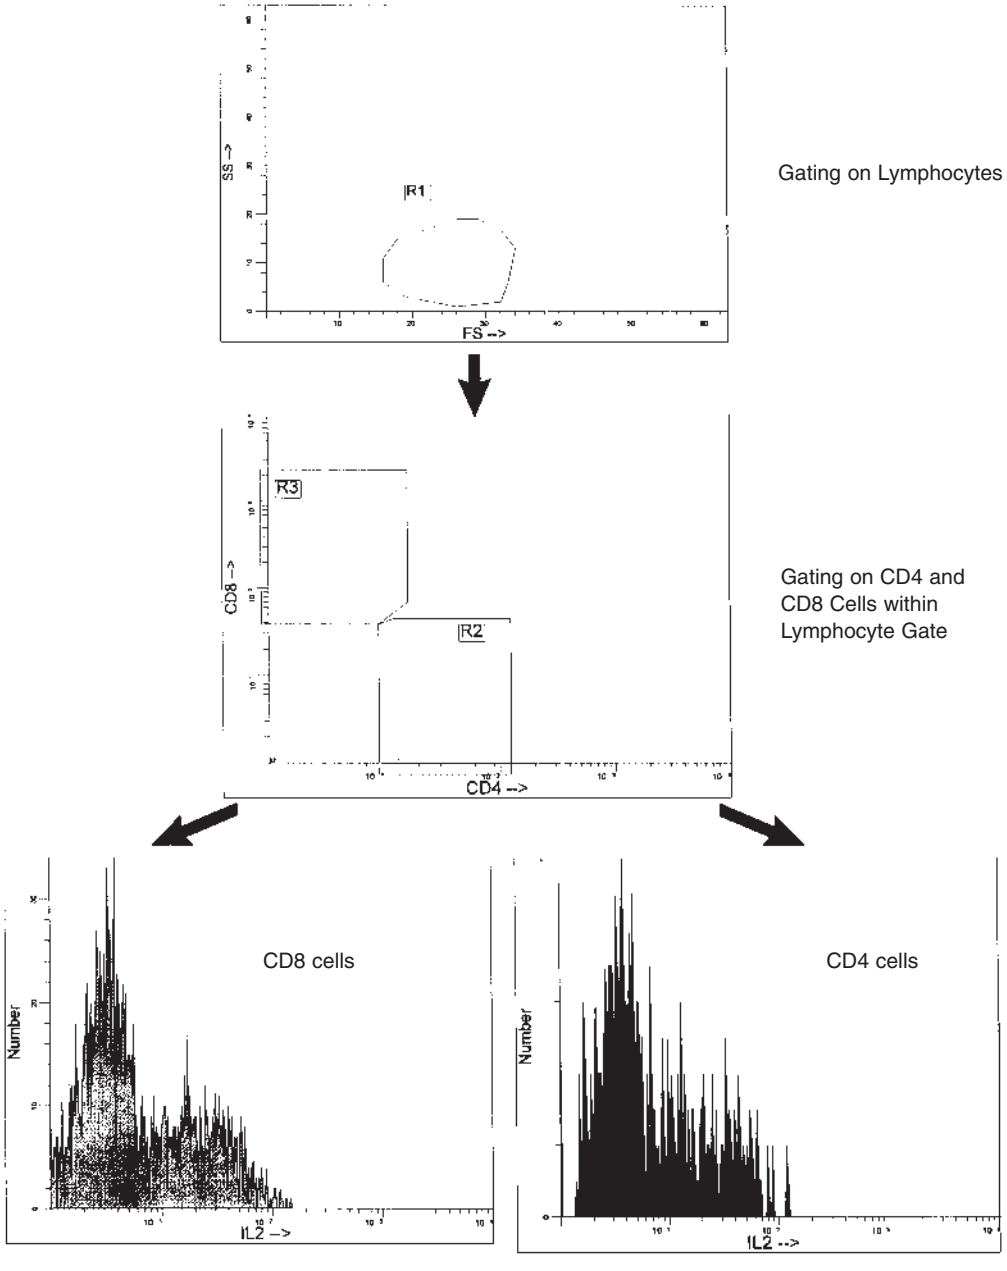

FIGURE 69-10 Fluorescent-activated cell sorter analysis (FACS). Use of flow cytometric (FACS) analysis to determine cytokine production at the single-cell level by mucosal lymphocytes. Intraepithelial lymphocytes may be studied separately from lamina propria lymphocytes, by separation of the entire epithelial compartment using ethylenediaminetetraacetic acid. Lamina propria lymphocytes are separated following collagenase digestion. The lymphocytes are first identified by "gating" on cells of appropriate size and density among the total population. Within that gate, cells expressing CD4 (T helper cells) or CD8 (cytotoxic/suppressor cells) can then be identified using monoclonal antibodies tagged with fluorescent markers—a whole panel of other cell lineage markers can be used if cell numbers and research budgets are adequate. Finally, the proportion of CD4 and CD8 cells spontaneously producing cytokines (here interleukin-2) can be identified.

The current ESPGHAN recommendations for the diagnosis of celiac disease suggest that dietary challenges are not necessary in older patients and that the demonstration of a flat mucosa with a good clinical response to gluten elimination affords a satisfactory diagnosis. However, young children under 2 years of age may require dietary challenge to confirm the diagnosis in view of other possible explanations for enteropathy in this age group.[56]

Those disorders in which small intestinal biopsy has a role in diagnosis may be placed into groups. First, there is a group of disorders for which biopsy is invariably of value in making a diagnosis (Table 69-1). These include disorders in which a proximal small intestinal enteropathy is a diagnostic prerequisite or in which there is a specific enzyme deficiency.

The demonstration of an enteropathy is an absolute requirement for the diagnosis of celiac disease, but it is not specific for this disorder. A flat small intestinal mucosa is characteristic of celiac disease, but there are other causes of a flat mucosa in childhood, and, on occasion, lesser degrees of mucosal abnormality may be found in children with celiac disease.

The enterocyte in abetalipoproteinemia cannot synthesize betalipoprotein, and, as a result, chylomicron formation is impaired. Thus, absorbed dietary fat is not properly mobilized from the enterocyte. As a result, the cytoplasm of those cells lining the upper half or two-thirds of the villi appears vacuolated in ordinary HE-stained sections. These cells can be shown to contain fat through the use of special stains on frozen sections. A similar appearance is seen in hypobetalipoproteinemia.

Children with agammaglobulinemia lack plasma cells in the lamina propria, but the mucosal architecture may range from a flat mucosa to a completely normal one.

In the enteropathy associated with multisystem autoimmune disease and the presence of circulating autoantibodies (autoimmune enteropathy) (Figure 69-11), the mucosa is severely abnormal at the time of diagnosis, sometimes with a flat mucosa. The demonstration of an enteropathy in the presence of circulating autoantibodies against the enterocyte in a child who has chronic diarrhea is essential for diagnosis of this syndrome. It is very important to do in-depth immunologic studies in these children to help identify therapeutic options.[20]

Microvillous atrophy can be diagnosed only by the demonstration of characteristic microvillous inclusions and an increase in secretory granules on electron microscopic examination of a small or large intestinal mucosal biopsy specimen.[32,57,58] An abnormal accumulation of PAS-positive material occurs within the apical cytoplasm of epithelial cells and corresponds to the increase in secretory granules seen on electron microscopic study.[32,57]

The presence of adhering bacteria can be seen on light microscopy; however, the resolution of transmission electron microscopy is required to recognize the microvillous loss and pedestal formation of the attaching and effacing lesion, which is typical of classic EPEC infections (see Figure 69-8).[35] EPEC infections are capable of causing severe protracted diarrhea and much morbidity and mortality. The recognition of an enteropathy with the presence of attaching– and effacing lesion–forming bacteria indicates that antibiotic therapy would be appropriate.[59] This is important because nonclassic serotypes of *E. coli*, so-called atypical *E. coli*, also can cause an attaching and effacing lesion,[60] and routine stool microbiologic study would not identify them.

Children who have either of the two primary disaccharide intolerances, namely congenital alactasia and sucrase-isomaltase deficiency, have normal small intestinal morphologic features, but the characteristic enzyme deficiencies are present on disaccharidase assay.

Second, when the lesion is nonuniform (ie, patchy) or when there is penetration of the mucosa by a parasite, biopsy may provide a specific diagnosis, but in this group of disorders, the absence of abnormality (ie, a normal mucosa) does not exclude the diagnosis (Table 69-2). It is possible in parasitic situations and infections with attaching and effacing *E. coli* that a more distal site of the intestine is affected, and the diagnosis is made on stool microbiology.

The trophozoite of *G. lamblia* is often found in the duodenal juice of children with giardiasis but also may be found on section of small intestinal biopsy specimens. Similarly, in children with strongyloidiasis, larvae of *Strongyloides stercoralis* may be found in juice and on section of the mucosal biopsy specimens. Cryptosporidial schizonts may just be visible by light microscopic study, but the characteristic morphologic features are readily identifiable by electron microscopic examination.

Small intestinal lymphangiectasia may be diagnosed by biopsy of the small intestinal mucosa, but because the lesion is often patchy, it can be missed on a single biopsy; multiple biopsies may be indicated.

Small intestinal lymphoma are rarely diagnosed by biopsy if the lesion has invaded the mucosa.

Children with hypogammaglobulinemia may be found to have hyperplastic lymphoid follicles on small intestinal biopsy, as well as a diminished number of plasma cells and variable morphologic abnormalities. *G. lamblia* is often found in the duodenal juice of such children.

Third, in another group of disorders in which the lesion may also be patchy, the demonstration of an enteropathy is nonspecific (Table 69-3). However, the finding of mucosal abnormality is diagnostically useful in such patients because it indicates the presence of disease in the small intestine. Some disorders in this group (eg, CMSE) may be diagnosed by serial biopsy related to dietary protein withdrawal and challenge, although no pathologic fea-

TABLE 69-1 DISORDERS IN WHICH BIOPSY IS VALUABLE

tures are specific for this disorder. It is unusual to perform challenges in CMSE, and diagnosis rests on a clinical response to an elimination diet with a return to normal histologic features before the reintroduction of cow's milk, when it is considered that the disease has resolved. AIDS must be added to the list of nonspecific abnormalities.

Finally, for completeness, a group of disorders in which small intestinal biopsy specimen is characteristically normal is listed in Table 69-4.

To conclude this section on the role of small intestinal biopsy in diagnosis, it is important to briefly review the diagnostic approach to a child thought to have small intestinal disease. This is summarized in Table 69-5.

The emphasis is not on demonstrating malabsorption (eg, steatorrhea or xylose malabsorption), as formerly was the case, but on pinpointing an anatomic abnormality of the small intestine, a structural abnormality of the small intestinal mucosa (ie, an enteropathy), or a specific infectious etiologic agent. Thus, barium studies, small intestinal biopsy, and stool examination are particularly important investigative tools. Hematologic investigations, such as a full blood count and serum folate levels, provide important evidence of a deficiency state that may need to be treated immediately or followed up as a marker of response to treatment. Radiologic studies are particularly important for diagnosing Crohn disease and congenital anatomic lesions of the small intestine.

LARGE INTESTINAL BIOPSY

Large intestinal pathology can be investigated using a variety of different types of biopsies of the bowel. For mucosal disease, mucosal biopsies taken during fiberoptic colonoscopy are employed. Suction rectal biopsies are suitable for the diagnosis of aganglionosis (Hirschsprung disease), but for other enteric neuromuscular diseases, full-thickness or seromuscular biopsies are required.

TABLE 69-2 DISORDERS IN WHICH BIOPSY MAY BE VALUABLE DIAGNOSTICALLY

Giardiasis
Strongyloidiasis

MUCOSAL BIOPSY TAKEN AT FIBEROPTIC COLONOSCOPY

Since its introduction in the early 1960s, the value of fiberoptic colonoscopy as a diagnostic procedure in adult patients has become well established. It is now clear that this is also a very useful technique in pediatric practice. One of its most useful aspects is in the provision of multiple large intestinal mucosal biopsies. The ileum can be entered in over three-quarters of cases with an experienced endoscopist,[61] affording an opportunity to assess the intactness of the mucosa and to study ileal histology. The availability of pediatric colonoscopy is restricted to pediatric gastroenterologic centers and is dependent on the availability of endoscopy skills. When these are available, this approach has largely overtaken the need for barium enema examination in the investigation of rectal bleeding and suspected chronic inflammatory bowel disease.[62]

The value of histologic assessment following full colonoscopy has been evaluated in the investigation of children when first presenting with inflammatory bowel disease.[61] Diagnosis of inflammatory bowel disease on morphologic criteria is possible in 85% of cases. Although sigmoid colonic and rectal biopsies can also confirm the diagnosis of inflammatory bowel disease in 65% of cases, over one-third would have been assigned to the wrong diagnostic category on the left-sided findings alone. This is particularly relevant in pediatric patients whose right colon is often affected without involvement of the rectosigmoid. Limited examination will also miss ileocecal Crohn disease and may miss multiple polyps. However, when colonoscopy is not available, rigid sigmoidoscopy must be used to obtain colonic and rectal biopsies.

The principal purpose of obtaining intestinal colonic biopsies in this context is for the diagnosis of chronic inflammatory bowel disease and Crohn disease in particular.

TABLE 69-3 DISORDERS IN WHICH BIOPSY RESULTS MAY BE ABNORMAL BUT ABNORMALITY IS NONSPECIFIC

Postenteritis syndrome	Tropical sprue
Cow's milk protein intolerance	Radiation enteritis
Transient-gluten intolerance	Drug-induced lesion, eg, by methotrexate
Soy protein intolerance	Protein-energy malnutrition
Intractable diarrhea syndrome	AIDS

TABLE 69-4 DISORDERS IN WHICH BIOPSY FINDINGS ARE NORMAL

Cirrhosis
Hepatitis
Exocrine pancreatic insufficiency
Toddler's diarrhea

However, there are other reasons, and Table 69-6 lists the indications for fiberoptic colonoscopy in children. The technique of colonoscopy is detailed in Chapter 67, "Gastrointestinal Endoscopy," and is not detailed here. An important diagnostic benefit from colonoscopy is the recognition of microscopic colitides that are apparent not on gross observation but only following histologic assessment of biopsies.

In recent years, rectal suction biopsy containing sufficient submucosa has replaced full-thickness biopsy for the diagnosis of Hirschsprung disease. This cannot be taken at routine colonoscopy and requires a special biopsy apparatus.[63] Full-thickness rectal biopsy or laparoscopic colonic seromuscular biopsies may still be required for the diagnosis of disorders involving the myenteric plexus or muscularis propria.[64–66]

Disorders Diagnosed by Large Intestinal Biopsy in Childhood

These disorders may be broadly grouped into inflammatory disorders and motility disorders. A general schematic approach to assessment of mucosal biopsies is recommended.[67] Questions to be asked are (1) if the tissue is normal or abnormal and (2) if changes suggest chronic inflammatory bowel disease whether they favor Crohn disease or ulcerative colitis. Alternatively, it is important to ask if the inflammation suggests an acute infective etiology or another form of inflammation, such as chronic granulomatous disease,[68,69] allergic colitis, tufting enteropathy involving the large bowel,[70] or intractable enterocolitis of infancy.[71]

In mucosal disease, the diagnostically important features to be assessed are the overall architecture, the cellularity of the lamina propria, the presence of a polymorphic neutrophilic or eosinophilic infiltrate, and epithelial changes. The histologic diagnosis of chronic inflammatory bowel disease in children specifically has been reported.[72,73] The principal features of histologic diagnosis are outlined below.

Mucosal Inflammatory Disorders. *Ulcerative Colitis*. This is a chronic intermittent disease that affects the large bowel mucosa. It is possible to make a suggested histopathologic diagnosis from biopsies taken at the initial presentation. Confident biopsy diagnoses can certainly be made in established disease. Sequential biopsies form part of the diagnostic workup and also monitor activity after treatment; symptomatic improvement may not be accompanied by endoscopic or histologic mucosal healing.[74] Ulcerative colitis usually commences in the rectum and may extend to involve the rest of the colon. Often inflammation may be absent or patchy in the rectum or sigmoid, particularly in the pediatric population.[75] Both the clinical picture and the histopathology may be considered in terms of three phases: active, resolving, and in remission (quiescent).[76]

TABLE 69–5 DIAGNOSTIC APPROACH TO CHILDREN THOUGHT TO HAVE SMALL INTESTINAL DISEASE

Initial assessment
Detailed case history
Physical examination
Analysis of centile charts for height and weight
Initial investigations
Full blood count and erythrocyte sedimentation rate in older child (? Crohn disease)
Serum and red cell folate
Antigliadin and antiendomesial antibodies
Stool culture for bacteria
Stool electron microscopy for viruses
Stool examination for *Giardia lamblia* and *Cryptosporidium*
Stool-reducing substances
Next stage
Small intestinal biopsy
Duodenal juice examination for *G. lamblia*
Bacterial culture for bacteria (anerobic and aerobic as indicated)
Barium follow-through
Gut autoantibodies
Response to elimination diet

Active Phase. The most specific feature is loss of crypt architecture with crypt distortion and branching (Figure 69-12). Polymorphonuclear neutrophils are present within the crypt epithelium, and there may be crypt abscesses (Figure 69-13). The epithelium shows varying amounts of degeneration and regeneration. There is mucin depletion and increased mitotic activity. The lamina propria shows capillary congestion and edema; it contains a heavy mixed inflammatory cell infiltrate. This is diffuse throughout the lamina propria and is composed of plasma cells, lymphocytes, and neutrophils. Eosinophils are also found and may be prominent, although the significance of this in relation to the natural history is not fully clear. Inflammatory cells may also be found in the submucosa; this may be associated with severe ulceration.

Resolving Phase. An important feature of ulcerative colitis is the fact that the biopsy appearances vary with time. In the resolving phase, the crypts remain distorted and branched; the surface may take on a villous appearance. Goblet cells reappear in the crypts but may be elongated. Inflammation in the lamina propria is reduced and may become focal; there is then a possibility of confusion with other disease, such as Crohn disease. There are few polymorphs at this stage.

TABLE 69-6 INDICATIONS FOR PROCEEDING TO FIBEROPTIC COLONOSCOPY IN THE PEDIATRIC PATIENT

Unexplained rectal bleeding
Bloody diarrhea in the absence of stool pathogens (with or without abdominal pain)
Abdominal pain associated with weight loss (with or without diarrhea)
Other features suggesting a diagnosis of chronic inflammatory bowel disease (eg, strictures, fistulae, disease activity extent as a guide to therapy)
Surveillance for malignancy (long-standing ulcerative colitis, polyposis coli, Peutz-Jehgers syndrome, Gardner syndrome)
Polypectomy

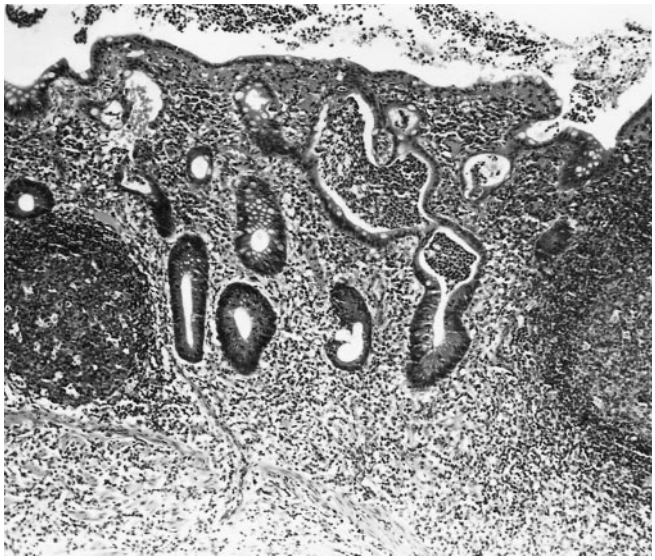

FIGURE 69-12 Chronic ulcerative colitis, active phase. Crypts are distorted and show mucus depletion; several contain neutrophils resulting in crypt abscesses. There is diffuse inflammation of the mucosa. Lymphoid follicles are also present (hematoxylin and eosin; ×100 original magnification).

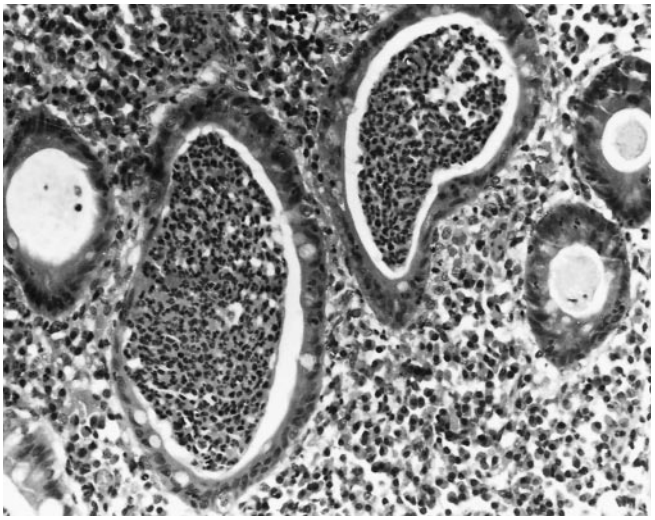

FIGURE 69-13 Chronic ulcerative colitis, active phase. High-power view showing crypt distortion, mucus depletion, and crypt abscesses. There is diffuse inflammation in the lamina propria (hematoxylin and eosin; ×250 original magnification).

Remission Phase. Here the crypts are atrophied and distorted. There is a gap between the muscularis mucosae and the crypt bases. Goblet cells are present, but there may be Paneth cell metaplasia and increased numbers of crypt endocrine cells.[77–79] There is no active inflammation; neutrophils are therefore absent.

Inflammatory Polyps (Pseudopolyps). These consist of granulation tissue, a mixture of glands and granulation tissue, or a tag of virtually normal mucosa. They are a frequent finding and indicate prior severe mucosal ulceration with irregular healing. Biopsy allows them to be distinguished from neoplastic polyps (adenomas).

Fulminant Acute Dilatation. This has been recorded in up to 13% of patients with ulcerative colitis in the early adult literature[80,81] but is probably much lower in pediatric practice today. The rectum is relatively spared, and the transverse colon is most severely affected. There are several misleading features in biopsies in this condition: inflammation may be transmural, and there may be fissuring ulceration; the crypt architecture is often intact, and inflammation may be mild.

Follicular Proctitis. Prominent lymphoid follicles are present, and there is an accompanying diffuse infiltrate of plasma cells and neutrophils. These features cause thickening of the mucosa. The crypt architecture is irregular. The differential diagnosis in this condition includes lymphoid polyps, malignant lymphoma, and lymphomatous polyposis.

Crohn Disease. Crohn disease may affect any part of the GI tract,[82–86] but most commonly it presents as regional ileitis,[87] ileocolitis, colitis, or perianal disease. It is characterized by its focal distribution and, unlike ulcerative colitis, often involves the full thickness of the bowel wall. The endoscopic appearances form an important part of the diagnosis in Crohn disease. The features include tiny aphthoid ulcers,[88] serpiginous ulceration, edema, linear ulceration ("cobblestoning"),[89,90] and, occasionally, inflammatory polyps. Areas of normal mucosa appear between abnormal areas and are thus termed skip lesions. Anal lesions consist of painless fissures, ulcers, fistulae, skin tags, and perianal abscesses.[91]

The crypt architecture and goblet cell population are usually preserved despite considerable inflammation (Figure 69-14).[92,93] However, there may be some crypt distortion close to areas of ulceration; such distortion may also occur in the early healing phase.[94] The inflammatory cell component consists of a mixture of lymphocytes, plasma cells, and polymorphs; their density varies across the biopsy.[95] Neutrophils are less conspicuous and more focal than in ulcerative colitis or infectious colitis, but crypt

FIGURE 69-14 Rectal biopsy in Crohn disease. There is chronic inflammation in the lamina propria, but crypt architecture is well preserved (hematoxylin and eosin; ×100 original magnification).

abscesses may be found.[96] Small aggregates of lymphocytes occur adjacent to crypt bases.[97] Granulomas are also found; these are composed of collections of epithelioid histiocytes, multinucleate giant cells, and, frequently, a cuff of lymphocytes (Figure 69-15).

Granulomas occur throughout the bowel wall in Crohn disease and may be seen in both inflamed mucosa and endoscopically normal mucosa.[72,73,98] Microgranulomas consisting of clusters of histiocytes and small numbers of inflammatory cells also occur.[98] Confluent granulomas with florid central necrosis suggest a diagnosis of tuberculosis; however, a small focus of central necrosis may be seen in granulomas in Crohn disease.

The incidence of granulomas in biopsies is variable, and published figures in adults range from 0 to nearly 30%.[99–105] In the pediatric population with Crohn disease, epithelioid granulomas have been reported to be present in 36%[71] and 44%.[61] This is clearly an underestimate and is a question of sampling because in an analysis of 17 operative specimens from children with Crohn disease, 14 had noncaseating granulomas (82%) (see Figure 69-15).

Other features of biopsies in Crohn disease include aphthoid ulcers; these are seen as small areas of ulceration immediately over a lymphoid follicle.[97] Fissuring ulcers also occur; they penetrate down through the submucosa and are characteristic of Crohn disease. Fibrosing stenoses may also be found.[102] The muscularis mucosa may appear thickened.[103]

Biopsies in Crohn disease should include a portion of the superficial submucosa: this will often show "disproportionate inflammation"[94] with a mixed inflammatory cell infiltrate. This reflects the transmural nature of the inflammatory process in the disease. Granulomas in the submucosa are helpful in the diagnosis. The following features are considered to be the most helpful in the diagnosis of Crohn disease when granulomas are absent: the patchy nature of the inflammation, relatively little crypt distortion or goblet cell depletion, and the presence of basal lymphoid aggregates. Unfortunately, aphthoid ulceration and fissures are rare in biopsies.

No studies have yet been able to correlate specific features with disease activity.[104] As already mentioned, granulomas may occur in normal-appearing mucosa. Fibrosis in the submucosa and splitting up of the muscularis mucosae indicate long-standing disease. Granulomas have been claimed to indicate a favorable prognosis,[105,106] but not all studies are in agreement with this.[107,108] Ulceration and fissuring have been claimed to be indicative of a poor prognosis.[109] Overall, there appears to be no universally accepted prognostic microscopic feature.[94,110]

Infective Colitis. Infective colitis may be classified etiologically into bacterial, viral, protozoal, and fungal infections and infestation by helminths. The bacterial diarrheas cause the vast majority of diagnostic problems. *Salmonella* species, *Shigella* species, enteroinvasive *Escherichia coli*, and *Campylobacter* species may also produce similar histopathologic appearances, which have been termed infective biopsy pattern (Figure 69-16). It is important to be familiar with these histologic features so that patients with infectious disease are not mislabeled as having ulcerative colitis or Crohn disease. History of foreign travel is important to suggest more exotic infections; other clues may be the presence of numerous eosinophils or granulomas.

It is not usually possible from a biopsy to distinguish among the main causes of bacterial colitis.

Examination of the biopsy specimen indicates that the mucosa is widened by edema. Clusters of polymorphs are present throughout the biopsy but particularly in the more superficial portion and often adjacent to dilated capillaries or next to crypts. Polymorphs may be present between the crypt epithelial cells, and although crypt abscesses occur, they are less common than in active ulcerative colitis or Crohn disease.[111] Clusters of polymorphs also infiltrate

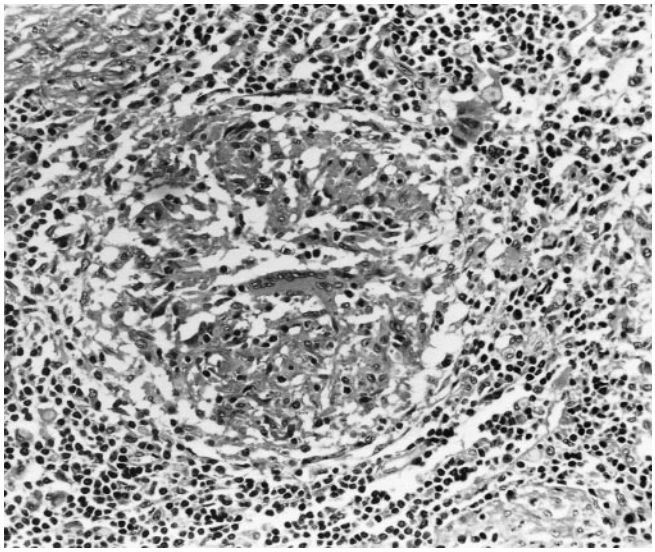

FIGURE 69-15 Crohn disease. A noncaseating granuloma in the submucosa (hematoxylin and eosin; × 250original magnification).

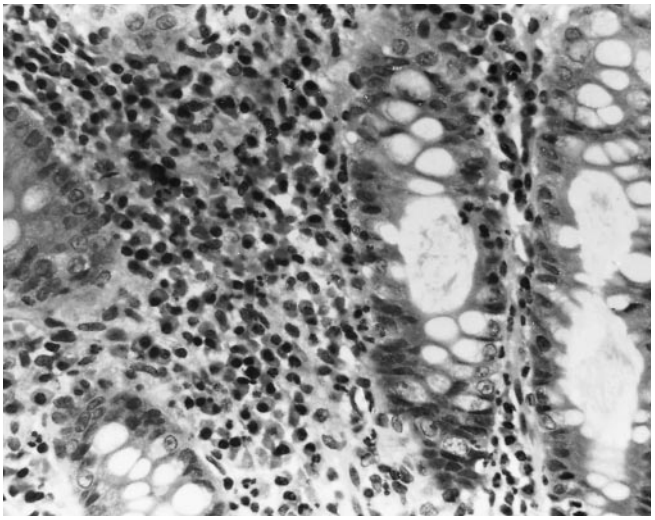

FIGURE 69-16 Infective colitis (*Campylobacter*). High-power view of a rectal biopsy showing patchy inflammation with neutrophil polymorphs in the lamina propria. One crypt is infiltrated by neutrophils (hematoxylin and eosin; ×400 original magnification).

between the cells of the surface epithelium. Although plasma cells and lymphocytes may be increased, this is often masked by edema, and polymorphonuclear neutrophils dominate the picture (see Figure 69-16).

The crypt pattern is regular, although the superficial crypt epithelium may show degenerative changes, and there is dilatation of luminal parts of the crypts (crypt "withering").[112,113] Mucin depletion and flattening of epithelial cells are also seen. Crypt destruction may be marked by a multinucleate giant cell. Other less specific abnormalities include luminal pus, margination of polymorphs, and capillary microthrombi.[114]

The above description represents a characteristic pattern and is most common in biopsies taken at the onset of symptoms or within the first 7 days.[112]

Differential Diagnosis of the Major Inflammatory Bowel Disease Entities. No single specific histologic feature is invariably present in one condition or absent from the others.[67] The concept of a spectrum of histologic appearances in chronic inflammatory bowel disease in childhood is useful and convenient for practical assessment.[72] This is particularly true in the early histologic appearance of children with Crohn disease when the definitive criteria may not be present. From the point of view of histologic assessment, particularly of mucosal biopsies, which are small in size, the histopathologist is faced with an apparent range of inflammatory changes falling within a continuous spectrum. This approach is not intended to imply that inflammatory bowel disease is generally a continuous spectrum of a single disease but reflects the difficulty of making a confident diagnosis by extrapolation from a very restricted sample of the organ in question. Although some findings may be highly suggestive of a particular diagnosis, in one study of children at first presentation of their illness, approximately one-third showed morphologic features suggestive of both conditions[61]—in particular, diffuse active chronic coloproctitis with crypt distortion suggestive of ulcerative colitis but also with granulomas and/or ileal disease too excessive for a backwash ileitis. It is not yet clear if these children will have a different natural history.

Key features of the various disorders are the following:

- *Ulcerative colitis*. There is crypt distortion, villous surface, goblet cell depletion, prominent crypt abscesses, and diffuse predominantly plasma cell infiltrate of the lamina propria.
- *Crohn disease*. Granulomas are present (25–28% of biopsies). Crypts remain well aligned with little mucin depletion despite a moderate inflammatory cell infiltrate. The infiltrate is often patchy. Basal lymphoid aggregates are helpful. Crypt abscesses and cryptitis are less constant than in ulcerative or infective colitis. There are microgranulomas (focal collections of inflammatory cells including histiocytes) and definite patchy inflammation.
- *Indeterminate colitis*. Although this term was first used in the histologic assessment of colectomy specimens, it has now gained general acceptance for mucosal biopsies.[67,72,115] It is used when features of chronic inflammatory bowel disease are present, but distinction as to type is not possible.
- *Infective colitis*. Crypts remain aligned but show degeneration. Polymorphs are the most conspicuous inflammatory cells; they cluster in the lamina propria and migrate between crypt epithelial cells, particularly in the superficial mucosa. Plasma cell infiltrate is light to moderate. Edema is prominent.

Other Recognized Abnormalities. The most common abnormality under this heading is a cellular infiltrate in the lamina propria with regular crypt architecture and variable goblet cell depletion. In some biopsies, a focal polymorph infiltrate in the lamina propria may be seen. A mild increase in plasma cells and lymphocytes may be an accompanying feature. The changes can be interpreted only after consideration of the clinical data (eg, Crohn disease may be suggested if there is evidence of disease at another site).[94] Some specific features that can easily be overlooked include the following:

1. *Microgranulomas in Crohn disease*.
2. *Spirochetosis*. This represents infection of colorectal epithelium by spirochetes that belong to the genus *Borrelia*. Histologically, this is seen as a basophilic fringe along the apical border of surface epithelial cells. It is not clear whether infection produces symptoms.
3. *Amoebae*. *Entamoeba histolytica* may cause large intestinal infection, which may closely resemble chronic inflammatory bowel disease in childhood.[116] Ulcers occur, which may result in perforation of the bowel wall. Amoebae are found on or just beneath the surface of ulcers, but in severe cases, they enter the inflamed bowel wall and may be seen within blood vessels. Diastase-PAS is a useful staining method for demonstrating them in histologic preparations.
4. *Cytomegalovirus*. This viral infection may occur in immunosuppressed children both in disease states such as AIDS or following organ or bone marrow transplant. Inclusions occur in endothelial cells, fibroblasts, and macrophages. More rarely, they are found in epithelial cells. Immunocytochemistry and polymerase chain reaction will increase the sensitivity of viral detection within the tissue.
5. *Chronic granulomatous disease*. This rare disorder is characterized by recurrent infections with catalase-positive organisms; the patients' neutrophils are unable to kill the organisms. Gastrointestinal involvement is well recognized; there may be narrowing of the gastric antrum owing to local granulomas, and perianal fistulae may occur. Clinically, the disease may mimic Crohn disease or tuberculosis, especially when there is ileal involvement with intestinal obstruction.[117,118] Histologically, the appearances consist of paucity of neutrophils and the presence of mainly eosinophilic inflammatory infiltrate, eosinophilic crypt abscesses, and pigmented (often reddish crystalline inclusions) macrophages in

the lamina propria of the mucosa.[68,69] Granulomas, if present, are exuberant

6. *Allergic colitis*. One manifestation of food protein allergies, in particular with cow's milk protein intolerance, is diarrhea and abdominal pain; perianal disease and constipation have also recently been reported.[119] Changes may be seen in the esophagus and duodenum and also within the colon. On endoscopy, the mucosa may appear edematous; histology shows intact architecture but large numbers of eosinophils in the lamina propria. Eosinophils may also show degranulation or infiltrate the crypt and surface epithelium.
7. *Microscopic colitis*. Histologic assessment allows separation into collagenous (a thickened [> 10 μm] collagenous band under the surface epithelium) and lymphocytic (increased intraepithelial lymphocytes) variants. Both are more common in adults and are associated with watery chronic diarrhea. This condition stresses the importance of performing biopsies in the absence of overt endoscopic abnormalities.
8. *Autism-associated colitis*. A number of children with autism and nonspecific GI symptoms have been described in whom there have been changes on endoscopy and on histology. This has included prominent lymphoid hyperplasia within the ileum and very focal active inflammation with more widespread chronic inflammation within the colon and rectum. The features are not thought typical for inflammatory bowel disease, but the findings have met with some controversy.[120]
9. *Intractable ulcerating enterocolitis of infancy*. This form of familial disorder was first described over a decade ago by Sanderson and colleagues.[71] The onset of disease is within the first few months from birth, and the condition responds poorly to immunosuppressive therapy requiring colectomies. Histologic appearances include deep well-circumscribed ulcers, which penetrate into the submucosa and reach even the muscularis propria. The mucosa between the ulcers shows only a mild increase in chronic inflammatory cells. The condition is associated with Epstein-Barr virus–related lymphoid proliferations, and patients can develop B-cell lymphomas (A. D. Ramsay, personal communication, July 2003).

Disorders of Motility

These are due to abnormalities in the enteric nervous system or defects in the enteric musculature, resulting in functional intestinal obstruction. Of these, Hirschsprung disease is the most common, with an incidence of about 1 in 4,500 live births. The condition results from congenital aganglionosis (absent enteric nervous system) of a variable length of distal bowel but can affect the entire colon and extend to involve the small intestine and beyond.[121]

Care should be taken with the use of the term intestinal neuronal dysplasia because it means different things to different people.[122]

Other neural disorders include hypoganglionosis and hyperganglionosis. The latter may be seen proximal to the aganglionic segment in some patients with Hirschsprung disease.[123] Only aganglionosis can be diagnosed on a suction rectal biopsy. For the diagnosis of hypo- or hyperganglionosis, the myenteric plexus must be examined.[124]

Suction Rectal Biopsy. *The Biopsy.* Ideally, three biopsies should be obtained 2 to 5 cm above the pectinate line and should include macroscopically obvious submucosa. The middle biopsy is processed into paraffin wax for 150 HE-stained 3 to 4 μm–thick serial sections to allow identification of any neurons present. A large number of sections must be examined to ensure that no neurons are missed even if the biopsy is taken from the physiologically hypoganglionic segment of the lower rectum.[125]

The other two are snap-frozen and cryostat sectioned alternately for HE (5–7 μm thick) and "spares" (10–12 μm thick). Two of the spares that include the most submucosa are incubated for acetylcholinesterase (AChE) activity by the standard method[126] or if the result is required urgently by the rapid method.[127]

In the case of an obstructed neonate, there is an urgency to confirm or exclude the diagnosis of Hirschsprung disease. The biopsies are usually taken not far from the dentate line. In this instance, the biopsies are snap-frozen, and serial cryostat sections are cut immediately and stained for HE. If no neurons are identified and the sections contain mucosa, muscularis mucosa, and submucosa, adjacent sections are cut and incubated for AChE activity initially using the rapid method. If the result is ambivalent, the standard method is applied on further sections. The remainder of the biopsy is fixed and processed into paraffin wax, and, subsequently, serial sections (as above) are cut and stained for HE.

Histologically normal rectal biopsy contains clusters of neurons in the submucosa in contrast to one from a patient with Hirschsprung disease, which has no neurons but has enlarged submucosal nerve trunks. However, biopsies taken from the physiologically hypoganglionic lower rectum close to the anal canal also have large nerves, particularly in association with large blood vessels. In this situation, one must not attempt to make the diagnosis of Hirschsprung disease. Of course, if an obvious neuron is found, then the diagnosis can be excluded. It is always wise to state, "Hirschsprung disease is excluded at the level examined" because the biopsy may have been taken above the aganglionic segment. Is not possible to know accurately how far from the anal verge the biopsy comes. On occasion, surgeons claim that the biopsy was performed at least 5 cm from the dentate line, but on histology, the biopsy contains anal skin instead of rectal mucosa.

AChE *Activity.* AChE-positive fibers are sparse and fine in the muscularis mucosae and lamina propria of the mucosa in normal rectum. There are, however, variations within normal limits. In Hirschsprung disease, at any age, there is an obvious increase in thick, knotted, crossing AChE-positive fibers in the muscularis mucosae and thick nerves in the submucosa, with no neurons present. With experience, it is possible to distinguish neurons from nerves on the AChE preparation, but it is safer to rely on the HE to do this. In an older baby with Hirschsprung disease, there is also an increase in the lamina propria in thick

AChE-positive fibers, which run not only vertically but also horizontally.

If no obvious neurons are found in the HE-stained cryostat section and the AChE pattern is not typical of Hirschsprung disease, it is vital to examine the 150 serial paraffin sections to be certain that the specimen is indeed aganglionic.

In rare cases of total colonic aganglionosis, AChE preparation may not be helpful. In these patients, there is no increase in AChE-positive fibers, and thick submucosal nerve trunks may also be absent. As many as possible serial HE-stained paraffin sections must be examined to identify any neurons present.

***Age of the* Patient.** In the newborn, the submucosal ganglia appear as small clusters of immature neurons, which are less easy to recognize than the larger neurons in an older baby or a child on an HE-stained section. Not differentiating the hematoxylin before the eosin helps, and if no neurons are seen, examination of the AChE pattern in the muscularis mucosae allows correct diagnosis.

Intestinal Ganglioneuromatosis. One serious condition one should be aware of is transmural intestinal ganglioneuromatosis. These appearances can be evident in the submucosa even in a suction rectal biopsy and consist of profound proliferations of neural tissue (neurons, supporting cells, and nerves) that appear as thickened nerve trunks embedded with mature nerve cells. If there is a suspicion of ganglioneuromatosis, this warrants further investigations to exclude multiple endocrine neoplasia type IIB (MEN IIB). This involves germline M918T and/or A883 F mutation analysis of the *RET* proto-oncogene.[128] Children with intestinal ganglioneuromatosis and the above-mentioned molecular diagnosis of MEN IIB inevitably develop medullary thyroid carcinoma. In our experience, monitoring the calcitonin concentrations and scanning for adrenal and thyroid masses are not sufficient because microscopic medullary thyroid carcinoma can be present without raised calcitonin concentrations, even with pentagastrin stimulation or without identifiable masses on imaging. A prophylactic thyroidectomy is recommended, as well as continued surveillance of the adrenal glands for evidence of pheochromocytoma.

Full-Thickness Intestinal and Seromuscular Biopsies. Identification of other intestinal neuromuscular disorders cannot be made on suction rectal biopsies. These require larger full-thickness bowel samples taken at the time of raising a stoma. However, seromuscular biopsies, if well oriented and of sufficient size, may be helpful in some myopathic disorders (fibrosis and/or abnormal contractile protein profile),[129] especially when using special stains and immunohistochemistry and acquired inflammatory conditions (ganglionitis or leiomyositis).[64,65,130]

Caution should be exercised when interpreting AChE preparations of biopsies sometimes taken from stoma sites, particularly from ileostomy sites. Small bowel normally has many AChE-positive fibers in the lamina propria, and AChE preparations on biopsies taken proximal to the splenic flexure may also be unreliable.[131]

HE-stained frozen sections of intraoperative seromuscular biopsies are used for positioning the stoma.

CHAPTER 70

GASTROINTESTINAL MANOMETRY: METHODOLOGY AND INDICATIONS

Samuel Nurko, MD, MPH

One of the most important functions of the gastrointestinal tract is to provide energy and nutrition. To accomplish this, the gastrointestinal tract has evolved not only specific functions for digestion and absorption but also complex mechanisms to allow for the ingestion of nutrients, their transport through different specialized areas, and the expulsion of unused portions at times when it is socially acceptable. The main result of this movement is the aboral transport or "propulsion" of gastrointestinal contents, and it results from the complex interaction between the muscles, the myenteric plexus, the peripheral nervous system. and the brain (see Chapter 4, "Motility").

Each area of the gastrointestinal tract has a specific pattern of motility. These patterns have been characterized for the esophagus, antroduodenum, jejunum and ileum, sphincter of Oddi (SO), colon, and anorectum. It has been shown that alterations in those patterns will produce functional dysfunction and clinical symptoms. By studying these alterations, it is often possible to determine if the problem that the patient has is related to motility dysfunction and if the dysfunction is occurring in the muscle or the intrinsic or extrinsic nerves.

When the symptoms of the patient suggest a motility disorder, careful exclusion of anatomic, mucosal, or metabolic disorders needs to be accomplished before motility studies are undertaken (Table 70-1).[1–3] The exclusion of an anatomic lesion is the initial and most important step, and the usual techniques that are used for this purpose are mainly radiologic or occasionally endoscopic and are reviewed in different chapters in this book.

Once a decision has been made that the problem is related to gastrointestinal motility dysfunction, transit through different segments can be evaluated, and the specific contractile or electrical activity may be studied (see Table 70-1). Research that is used to study transit includes mainly scintigraphic methods, although other techniques, such as different markers or ultrasonography, have been used. These techniques are discussed in other sections of this book. The main focus of this chapter is on tests that have been designed to study the myoelectric and motor phenomena of the gastrointestinal tract.[1]

GASTROINTESTINAL MANOMETRY

Gastrointestinal manometry has evolved during the past years and has changed from being a research technique to becoming a useful diagnostic tool.[1] The role of gastrointestinal manometry has been defined more clearly for

TABLE 70-1 APPROACH TO THE PATIENT WITH SUSPECTED MOTILITY DISORDER

1. Exclude anatomic problems (*the most important initial step, and it should be undertaken in all patients*)
   - Radiography
     - Plain films, upper gastrointestinal series with small bowel follow-through, barium enema, endoscopy
2. Exclude mucosal or metabolic disorders
   - Endoscopy and biopsy, laboratory tests (metabolic, endocrine, etc)
3. Evaluate transit (*provides actual information on how effective the motility is*)
   - pH probe/impedance
   - Scintigraphy
     - Gastric emptying
     - Esophageal emptying
     - Gallbladder emptying
     - Small bowel–colon transit
   - Barium
     - Videofluoroscopy barium swallow
     - Esophageal emptying
   - Other studies to evaluate transit
     - Marker-perfusion studies
     - Oroanal transit—color markers, radiopaque markers
     - Orocecal transit—lactulose breath test
     - Colonic transit—radiopaque markers
     - Ultrasonography
     - Breath tests
4. Evaluate contractile activity (*provides information on contractile activity and allows the detection of problems in smooth muscle, intrinsic or extrinsic nerves*)
   - Gastrointestinal manometry
5. Evaluate electrical activity (*provides information on the myoelectrical activity*)
   - Electrogastrography, electromyography
6. Establish etiology and other associated problems
   - Is this a primary or a secondary motility problem?
   - Exclude systemic illness (endocrine, connective tissue disease, metabolic, etc)
   - Associated abnormalities (autonomic dysfunction, muscle/nerve abnormalities, etc)

anorectal and esophageal manometry, and it has become better defined for small bowel and colonic motility.[1] In general, the manometric evaluation may detect aberrations that may be clinically insignificant,[4,5] and care needs to be exerted to avoid overinterpretation.[5] It is also important to remember that a dichotomy frequently exists between the use of manometry as an investigation technique or as a useful clinical test.

There are two main methods to perform gastrointestinal manometry. One requires the use of water perfusion with low-compliance systems, and the other uses miniature strain gauge pressure transducers mounted within thin catheters.[1] Most laboratories have water-perfused systems, in which the catheter is connected indirectly to a physiograph or computer by a series of transducers. The pressure is recorded from a predetermined opening in the catheters. The catheter is perfused with a pneumohydraulic pump at a predetermined rate, and pressure changes in the orifices are transmitted to pressure transducers with the use of low-compliance capillary tubing. The hydraulic capillary infusion system achieves high-fidelity recording of intraluminal pressure at infusion rates that go from 0.1 to 0.4 mL/min per port. Some disadvantages are that the system may not accurately reflect when measuring transient high-pressure events, the size of the catheters, and the amount of perfusate that can represent a large fluid bolus in small children and premature infants.

Solid-state catheters have strain gauge pressure transducers incorporated into specially designed catheters. The information is captured by digital recording systems and is later downloaded into computers for analysis. The main advantage of the solid-state catheter is that it does not have the risks associated with the perfusion, as well as the fact that it allows the performance of prolonged ambulatory studies. The main limitations have been the cost and the fact that it requires a minimum-size catheter, so these catheters cannot be used in small infants or children.

Independently of the method used, gastrointestinal manometry provides direct evidence about the contractile events of the organ that is being studied. Even though the study of gastrointestinal motility in children is similar to the study in adults, the performance of those studies in the pediatric population has certain important characteristics that make this more challenging. The first is related to the developmental aspects, the second to a paucity of studies in normal controls, and the third to technical difficulties.

The developmental aspects of gastrointestinal motility have been discussed in detail in previous chapters, but it must be remembered that any manometric findings need to be placed in that context before a study is considered abnormal.[1,6]

The lack of normal controls has been another important limiting factor for the establishment of normal motility patterns in children. This lack of control information can make the interpretation difficult and subjective and, as mentioned, may lead to overinterpretation.

Finally, there are special technical aspects that are unique to the performance of gastrointestinal manometry in children. Some are related to the size of the catheters, the amount of fluid delivered with the perfused systems, or the lack of cooperation that may be found in younger children.[1] The size of the catheters can be a limiting factor because the standard manometric catheters have a diameter of 4.5 to 5 mm. The recent development of silicone extrusion tubing has allowed the creation of very small catheters that may include sleeves.[6,7] Studies have shown that manometric channels with diameters of 0.35 mm have acceptable fidelity and pressure increase rates with perfusion rates as low as 0.02 mL/min.[6] Multilumen catheter assemblies that measure less than 2 mm have been developed,[6] including the use of sleeves.[6–8]

APPROACH TO THE PATIENT

It is important to remember that for manometric studies to be successful, there must be a certain degree of patient cooperation. The understanding and degree of cooperation will vary according to the developmental age and previous experiences of the child. Results and patterns are difficult to interpret when there is crying or movement artifact, which can obscure pressure tracings.[1] Age and developmentally appropriate techniques should be used. The parents should be allowed to stay during the tests, and they can be an important resource for the child. The interaction between the parents and the children can be observed and can be important in understanding the child's symptoms.[1]

Young children may require sedation for the performance of the studies.[1] Medications that have been employed principally include chloral hydrate and midazolam. There are limited data on their effect on motility function. Studies have found no difference in esophageal or rectal manometry with chloral hydrate[9] or midazolam.[10]

SPECIFIC GASTROINTESTINAL MANOMETRY STUDIES

Recently, a pediatric task force of the American Motility Society (AMS) established minimum standards for the performance of manometric studies in children.[1] Standards for esophageal, antroduodenal, colonic, and anorectal manometry were published.[1]

Esophageal Manometry

Esophageal manometry is the gold standard for the diagnosis of primary motor disorders of the esophagus (Table 70-2).[4,11,12] It is most frequently performed in children with dysphagia who have no evidence of anatomic obstruction, and the clinical use of esophageal manometry is in defining the contractile characteristics of the esophagus.[1]

There are three functional regions of the esophagus: the upper esophageal sphincter (UES), the esophageal body, and the lower esophageal sphincter (LES). Both sphincter regions have a resting tone and relax in response to swallowing or other stimuli, and the body has contractions that propagate (Figure 70-1).

The UES is striated muscle that is maintained closed between swallows by tonic stimulation of the somatic nerves. It exhibits marked radial and axial asymmetry, with

TABLE 70-2 INDICATIONS FOR MANOMETRY STUDIES

Esophageal manometry
Esophageal dysfunction that is not explained by anatomic or well-defined problems
Dysphagia, odynophagia
Diagnosis of achalasia and other primary esophageal motor disorders
To support the diagnosis of connective tissue diseases or other systemic illness
Evaluation of patients with achalasia post-treatment and recurrent symptoms
Noncardiac chest pain
Patients with gastroesophageal reflux in whom the diagnosis is not clear (to exclude primary motility disorders)
Before a fundoplication when a severe motility disorder is suspected
To localize lower esophageal sphincter before pH probe placement in patients with abnormal anatomy (eg, hiatal hernia)
Anorectal manometry
To diagnose a nonrelaxing internal anal sphincter
To diagnose pelvic floor dyssynergia
To evaluate postoperative patients with Hirschsprung disease who have obstructive symptoms and to evaluate the effect of botulinum toxin
To evaluate patients with fecal incontinence
To evaluate postoperative patients after imperforate anus repair
To decide if the patient is a candidate for biofeedback therapy
Antroduodenal manometry
To establish the presence of pseudo-obstruction
To classify pseudo-obstruction into myopathic or neuropathic forms
To exclude a motility problem as the basis of the patients' symptoms; showing normal findings in children with "apparent intestinal failure"
Evaluation of unexplained nausea and vomiting
To distinguish between rumination and vomiting
To exclude generalized motility dysfunction in patients with dysmotility elsewhere (eg, before colectomy)
Indicated in patients with pseudo-obstruction being considered for intestinal transplant
May be useful to predict outcome after feeding or after drug use in patients with pseudo-obstruction
May suggest unexpected obstruction
Colonic motility manometry
In the evaluation of selected patients with intractable constipation because it can be helpful to differentiate functional fecal retention from colonic pseudo-obstruction[78]
Evaluation of children with pseudo-obstruction to establish presence of colonic involvement and to characterize the relationship between motor activity and persistent symptoms
To establish the pathophysiology of persistent symptoms in selected children with Hirschsprung disease, imperforate anus, and other colorectal problems
To assess colonic motor activity prior to intestinal transplant

Adapted from DiLorenzo C et al.[1]

greater values anteriorly and posteriorly than laterally.[4] It measures 0.5 to 1 cm at birth and increases in length to 3 cm in the adult.[13] UES relaxation occurs with swallowing. The manometric study of the UES has been difficult because the brisk movement of the larynx and sphincter is discordant with the movement of the intraluminal recording device. With the use of systems that can record changes greater than 400 mm Hg/s or sleeve devices, accurate measurements have become more feasible.[4] In adults, there is a wide range of reported UES pressure measurements, from 40 to 193 mm Hg, depending on the method used.[4] The information in normal children is very limited. It was reported to vary from 18 to 44 cm H_2O in one study.[14]

The esophageal body varies in length depending on the age of the patient. It is composed of striated and smooth muscle. In adults, approximately the upper 5% is exclusively striated muscle, the middle 35 to 40% is mixed, and the distal 50 to 60% is entirely smooth muscle.[15] No similar information is available in children. The resting pressure is usually lower than the gastric pressure and varies with respiration. Different types of esophageal contractions can occur in the esophageal body. *Primary peristalsis* is the one that occurs after swallowing. It is an orderly and progressive series of peristaltic contractions that begins in the pharynx and advances aborally (see Figure 70-1).[4,13] *Secondary peristalsis* can be elicited in response to luminal distention with air, liquid, or a balloon. *Tertiary contractions* consist of random, spontaneous, usually simultaneous, nonperistaltic contractions.

During primary peristalsis, the contractions usually progress at a speed of 2 to 4 cm/s, and there is a closely coordinated process between the UES and the LES. The mechanical effect is a stripping wave that milks the esophagus clean from the proximal to the distal end.[4] In general, a pressure complex in the distal esophagus with an amplitude < 35 mm Hg is considered hypotensive,[4,16] whereas contractions > 180 mm Hg are considered hypertensive.[4,16] Based on simultaneous manometric and videofluoroscopic studies, a cutoff of 30 mm Hg is now used to separate effective from ineffective peristalsis.[15,17] Failed peristalsis can occur in 4 to 15% of swallows in normal adult volunteers.[16] The typical duration of peristaltic contractions is around 4 seconds,[16] and double-peak contractions can occasionally occur in normal controls.[16] No similar information is available in healthy children.

The LES is tonically contracted and found at the distal end of the esophageal body (see Figure 70-1). LES pressure varies depending on the individuals and the methods used. Wide ranges have been reported. For example, Hillemeier and colleagues reported a mean LES pressure of 22.4 ± 4.7 mm Hg,[18] Cucchiara and colleagues reported 15 ± 2 mm

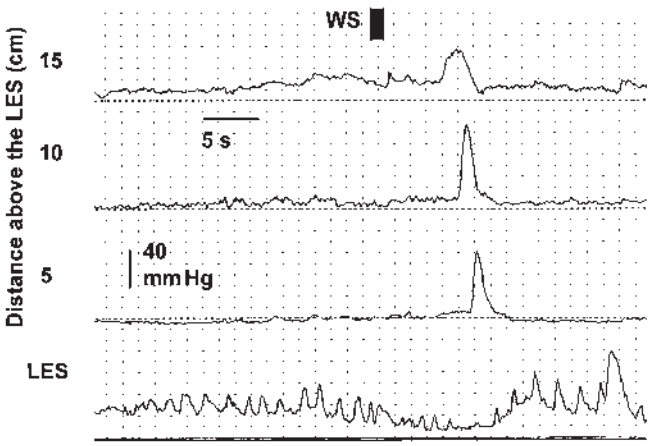

FIGURE 70-1 Normal esophageal manometry. The tracing shows the normal response to a wet swallow (WS). A peristaltic wave traveling aborally from 15 cm above the lower esophageal sphincter (LES) to the lower esophagus can be observed. Also, a normal LES relaxation after swallowing can be noted.

Hg,[19] and Moroz and colleagues reported 29.1 ± 2.4 mm Hg.[20] In adults, LES pressure varies from 10 to 45 mm Hg.[15] The LES is also asymmetric, with maximal pressures in the left lateral aspect. LES relaxation usually occurs with swallowing (see Figure 70-1), although it has been shown that it can also occur transiently when no swallowing is occurring.[15] An increased amount of transient relaxations has been reported both in adults and children with gastroesophageal reflux (GER).[15,19] The measurement of LES pressure is always performed relative to intragastric pressure. LES relaxation needs to be coordinated for more than 90% of wet swallows and complete with a drop to intragastric pressure. Different methods that have been used to measure basal sphincter pressure include either the midrespiratory or end-expiratory points. The midexpiratory pressure is the mean pressure at the midpoint of amplitude of the phasic respiratory component, whereas the end-expiratory pressure is when the tonic component is used alone.[4]

The manometry catheter is usually placed nasally, although, if necessary, it can also be placed orally, particularly in premature infants. In older children, nasal topical anesthesia with topical cocaine or viscous lidocaine is frequently used. Medications known to affect gastrointestinal motility (eg, prokinetics, anticholinergics, narcotics) are held for 48 hours before the procedure, and children are asked to fast for 4 to 6 hours, depending on the age and the need for sedation.

There is no standardized protocol to perform esophageal manometry in children. Adding to the difficulties is the fact that esophageal length varies with age, making the adoption of a standard catheter that can provide all of the information impossible. The pediatric task force of the AMS recommended the use of the slow pull-through technique.[1] Usually, detailed analyses of the LES and of the esophageal body are then done.[1] Even though UES measurements can be obtained, it is not clear that manometric findings are sensitive enough to have a clear impact on patient management.[4]

The responses to swallowing are observed. If possible, a swallowing marker is used, although, particularly in young children, careful observation and manual recording are employed. It is preferable to do "wet" swallows of water at room temperature (approximately 1 mL in infants and 3 to 5 mL in older children).[1] It has been shown that swallows with water give a more consistent peristaltic response than those that occur only with saliva.[16] In a typical study, 10 wet swallows are evaluated.

In young children, it is difficult to obtain swallows, and different techniques have been employed. Gently blowing air in the child's face (the Santmeyer reflex) may induce swallowing in young infants and neurologically abnormal children.[21]

In some centers, sleeve catheters are used to assess the LES. The sleeves are more accurate because they straddle the sphincter over 3 to 5 cm. Esophageal peristalsis is then measured by positioning the catheter at different segments of the esophageal body and using wet swallows. The amplitude, duration, and peristaltic characteristics of the contractions are measured.[16]

The UES is evaluated at the end. Techniques to measure it are the same as for the LES, although the recording speed may need to be increased. The UES relaxes to baseline, and the relationship between pharyngeal contractions and UES relaxation is determined. The clinical utility of UES/pharyngeal measurements is the least established.

Developmental Aspects. Recent advances with the use of microperfusion techniques and catheter size have allowed the study of even small premature babies.[6,8,22] It has been shown that in premature infants 26 to 33 weeks gestational age, esophageal pressure waves triggered by dry swallows were predominantly peristaltic (84%) in propagation sequence.[6] Swallow-unrelated pressure waves were usually nonperistaltic, and the researchers concluded that in infants 26 weeks or older, the control of swallow-induced peristalsis is fully developed.[6] All had tonic LES contraction with a mean resting pressure of 13.6 ± 4.2 mm Hg (range 5.0 ± 4.1 to 20.0 ± 4.8 mm Hg). In all infants, the LES relaxed in response to pharyngeal swallows. The duration of LES relaxation was 5.8 ± 3 seconds, and transient LES relaxations occurred an average of 2.6 ± 1.6 times per study. Those patterns are similar to the ones described in older premature infants.[23] Premature infants > 33 weeks of age had a mean LES pressure of 20.5 ± 1.7 mm Hg preprandially and 13.7 ± 1.3 mm Hg postprandially. It has also been shown that the patterns of LES relaxation were similar to those seen in healthy adults.[8]

Clinical Significance. Esophageal motility is mandatory for the diagnosis of primary motility disorders (Table 70-3) (see Chapter 26, "Other Motor Disorders").[1,2,4]

Esophageal motility remains the study of choice to make the diagnosis of achalasia.[1] Four manometric findings are characteristic of achalasia, as shown in Table 70-3 (see Figure 26-3 of Chapter 26).[24,25] The absence of peristalsis is the hallmark of the disease. Even though most patients with achalasia have incomplete or absent LES relaxation, the LES may occasionally show complete relaxation.[25] Manometry also provides quantitative information about the severity of the achalasia and the response to treatment.[1]

Esophageal manometry allows the diagnosis of diffuse esophageal spasm, nutcracker esophagus, or nonspecific esophageal motility disorders. The term nonspecific esophageal motility disorders has been used to describe manometric findings that are abnormal but not diagnostic of any established motility disorder.[26] Manometric features include apersitaltic, repetitive, or multipeaked contractions; low-amplitude contractions; intermittent segmental contractions; and prolonged contraction duration.[27]

Esophageal manometry is indicated to assess esophageal function in children and adolescents with dysphagia, odynophagia, and chest pain of noncardiac origin.[1]

Esophageal manometry can also be used to locate the LES for pH probe placement, particularly in patients with abnormal anatomy, such as a hiatal hernia.

Manometry has no role in the diagnosis of GER, and the exact role of esophageal motility in the preoperative evaluation of children is not clear. The only clear role it has

TABLE 70-3 DIAGNOSIS OF PRIMARY ESOPHAGEAL MOTOR DISORDERS

Achalasia* (four manometric findings are characteristic of achalasia[24,25])
Increased LES pressure
Absence of esophageal peristalsis (the hallmark of the disease; see Figure 70-3)
Incomplete or abnormal LES relaxation
Elevated intraesophageal pressure compared with intragastric pressure
Diffuse esophageal spasm†
Repetitive, simultaneous (nonperistaltic) contractions, at least 20% of wet swallows
Periods of normal peristaltic sequences
Alterations in the contraction waves (repetitive, increased duration and amplitude), although there are patients who can have normal amplitude
A normal LES in most patients, although incomplete LES relaxation or a hypertensive sphincter has been described[166–168]
Nutcracker esophagus‡
Increased distal peristaltic amplitude (180 mm Hg)
Increased distal peristaltic duration (> 6 s)
Nonspecific esophageal motor diosrders§[26,27]
Low-amplitude contractions (< 30 mm Hg)
Triple-peaked waves, spontaneous isolated contractions, retrograde contractions
Prolonged contractions (> 6 s)
Aperistalsis or nontransmitted contractions (during > 20% of wet swallows)
Simultaneous contractions (> 30% of wet swallows)

LES = lower esophageal sphincter.
*To make the diagnosis of achalasia, absence of esophageal body peristalsis is necessary; other criteria are often fulfilled but are not required.
†Primary finding is uncoordinated motility.
‡Primary finding is increased distal peristaltic amplitude.
§Abnormal manometric patterns that do not fit a defined entity.

in the diagnosis and medical management of GER is when there is uncertainty about the correct diagnosis and a primary motility problem such as achalasia is suspected.[4] In general, when used in the preoperative evaluation of patients with GER, it has not been shown to predict outcome.[4] The role that preoperative esophageal peristalsis plays in the development of dysphagia after fundoplication has been controversial.[28] Studies comparing preoperative patients with or without esophageal dysmotility have shown no difference in the prevalence of dysphagia after the operation.[28] At present, it can be concluded that insufficient data exist to evaluate the benefit of the routine preoperative assessment of peristaltic function.[4] However, it may have a role when there are severe preoperative dysphagia or atypical symptoms or when severe dysmotility is suspected. In children, the latter problem is commonly found in patients with scleroderma or tracheoesophageal fistulas,[29,30] in which a fundoplication may create a functional obstruction in a dysmotil esophagus.

Manometry may be useful in the diagnosis of connective tissue diseases, in which it may confirm the clinical suspicion.[1,15] Of all of the collagen vascular disorders, scleroderma shows the most marked esophageal abnormalities.[31,32] The manometric findings are quite suggestive of the diagnosis, although not pathognomonic, because severe reflux esophagitis can have the same manometric appearance.[32] The characteristic esophageal manometric findings are (1) an incompetent LES, (2) low-amplitude esophageal contractions in the smooth portion of the esophagus, and (3) later alterations in the striated muscle section.[31–33] Even though the esophageal motor abnormalities of scleroderma have been well characterized, other connective tissue diseases also have motor alterations,[33] particularly in patients with systemic lupus erythematosus and those with mixed connective tissue diseases.[33]

Esophageal manometry is useful in the evaluation of noncardiac chest pain.[1] Manometry should not be routinely used as the initial test[15] but may be useful when other tests have not provided an explanation. Manometric abnormalities are prevalent in patients with chest pain, dysphagia, or both. Achalasia or diffuse esophageal spasm accounts for the minority,[15] and most patients fall under the category of "nonspecific disorders." In a recent report of esophageal manometric findings in 154 children, the authors described the findings in 45 children with chest pain or dysphagia not associated with GER.[26] Esophageal manometry was described as abnormal in 30 (67%). Among those, a variety of motility disorders were diagnosed in 17 patients (achalasia in 12, pseudo-obstruction in 3, diffuse esophageal spasm in 1, and dysmotility after tracheoesophageal fistula repair in 1), whereas nonspecific esophageal motor disorders were diagnosed in 13 patients (8% from the initial 154). Those children had a higher incidence of food impaction.[26]

Recently, technical advances with solid-state catheters and digital recording devices have allowed the performance of prolonged monitoring of esophageal pressure.[34] There are no control values for children, and the number of controls in adults is limited. The manometry is performed with a solid-state catheter that has pressure transducers and usually one or two pH electrodes, allowing the correlation of symptoms with both motor events and reflux. Most software does not allow the measurement of continuous LES pressure. The primary indication is for the evaluation of patients with noncardiac chest pain[34,35] because it allows the demonstration of associated esophageal events (either motor or reflux related) with the pain.[34] Preliminary reports in children have shown that it is a technique that may be useful.[36,37]

The role that provocative tests play during esophageal manometry in children has not been established, so their use is not recommended.

The future for the study of esophageal physiology may be promising. The advent of mutlichannel intraluminal impedance combined with manometry has allowed the simultaneous evaluation of esophageal contractions and bolus transit.[17] Recent publications have established normal reference values for adults,[17] and there is still no information available for children. The results in adults have already shown that the manometric evidence of ineffective peristalsis may underestimate the true bolus clearance and that the combined impedance with manometry may be a more sensitive technique to assess esophageal function.[17] More information is needed before any firm conclusions can be established.

Indications. The primary indication continues to be in the evaluation of children with esophageal dysfunction that is not explained by anatomic or well-defined problems (see Table 70-2).[1,2]

Esophageal manometry is indicated when a primary motility disorder is suspected and to support the diagnosis of connective tissue diseases or other systemic illness. Manometry may be indicated in the evaluation of patients with achalasia post-treatment who develop recurrent symptoms when there is doubt about the physiopathology. Manometry is not indicated in the routine evaluation of GER, but it should be performed in those patients with GER in whom the diagnosis is not clear, as well as before a fundoplication when a severe motility disorder is suspected. It is also used to localize the LES before placement of a pH probe in patients with abnormal anatomy (eg, hiatal hernia). Esophageal manometry, particularly 24-hour recording, is indicated in the evaluation of children with noncardiac chest pain who have no diagnosis and have not responded to antireflux therapy.

Antroduodenal Manometry

Antroduodenal manometry measures the intraluminal pressure of the antrum and duodenum.[1,7,38,39] Antroduodenal motility has been clearly established as an important research tool, and even though it is being gradually introduced into clinical practice, the exact role that it plays in the evaluation of children and adults has not been firmly established. Manometric data are not necessary for patient management when there is a known underlying cause of dysmotility (see Table 70-2).[1]

Clinically, manometry provides useful information regarding contraction patterns in the region. In children, its utility has been mostly hampered by the lack of data that establish patterns in normal controls because it is not ethically possible to perform those tests in healthy children.[38] Therefore, reported controls have been derived by different authors from patients referred for antroduodenal motility who later were considered as not having upper gastrointestinal motility problems.[40] These difficulties in interpretation can be illustrated in reports in which abnormal manometric patterns occurred with equal frequency in healthy and symptomatic adults.[41] Therefore, definition of what constitutes a significant abnormality remains controversial. Because of this lack of controls in children, great care needs to be exercised in the interpretation of the studies to avoid overinterpretation of the findings.[5]

Small bowel motility can be performed with solid-state pressure transducers, impedance sensors, or perfused catheters.[1] The patient stops medications that can affect motility for at least 48 hours before the test. The catheter is introduced nasally or through an existing gastrostomy or jejunostomy. The catheter requires postpyloric placement and can be introduced either endoscopically or fluoroscopically, and, ideally, it is advanced beyond the angle of Treitz. Most importantly, however, the transducers need to be positioned across the antroduodenal junction.[42] The configuration of the catheters varies, but the minimum recommended recording ports include one in the antrum and three small bowel recording sites.[1] The distance for the duodenal/jejunal ports varies depending on the age of the patients, with a range that goes from 3 to 10 cm between ports. In most children, a distance of 3 cm is sufficient. The position of the catheter needs to be checked frequently during the performance of the test to ensure the correct position across the antroduodenal junction. It has been suggested that, on average, a stationary study requires an average five adjustments of tube location in the postprandial period to ensure accurate antral recordings.[3] At times, it is necessary to reconfirm placement during the test with radiography or fluoroscopy.

When perfused studies are performed, a close follow-up of the patient is necessary to avoid fluid overload, particularly in small children.[43] With the regular perfusion equipment available in most laboratories, steel capillary or other tubes that control the rate of flow are used, and the usual perfusion rates vary from 0.1 to 0.4 mL/min per port. If six ports are being used, and the test lasts 6 hours, a large amount of fluid is being administered. This could produce volume overload or, theoretically, hyponatremia. Even though in adult laboratories, the catheter is perfused with distilled water, in children, many centers use 0.2 to 0.5 normal saline or oral hydration solutions[1,2] to avoid hyponatremia. To be able to study premature and young infants, the system has been adapted by some investigators to decrease the perfusion rate to 0.01 to 0.02 mL/min.[7,44]

It is preferable to avoid anesthesia and sedation. The effects of benzodiazepines on motility recordings have not been evaluated,[42] but in some centers, it has been suggested that sedation with midazolam (2–5 mg) followed by reversal with intravenous flumazenil (0.2–0.4 mg) does not result in any appreciable change in motility recordings. The use of sedation or general anesthesia is usually necessary in children, particularly when the catheters are being placed endoscopically. To avoid the possible effects of the sedation or anesthesia, in most centers, the study is performed the day after the catheter has been placed.

The optimum duration of the test is not known. Even though most centers use 3 to 4 hours of fasting followed by 2 hours postprandially,[42,45] some authors have advocated the use of prolonged ambulatory studies. The pediatric task force of the AMS recommends at least 3 hours of fasting (or two migrating motor complexes [MMCs]) and at least 1 postprandial hour.[1] Soffer and Thongsawat have shown that prolonged tests, including sleep periods, enhance the diagnostic accuracy of the test.[45] Most of the improvement came from extra information gained by longer fasting periods. Because of frequent catheter displacement, ambulatory tests cannot be used reliably to assess postprandial antral activity.[3,42] Therefore, if the objective is to assess postprandial antral function, a stationary manometry is necessary.[3,42]

The analysis is usually performed by visual inspection.[1] Antroduodenal manometry provides identification of certain "patterns" and limited quantitative features.[42] At times, it may be possible to administer provocative medications and analyze the responses.

During fasting, the stomach and small bowel show a cyclic pattern, known as the MMC.[40] This cyclic activity is

usually divided into three phases. Phase III is the most characteristic and consists of regular rhythmic peristaltic contractions that start proximally and migrate down to the ileum. Phase III shows regular contractions that in the antrum occur at a rate of 2 to 3/min and in the small bowel at 11 to 12/min (Figure 70-2). The velocity of propagation of phase III decreases significantly, whereas the duration increases significantly with increasing distance from the mouth. Phase III is followed by a period of quiescence (phase I) that is interrupted by irregular motor activity (phase II). During phase I, contractions are not recorded. During phase II, the contractions vary in amplitude and periodicity. Phase I seems to be the most predominant in the antrum, whereas phase II is predominant in both the duodenum and the jejunum. In adults, phase I lasts from 12 to 20 minutes, phase II lasts from 30 to 130 minutes, and phase III lasts from 3 to 15 minutes.[3,42,46,47] There is also a large variation in cycle duration between individuals and within the same individual when studied on separate days.[42] There are no established standards for normal duration of the cycle in children, but in the series reported in the literature, the duration seems to be similar,[46] although it has been suggested that the cycle may be shorter.[40,48,49]

In one study of 18 children aged 2 to 12 years without upper gastrointestinal symptoms in whom antroduodenal manometry was performed, the authors found a phase III in 14 of the children during fasting, and it was induced in the other 4 children by erythromycin. Phase III propagation velocity increased with age, and the cycle length showed no age-dependent variation. Phase III occupied around 3%, phase I around 10%, and phase II around 87%.[40] These authors concluded that antroduodenal motility findings in those children were similar to those found in adults.[40]

After the ingestion of nutrients, the fasting pattern is interrupted by what has been denominated the fed pattern (Figure 70-3). The fed pattern is characterized by an irregular occurrence of contractions with various amplitudes.

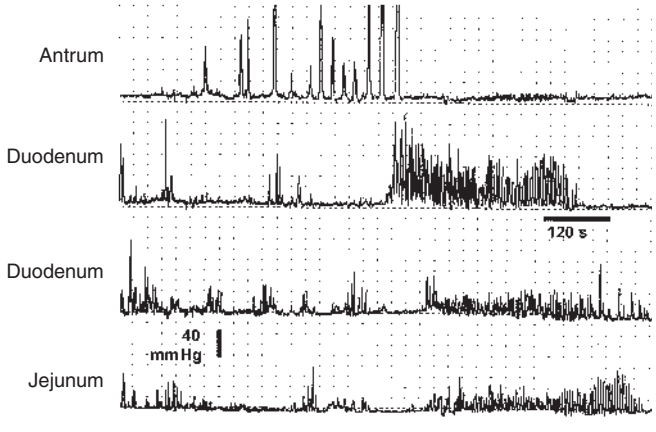

FIGURE 70-2 Normal fasting antroduodenal manometry. A normal phase III front originating in the antrum and migrating aborally along the duodenum into the jejunum can be observed. During phase III, the antrum contracts at a frequency of 3/min, whereas the small bowel contracts at a frequency of 11 to 12/min. Phase III is followed by a period of quiescence (phase I) and is preceded by intermittent irregular contractions (phase II).

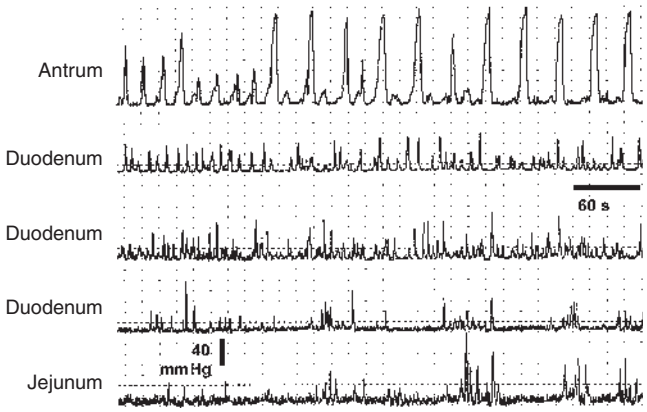

FIGURE 70-3 Normal postprandial pattern in a small bowel manometry. There are irregular persistent phasic contractions in the antrum and small bowel.

After solid meals, strong, repetitive contractions are often induced in the antrum, and the duodenal response looks similar to that of phase II, although the amplitude and frequency of contractions are greater in the fed state.[1]

An antral motility index has been used to calculate both the frequency and the amplitude of contractions. The following formula has been commonly used:

$$\text{Motility index} = \ln(\text{amplitude} \times \text{number of contractions} + 1)$$

with a normal value being 13.67 to 15.65 (5–95th percentile).[42,50] For this calculation to be useful and comparable, it must include 2 hours, assessed by pneumohydraulic perfusion manometry of the prepyloric antrum, and it must quantitate contractions 1 to 2 cm proximal to the pylorus.

The characteristics of the fed pattern vary with the type, composition, and amount of nutrients. For example, liquid nutrients decrease the amplitude of antral contractions and generate an irregular movement in the small bowel, whereas solid food produces high-amplitude contractions in the antrum and a pattern similar to that of liquids in the small bowel. In adults, the meal has been standardized to be at least 400 kcal to ensure a postprandial response of 2 hours duration.[42,51] The solid or liquid meal should be balanced and typical of an average US diet, with 20 to 25% fat, 20 to 25% protein, and 50 to 55% carbohydrate.[42] It has recently been shown that the caloric value of the meal regulates the duration of the fed pattern over a wide range of calories and that for caloric loads up to 1,100 kcal, there does not seem to be a maximum duration of postprandial motor activity. In children, no studies address this question, and there is no standardization, but most authors have used 5 to 10 mL/kg,[52] 20 cal/kg,[53] or 400 to 600 kcal. The AMS task force recommends that the type and size of the meal should be adjusted according to the patient's age and preference (at least 10 kcal/kg or 400 kcal; > 30% kcal from lipids).[1] The task force recommends administering the meal by mouth or intragastrically if possible.[1]

Development. Because of the recent technical advances described above, there is now a fair amount of information regarding normal patterns and age-dependent maturation

in preterm infants and full-term neonates.[7,43] Duodenal motility patterns differ in preterm and term infants. Gastric and duodenal MMCs are present after the 32 to 35 weeks of gestation. Approximately two-thirds of phase III activity starts in the duodenum, and its duration is similar to that in older children and adults. In contrast, premature infants with a postconceptual age less than 32 weeks do not have phase III activity, and there are no cyclic changes in the motility patterns. They show mostly sporadic and nonmigrating clusters of contractions. The number and amplitude of duodenal contractions increase significantly between 29 and 32 weeks, and there seems to be a gradual maturation of these parameters. With maturation, the frequency of these clusters decreases until a mature pattern is observed. As they develop phase IIIs, they differ from adults, with a slower migration velocity, a shorter interval between contractions, and a smaller peak amplitude of the contractions.

In premature and full-term infants, antral motor activity was similar to that in the fasting state. Antral motility consisted of isolated single contractions and clustered phasic contractions. There were no differences in the occurrence of antral activity, and the only differences observed were in duodenal activity. The proportion of antral clusters that were temporally associated with duodenal activity was also significantly lower in preterm infants than in term infants. After feeding, motor activity changes in both full-term and premature infants. It has been shown that in term infants, there is usually a mature response (similar to the one observed in adults), whereas only a third of preterm infants have a mature response. In the term infant, the number of antral waves, the duration of antral clusters, and the antral motility index decreased by one-third; the duodenal motility index and cluster activity increased significantly. This divergent response was also seen in premature infants.[43] In a study of premature infants, the conversion from fasted to fed patterns depended on caloric strength. The threshold concentration was about 22 cal/dL when 5 mL/kg of milk was given.

In infants, phase III does not appear right after feeding. There may be differences in the response depending on the nutrient. For example, in one study with healthy neonates, phase III appeared within 3 hours after breast milk in 10 of 12 breastfed infants but in 2 of 12 infants who were formula-fed.[54] The study of the fed patterns of antropyloric motility measured with the use of high-resolution manometric microperfusion techniques has indicated that the neuroregulatory mechanisms responsible for the coordination of motility and gastric emptying are well developed by 30 weeks gestation.[7]

It has been suggested that antroduodenal motility may be useful to establish feeding readiness in premature infants[44,55] or the best way to feed them.[56] It has been shown that in premature infants, continuous infusions produce better responses and tolerance than bolus feedings and that full-strength formula triggers adult-like motor activity.

Clinical Significance. Antroduodenal motility has been used to study the physiopathology of gastrointestinal motility disorders. Different patterns also allow the classification into neuropathic (Figure 70-4) or myopathic abnormalities (Figure 70-5).[1] They are defined based on qualitative abnormalities.[1] In general, most authors consider findings abnormal if there is abnormal propagation or configuration of the MMC, uncoordinated intestinal bursts of phasic pressure activity sustained over 30 minutes, uncoordinated intestinal pressure activity, and failure of the meal to produce a fed pattern (see Figures 70-4 to 70-6).

Based on these abnormalities, the following patterns can be seen:

1. *Antral hypomotility*. A reduced motility index of postprandial distal antral contractions is significantly correlated with the impaired gastric emptying of solids from the stomach (see Figure 70-6).[50,57]
2. *Myopathic disorders*. These disorders are characterized by low-amplitude contractions < 20 mm Hg[58] and, on average, are < 10 mm Hg. However, it is important to remember that amplitude measurements with a point sensor depend on luminal diameter and may be low because of a nonspecific dilatation (see Figure 70-5).[42]
3. *Neuropathic disorders*. These disorders have been associated with antral hypomotility, absence of phase III activity, abnormal propagation of MMC, bursts and sustained uncoordinated pressure activity (hypercontracility), and a lack of a fed response (see Figure 70-4).[59]
4. *Mechanical obstruction*. Even though mechanical obstruction needs to be diagnosed by other means, if undetected, it may be suggested by manometry. Two patterns suggestive of obstruction have been described: postprandial clustered contractions (> 30 minutes duration) separated by quiescence or simultaneous prolonged (> 8 seconds) or summated contractions.[42,60]

In an attempt to define normal fasting antroduodenal patterns in children, Tomamasa and colleagues compared the results obtained in 95 patients with symptoms suggesting a gastrointestinal motility disorder with 20 children

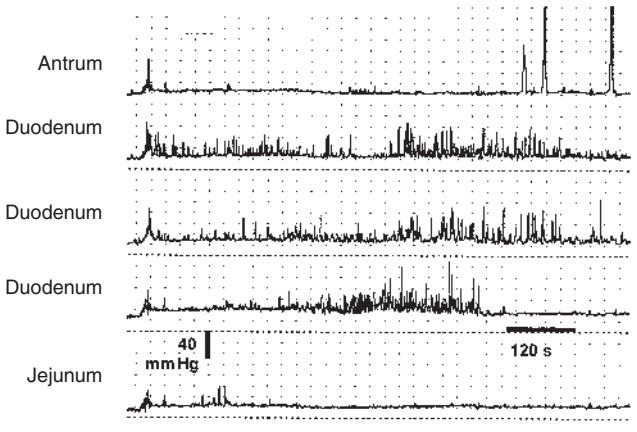

FIGURE 70-4 Antroduodenal manometry in a patient with neuropathy. The tracing shows abnormalities in the phase III of the migrating motor complex. Some uncoordinated clusters, as well as isolated irregular phasic contractions, can be observed. Throughout the study, there was no organized activity, and irregular phasic contractions were seen. No phase III could be observed, even after provocative medications.

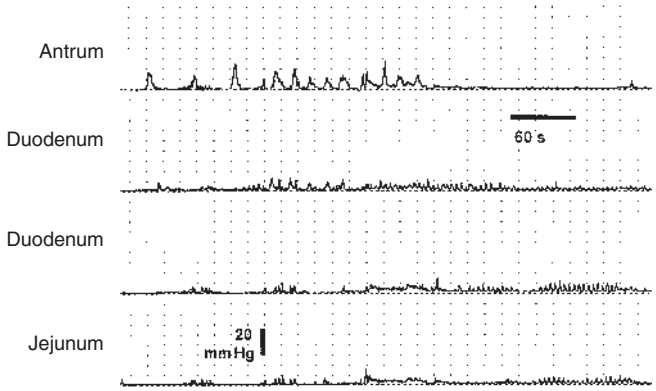

FIGURE 70-5 Antroduodenal manometry in a patient with visceral myopathy. The tracing shows the normal propagation of the interdigestive motor complex, although the amplitude is much lower than normal (see Figure 70-2).

without upper gastrointestinal disease.[38] They concluded that the following five manometric features have a clear association with pediatric gastrointestinal motility disorders: (1) absence of phase III of the MMC, (2) abnormal migration of phase III, (3) short intervals between phase III episodes, (4) persistent low-amplitude contractions, and (5) sustained tonic-phasic contractions. They mention that short or prolonged phase III, low amplitude of phase III in a single recording site, and clusters of contractions or prolonged propagating contractions during phase II were not more frequent in patients than in controls.

The presence of phase III activity appears to be a marker of neuromuscular integrity,[1,38,40,42,61] and it has been reported that the absence of phase III activity is abnormal (see Figure 70-4).[42] One-third to half of the activity front may commence distal to the stomach.[42,62,63] Hence, the absence of the antral component of phase III is not necessarily abnormal.[42,62]

In stationary studies, 66 to 75% of adult patients will have at least one duodenal/jejunal phase III activity during the 3-hour study.[42] Because even some normal adult subjects may have no phase III activity during stationary studies, this finding may have limitations in the interpretation of suspected neuropathic disorders.[41,45,64] Data from 24-hour ambulatory studies show that normal adult volunteers have at least one or more MMCs per 24 hours.[45,47,65] Therefore, the most definitive evidence of normal enteric neuromotor function can be obtained from prolonged studies.[45] In a study comparing the accuracy of short versus long manometry, the two analyses agreed in 81 of 91 cases. In 7 of 10 cases, a study was diagnosed as abnormal in the short recording but was considered normal after review of the long recording, whereas the opposite occurred in the remaining 3 cases.[45] There is no similar information in children, but it has been suggested that children have a shorter MMC cycle duration than do adults.[48,49]

If no spontaneous phase III activity is observed, intravenous erythromycin has been administered.[1,66] Erythromycin, at doses that are 10 to 20% of those used for its antibiotic properties, acts as a motilin receptor agonist.[66–68] In one study, erythromycin induced phase III activity when given to patients with functional gastrointestinal symptoms. It induced phase III in 18 of 20 children who had phase III activity during fasting, as opposed to 1 of 15 who did not. A dose of 3 mg/kg induced a higher antral motility index when compared with 1 mg/kg, although both doses were equally efficacious in inducing phase III. The lower dose was associated with less side effects.[66] In another study, the effect of erythromycin 3 mg/kg/h was compared among 10 controls, 7 patients with functional dyspepsia, and 6 patients with pseudo-obstruction.[68] In controls, erythromycin induced a premature activity front occurring 15 ± 3 minutes after starting the infusion. The propagation and duration did not differ from the spontaneous activity front. In patients with functional dyspepsia, erythromycin induced various patterns, such as a premature antroduodenal activity front, antral phase III–like patterns with short duodenal bursts, or prolonged phasic antral waves without duodenal activity. In patients with neurogenic pseudo-obstruction, rare or absent antral activity was present with uncoordinated or absent activity, and no contractions were elicited in those with myopathic pseudo-obstruction.[68] It has therefore been suggested that in children who have a normal MMC during fasting, erythromycin produces normal phase III, whereas it is abnormal in all patients with abnormal fasting motility. Therefore, some authors have suggested that in children, a 1-hour infusion of erythromycin could replace the 4-hour fasting portion of the test as a way to establish if there is presence or absence of phase III.[49] This observation has not been validated, and the disadvantage of a shorter test would be the inability to evaluate other aspects of fasting motility. The AMS task force recommended the use of erythromycin 1 mg/kg over 30 minutes if no MMC is recorded during fasting.[1]

The administration of erythromycin to full-term neonates induces phase III activity.[67,69] However, it induces a response only in premature infants older than 32 weeks.[70]

The usefulness of antroduodenal manometry to directing therapy has not been definitely established in adults. In children, it has been suggested that absent MMCs are an indicator of a poor response to enteral feeding[53] or to cis-

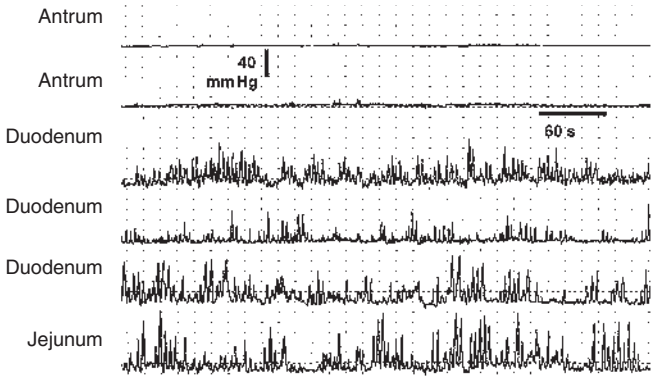

FIGURE 70-6 Antroduodenal manometry in a patient with antral hypomotility. The tracing shows normal postprandial activity in the small bowel and absent response in the antrum. This pattern is frequently seen in patients with gastroparesis.

apride.[71] Antroduodenal manometry may also be useful to study the effects of medications that may have a role in the treatment of children and adults with motility disturbances, such as octreotide.[72,73] Octreotide has been shown to induce phase III activity in the small bowel[72] and has varying effects on the antrum.

It has been suggested, however, that one of the most important contributions of the test may be in showing normal physiology in those patients with apparent intestinal failure (see Table 70-2).[1,5,38,40] Fell and colleagues tried to assess if antroduodenal manometry in the first 2 years of life helped define a neuropathic or myopatic etiology or clinical outcome in cases of pseudo-obstruction.[74] They studied 14 children histologically (5 with myopathy, 4 with neuropathy, and 5 unclassified) and manometrically. They found four abnormalities in the manometry: no detectable motor activity in 4 children, low-amplitude phase III activity in 5 children, poorly formed phase III activity in 3 children, and well-formed cyclic phase III activity with abnormal propagation in 2 children. The seven children with a low-amplitude phase III motility index < 10 pka/min had poor outcomes (death or dependence on total parenteral nutrition). The authors concluded that manometry was useful not only as an aid in diagnosing the etiology of pseudo-obstruction presenting in infancy but also in predicting outcome.[74]

Indications. Antroduodenal manometry is indicated when patients have unexplained upper gastrointestinal problems, such as nausea and vomiting or other symptoms suggestive of upper gastrointestinal dysmotility (see Table 70-2). Its main use had been in confirming or excluding the diagnosis of pseudo-obstruction or a motility disorder, and it helps to establish if the dysmotility is neuropathic or myopathic. Most importantly, a normal study may indicate that motor dysfunction is not the cause of the symptoms.[1,42] It is also used to decide if there is generalized dysmotility in patients with dysmotility elsewhere (eg, chronic constipation when surgery is contemplated, severe reflux with evidence of distal dysmotility when a fundoplication is being considered, or after a failed fundoplication that requires reintervention).[1]

It may be useful to distinguish between rumination and vomiting.[1] Some studies have also suggested that antroduodenal motility may be useful in patients with abnormal motility to predict outcome after drugs or ability to tolerate enteral feedings. It is also indicated in patients with pseudo-obstruction being considered for intestinal transplant and may suggest an unexpected obstruction.[1]

Colonic Manometry

Measurement of colonic intraluminal pressure has been performed for many years but has been confined mostly to the distal colon (anorectosigmoid segments). The study of colonic motility of more proximal segments is a technique that has recently been introduced.[75] Even though colonic intraluminal measurements alone do not have a clear role in clinical practice, the test has been shown to be useful in the evaluation of the pediatric patient with intractable constipation.[1] In adults, colonic motility does not seem to discriminate subgroups of chronic constipation more accurately than transit and pelvic floor tests. It may be helpful in confirming a diagnosis of slow-transit constipation (colonic inertia) in patients considered candidates for surgical treatment.

In humans, there is no interdigestive cyclic motor activity. The characteristics of colonic motility are the presence of irregular alterations of quiescence with nonpropagating and propagating contractions. In humans, colonic propagated events are basically of two types, arbitrarily defined on the basis of their amplitude: low-amplitude propagated contractions (LAPCs) and high-amplitude propagated contractions (HAPCs). LAPCs have been poorly investigated and are propagated waves of 5 to 40 mm Hg. Their exact physiologic significance is still unknown but may be involved in the transport of colonic contents and the occurrence of flatus.[75] In the fasting state, the motor activity is represented mostly by low-amplitude (5–50 mm Hg), nonpropulsive, segmental contractions; peristaltic movements seldom occur.[75] Some contractions last more than 30 seconds and are considered tonic; others are shorter and are considered phasic. Segmental nonpropagating contractions are rare in infants but are more common in toddlers.[76]

HAPCs have been defined as contractions of at least 80 to 100 mm Hg, lasting 10 seconds and propagating for at least 30 cm.[75,77] HAPCs can reach amplitudes > 200 mm Hg. HAPCs originate in the proximal colon and migrate distally > 95% of the time, usually stopping in the distal sigmoid colon (Figure 70-7).[75]

Food ingestion has an important influence on colonic motility.[75] The response lasts 2 to 3 hours and is mostly composed of segmental contractions; it is also accompanied by an increase in colonic smooth muscle tone and can also have HAPCs, which have also been described in pediatric patients.[1,78–80] The colonic response to eating is influenced by the caloric content and meal composition. Fat and carbohydrate represent an important stimulant, whereas protein may have an inhibitory effect.[75]

Another cyclic activity that can be found during colonic manometry occurs distal to the rectosigmoid junc-

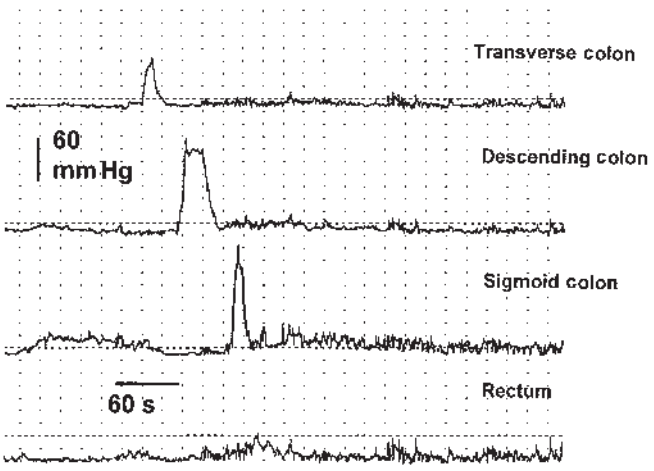

FIGURE 70-7 Normal colonic manometry. The tracing shows the presence of a high-amplitude propagating contraction that is originating in the transverse colon, advancing aborally along the large bowel, and stopping in the sigmoid colon.

tion and has been labeled the rectal motor complex.[75] This lasts an average of 10 minutes and has contractions with a mean frequency of two to four per minute and a wave amplitude of > 5 mm Hg. It occurs in adults every 90 to 300 minutes during the day and every 50 to 90 minutes at night.[75] Its physiologic role is unknown, although it is accompanied by a rise in anal canal pressure and probably represents a mechanism to preserve fecal continence, particularly during sleep.

It has been suggested that colon preparation alters colonic motility. Unfortunately, studies of colonic motility are difficult to perform in unprepared colons, so most data are available from studies in which the colon has been cleaned.[77] Usually, the patient's colon is cleaned with the use of a balanced electrolyte solution. In most studies performed in children, this is administered by a nasogastric tube. Usually, no enemas are given, no colonic preparation is given the day of the study, and medications that can influence motility are stopped at least 48 hours before the study.

The spacing of the recording ports varies, but they are generally separated by 10 to 15 cm. The catheter is placed with the use of colonoscopy. In general, a guidewire is placed into the transverse/hepatic flexure, and the colonoscope is withdrawn, leaving the guidewire in position. The motility catheter is then fed over the wire. The position of the tube is checked fluoroscopically.[49,77,79,80] The catheter can also be dragged with the colonoscope during the colonoscopy and placed directly in the desired location.

The colonoscopy is performed using either general anesthesia or intravenous sedation. When intravenous sedation is used, and only benzodiazepines are used, the motility study may be done on the same day, after the child has recovered from the sedation (mean of 3.5 hours).[77] However, the influence that the sedation or the colonoscopy may have on motility is not known. Therefore, in many cases, the catheter is placed on one day, and the study is performed on the next day.

A fasting recording is done for 2 hours, and then the patient is fed. There is no standardization of the meal. In adults, a 350 kcal meal did not stimulate colonic motility, but a 1,000 kcal meal did. In one pediatric study, patients received a combined liquid and solid meal (≥ 20 kcal/kg, with fat providing > 30% of the energy).[79] In another study, 240 mL of whole milk or formula was used in those enterally fed, and in those who were dependent on total parenteral nutrition, they gave the maximum amount of milk that the patients were able to tolerate without symptoms.[80] Usually, a motility index is calculated by measuring the area under the pressure for at least 30 to 60 minutes before and 30 to 60 minutes after the completion of the meal. HAPCs are excluded from the analysis.[77] It has been shown that meals stimulate colonic motility in healthy subjects.[79,80]

Clinical Significance. Constipated adults with slow-transit constipation have an impairment of colonic propagated activity, principally related to a decrease or an absence in HAPCs. The enteric neural program controlling colonic propagation and its ability to contract in response to exogenous stimulation may still be preserved in some patients, as shown by the elicitation of HAPCs after intraluminal instillation of bisacodyl. Patients may also have an abnormal response to eating,[75] which may be blunted or absent.

The patterns of colonic motility in healthy children have not been established. Most information comes from studies in which children referred for evaluation of neuropathy, constipation, or nonulcer dyspepsia have been studied.[76,77,79,80] From those studies, it has been suggested that in children, HAPCs also increase after meals. These authors have described that in the postprandial period, one HAPC is usually followed by others 3 to 4 minutes later.[76,77,79,80] In a study of 32 children with a median age of 5.5 years (15 with functional fecal retention, 10 with nonulcer dyspepsia, and 7 with Munchausen syndrome by proxy), it was suggested that there was an inverse correlation between the number of HAPCs and age (before and after administration of a meal) and that colonic contractions different from HAPCs increase with age.[77] The authors found at least one HAPC in 28 of 32 subjects, and the 4 subjects without it were > 8 years. HAPCs were also more frequent in the fasting period in those ≥ 4 years when compared with those who were older (8/13 vs 3/19). There were also differences in the number of HAPCs within 30 minutes of the meal (13/13 age 4 years vs 12/19 > 4 years), whereas there were no differences in the second 30-minute interval.

It has been suggested that colonic manometry offers a tool to differentiate children with different causes of constipation and to differentiate between myopathy and neuropathy.[1,80] In one study, it was suggested that children with neuropathy could be differentiated from those with functional fecal retention (see Figure 70-7) by a lack of HAPCs and a lack of increase in the postprandial motility index (Figure 70-8).[79] Di Lorenzo and colleagues have also suggested that in young children, the lack of HAPCs is a sensitive marker of disease, but these data require further validation.[77,79,80]

Intracolonic bisacodyl has been administered to try to shorten the duration of the motility study in ill children or in

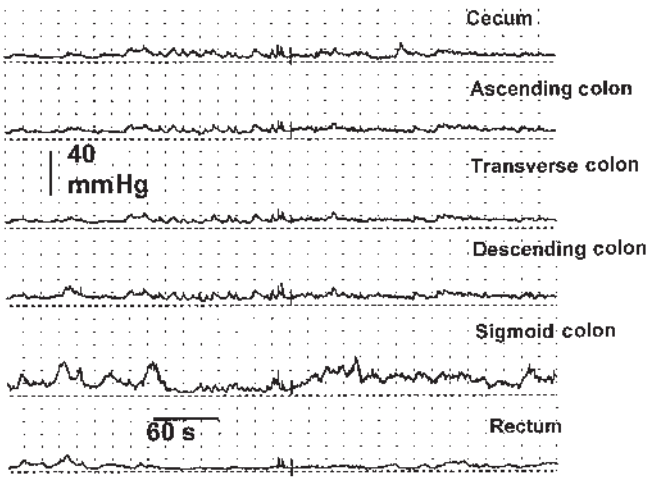

FIGURE 70-8 Abnormal colonic manometry. No high-amplitude propagating contractions (HAPCs) or changes in the motility index were seen in this patient with a colonic neuropathy. No HAPCs were seen even after the administration of bisacodyl.

those who cannot eat.[78] It has been shown that the HAPCs induced after bisacodyl were similar in amplitude, duration, propagation velocity, and sites of origin and extinction to naturally occurring HAPCs.[78] They found that the effect of intrarectal bisacodyl was similar to that of intracecal bisacodyl, except for a delay of 10 minutes in onset.[78] In their study of 28 patients with functional fecal retention, 22 had spontaneous HAPCs, whereas the 28 patients had HAPCs induced by bisacodyl. From 9 with pseudo-obstruction, none had spontaneous HAPCs, whereas 2 had HAPCs after bisacodyl. The interpretation of HAPCs in those 2 children is difficult because it raises the possibility that those children did not have pseudo-obstruction.

The use of colonic motility in children has also been found to be useful in the understanding of postoperative problems in patients with Hirschsprung disease[81] and imperforate anus.[82] It has also been suggested that colonic motility may help in the detection of abnormal colonic segments that may require surgical resection, but these findings need further validation.[81]

Indications. The information obtained from colonic motility still needs to be considered within the context of there being no normal controls in children and many unanswered questions about normal colonic function, the effects of colonic preparation on the results, and so on.[1]

Colonic motility is indicated in the evaluation of selected patients with intractable constipation because it can be helpful to differentiate functional fecal retention from colonic pseudo-obstruction.[1,78] It is also indicated in the evaluation of children with pseudo-obstruction to assess for the presence of colonic involvement and to characterize the relationship between motor abnormalities and symptoms, particularly when a colectomy is being considered. The test is also indicated to determine the relationship between motor activity and persistent symptoms following surgery for Hirschsprung disease and other colorectal problems. Colonic motility should also be performed to assess colonic motor activity prior to intestinal transplant.[1]

Anorectal Manometry

Anorectal manometry is used for the evaluation of children with defecation abnormalities (see Table 70-2)[1,2] and probably represents one of the most frequently performed motility tests in children. The main indication is for the exclusion of Hirschsprung disease,[1,2,83] but it also has an important role in the evaluation of children with fecal incontinence from various etiologies such as myelomeningocele or imperforate anus.[2]

Anorectal physiology has been studied because it has a vital role in maintaining continence. Normal continence and defecation are complex functions. Continence is maintained by the interaction of several mechanisms, including stool consistency, delivery of colonic contents to the rectum, rectal capacity, anorectal sensation, sphincteric function, and muscles and nerves of the pelvic floor. Intra-anal pressure is a combination of both internal and external anal sphincter interaction, with the former providing about 75 to 85% of the total pressure.[84] In adults, the proximal anal canal pressures are lower in the anterior quadrant, and, distally, the pressures are lower in the posterior quadrant. The internal anal sphincter (IAS) is smooth muscle and is in a state of continuous contraction.[85] The external anal sphincter (EAS) and the muscles of the pelvic floor also maintain continuous tone. When a fecal bolus enters the rectum, there is a reflex relaxation of the IAS (rectoanal inhibitory reflex [RAIR]) (Figure 70-9) and transient contraction of the EAS.[85] This relaxation is limited, and the sphincter reacquires its tone as the rectum accommodates to the distention. The relaxation of the IAS occurs independently of the spine and is lost when there is a lack of inhibitory ganglion cells (as in Hirschsprung disease) (Figure 70-10).[86] This relaxation enables the rectal contents to come into contact with the upper anal canal ("sampling reflex"), and normal people can discriminate among solids, liquids, or gas. The transient simultaneous contraction of the EAS allows time for the IAS to recuperate, avoiding incontinence. Further rectal distention with increasing volumes results in nonrecovery of the IAS. If it is socially acceptable, the person has a bowel movement; if not, the conscious contraction of the EAS and rectal compliance allow for postponement until it is socially acceptable.

Different techniques have been used to perform anorectal manometry. In children, the most common method used is with water-perfused catheters that have side holes at different levels of the longitudinal and radial axis.[1,86–89] A balloon is attached to the distal segment and inflated to produce rectal distention.[88] Usually, it is made of latex, and care should be taken when the test is performed in children who may be allergic to it. Solid-state catheters have also been used, but they are much more expensive. Another technique involves the use of a double-balloon device, but its use in pediatrics is limited, particularly because the size is too large for smaller children. The recent advent of micromanometric techniques with the use of sleeve sensors has allowed the accurate study of anal sphincters even in the very low birth weight patient.[90]

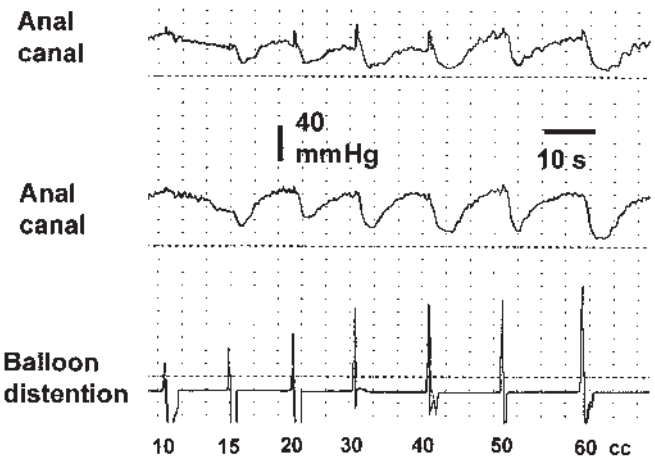

FIGURE 70-9 Normal anorectal manometry. The tracing shows the response of the internal anal sphincter to balloon distention. A normal sphincter relaxation after balloon distention can be observed. The relaxation follows a dose-response curve.

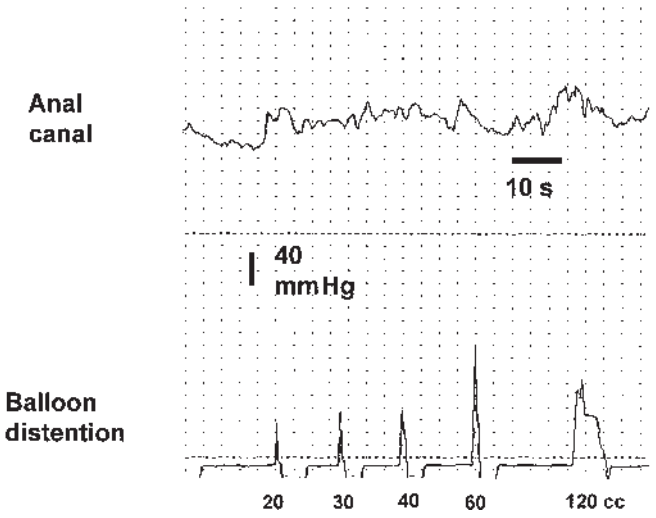

FIGURE 70-10 Anorectal manometry in a patient with Hirschsprung disease. Tracing in which balloon distention does not induce the rectoanal inhibitory reflex, even after large balloon volumes were used. This patient was later proven to have Hirschsprung disease.

In older patients, a phosphate enema is usually given the night before the manometry, and medications known to change anorectal function are stopped 48 hours before the test (eg, opiates, prokinetics, anticholinergics). If the patient is severely impacted, a cleanout is performed 2 to 3 days before the test. Children receive nothing by mouth for 4 to 6 hours before the procedure (depending on the age) if they will be sedated or when the primary indication for the test is to exclude Hirschsprung disease in case a rectal biopsy is needed.

During anorectal manometry in pediatric patients, a slow pull-through is performed in which the manometric assembly is pulled until a high-pressure zone is identified (intra-anal pressure). The probe is then positioned at the level of the maximum pressure, which is usually 1 to 2 cm above the anal verge. The balloon is then inflated to elicit the RAIR (see Figure 70-9).[1,86,88] The characteristics of the relaxation are studied. The minimum amount of air required to elicit a relaxation is determined (threshold of relaxation). The amount of relaxation is influenced not only by the volume but also by the speed of the inflated balloon, as well as by rectal resting volume and compliance. It is important to use large balloon volumes in patients with megarectum because a lack of sphincter relaxation may result from an inadequate distention of the rectal wall. The volume necessary for constant relaxation, which is the minimal amount of air that is necessary to produce a complete sustained relaxation of both the IAS and the EAS, is determined by adding air progressively until either there is constant relaxation or the patient has reached the critical volume (see below).[85]

Besides measuring the resting pressure of the anal canal, the patient is also asked to squeeze at each station. The squeeze pressure is then measured as the maximum pressure obtained above anal resting pressure.[1,88]

During manometric testing, some sensory information is obtained.[1] The most common technique is with the use of balloon distention. In cooperative children, the threshold required to perceive the distention is established (smallest volume of balloon distention) (threshold of sensation).[88,91,92] The threshold of sensation is usually determined with the use of a rectal balloon that is inflated with a handheld syringe. The air is rapidly injected and immediately withdrawn. The type of inflation (speed, phasic vs continuous), the size and shape of the balloon, or the distance of the balloon to the anal verge can affect the threshold. Critical volume has been defined as the minimum amount of air that produces a lasting urge to defecate[85,88] and the sensation of pain, which is defined as the maximum tolerable volume, although the clinical significance of those measurements is not clear.[85]

Compliance is measured as the ratio of pressure to volume at several distending volumes. Measurements are usually inaccurate and not reproducible unless a barostat is being used. Decreased compliance may be associated with an increase in stool frequency, rapid transit of stool in the rectum, and increased risk of fecal incontinence.[85] On the other hand, increased compliance may be found in patients with megarectum. There is a paucity of information on its use in pediatrics.

The study of defecation dynamics may be important (Figure 70-11).[1] This is done with the use of either electromyographic (EMG) surface electrodes or with the manometric assembly. Patients are asked to bear down, and the responses of the sphincters are recorded. Pelvic floor dyssynergia (anismus) is present when there is failure of relaxation or even an increase in pressure while attempting to defecate (Figure 70-12).[88,91,93] There has been some controversy as to whether this observed pattern is sufficient for the diagnosis. In one study, when the manometry indicated dyssynergia, the defecography was in agreement only 36% of the time, whereas when manometry was normal, defecography was normal in 88%.[94] No similar information is available in children.

Development. Studies of the developmental maturation of the rectoanal reflex have produced inconsistent results.

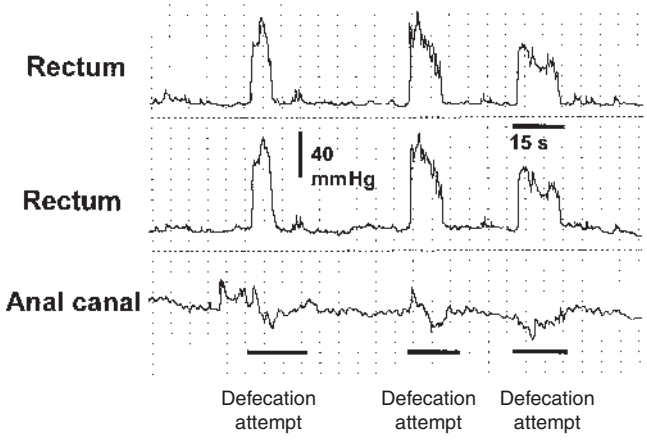

FIGURE 70-11 Normal defecation dynamics. The tracing shows the pressure changes in the rectum and anal canal when a normal child is trying to defecate. Note an increase in rectal pressure with a decrease in anal pressure.

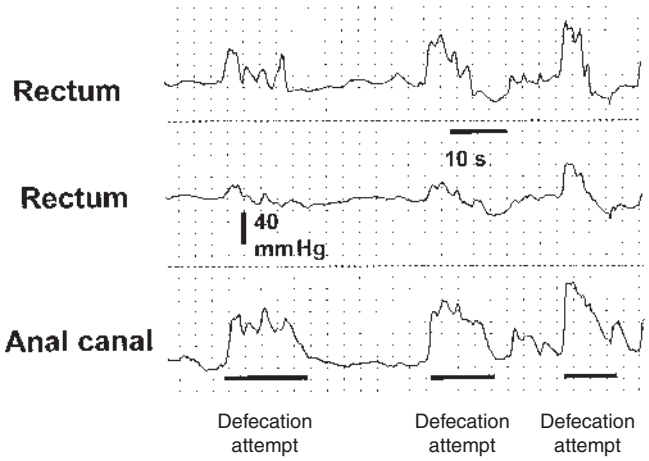

FIGURE 70-12 Abnormal defecation dynamics. The tracing shows the pressure changes in the rectum and anal canal when a child with anismus is trying to defecate. Note an increase in rectal pressure with a simultaneous increase in anal pressure.

The advent of micromanometric techniques and the use of sleeve sensors have allowed the accurate study of different sphincters even in the very low birth weight patient.[8,23,90]

Initial studies in premature infants have suggested that they do not have a RAIR. Some have shown that the RAIR may be physiologically absent up to 12 days of life in newborns, particularly if they are sick.[95] Ito and colleagues reported that the RAIR does not appear before a maturational age of 39 weeks.[96] Recently, however, other authors have found that the RAIR may be present in the first hours even in otherwise healthy premature infants,[86,89,97,98] although in three normal infants, there was absence relaxation at birth. On repeat manometries a few weeks later, the RAIR was preset, suggesting that there may be a maturational response. In a study of neonates, the range of anal resting tone was between 16 and 72 mm Hg.[86] The magnitude of anal tone was inversely correlated with weight but not gestational age. The amplitude of the RAIR in premature infants did not correlate with maturational age but correlated inversely with weight.[86]

A study of the anal inhibitory reflex in premature infants using micromanometric techniques and a sleeve has recently been published.[90] The authors studied 22 healthy neonates with a mean conceptual age of 32 weeks (30–38 weeks). They showed that the mean intra-anal pressure was 40 mm Hg (range 7–65 mm Hg), and they were able to induce a RAIR in 21 of 22 infants. The infant in which the RAIR was not present had a very low sphincter pressure (7 mm Hg), which made the determination of the reflex impossible. Resting anal pressure correlated significantly with postmenstrual age. The authors also found that gestational age, postnatal age, and time from birth to passage of the first stool did not correlate with any parameter of anorectal function. They asserted that air insufflation is the preferred method to produce the RAIR in children less than 34 weeks gestational age.[90]

Clinical Significance. Normal values for anorectal manometry in adults have been published.[85,99] The length of the anal canal was reported to range from 2.2 to 4.0 ± 1.0 cm in women and from 2.8 to 4.0 ± 1.0 in men. Anal resting tone varied from 49 ± 3 to 58 ± 3 mm Hg in women and from 49 ± 3 to 66 ± 6 mm Hg in men. Maximum squeeze ranged from 90 ± 9 to 159 ± 45 mm Hg in women and from 218 ± 18 to 238 ± 38 in men. The threshold for IAS relaxation varied from 14 ± 1 to 25 ± 2 mL, and the threshold for sensation varied from 12 ± 1 to 17 ± 9 mL.[99]

No similar comprehensive information is available for children. Values for normal controls have been published by different authors. The mean normal anal resting pressure in children ranges from 57 ± 10 mm Hg[88] to 67 ± 12 mm Hg.[100] The maximum squeeze pressure ranges from 118 ± 42 mm Hg[88] to 140 ± 52 mm Hg,[100] anal length is around 3.3 ± 0.8 cm,[100] the threshold to produce relaxation (RAIR) ranges from 5 ± 1 mL[88] to 11 ± 5 mL,[100] the threshold of rectal sensation ranges from 5 ± 2 mL[88] to 14 ± 7 mL,[100] the volume of constant relaxation is 104 ± 49 mL,[100] and the critical volume is 101 ± 39 mL.[100]

The main indication for anorectal manometry in pediatrics is to exclude the presence of a nonrelaxing IAS (see Table 70-2).[1] The finding of sphincteric relaxation (RAIR) excludes Hirschsprung disease (see Figure 70-9), particularly in older children,[101] and avoids the performance of more invasive testing such as a biopsy.[86] On the other hand, the lack of sphincteric relaxation strongly indicates the presence of Hirschsprung disease (see Figure 70-10), but a confirmatory biopsy is necessary.[86,100] In those patients in whom there are no technical difficulties and who have a nonrelaxing IAS with normal biopsies, a diagnosis of IAS achalasia needs to be considered.[102] The accuracy for the diagnosis of Hirschsprung disease by manometry varies with the age of the patients.[101,103] Anorectal manometry seems to be more accurate in older children,[104,105] for whom recent studies have suggested an accuracy of 90 to 100%. Most authors report that the accuracy in neonates is lower.[86,96,101,104–106]

A recent study of 59 patients (2–90 days) reported a sensitivity, specificity, positive predictive value, and negative predictive value of anorectal manometry for the diagnosis of Hirschsprung disease of 0.91, 0.56, 0.84, and 0.92, respectively.[103] In other studies, the overall accuracy, sensitivity, specificity, and positive and negative predictive values were 90%, 0.79, 0.97, 0.94, and 0.88, respectively, whereas in neonates, it was 90%, 0.86, 1, 1, 0.75, and in infants, it was 94%, 0.9, 1, 1, and 0.89, respectively.[106]

In the largest study of 229 manometries, there were 10 false-positive and 8 false-negative results, indicating an overall 7.8% error rate.[101] However, in a group of 38 neonates (including 7 premature infants), 26% had an inaccurate diagnosis. In 6 newborns with Hirschsprung disease, the manometry was normal, whereas in 4 normal newborns, there was no RAIR.[101] The numbers are even more inaccurate in premature infants. In that series, the diagnosis was incorrect in 71.4% of premature infants, in whom the authors found 2 children with proven Hirschsprung disease but 3 false-negative and 2 false-positive manometric findings.[101] In 39 children from 1 to 6 months of age (8 with Hirschsprung disease), there were

2 false-positive cases and 1 false-negative case, with a 7.7% error rate. From 41 children 6 months to 2 years of age (8 with Hirschsprung disease), there were 2 false-negative cases and 1 false-positive case, with a 7.3% error rate. In 47 children from 2 to 5 years of age (1 with Hirschsprung disease), there was 1 false-positive case, for an error rate of 2%. In 64 children from 5 to 15 years (2 with Hirschsprung disease), there was 1 false-negative case, for an error rate of 1.5%. This and other studies confirm the impression that accuracy increases as age increases.

Studies specifically performed looking at the experience in neonates have confirmed those observations. In some studies, it has been reported that manometry has led to the wrong diagnosis in up to 26% of neonates,[86,96,101] and it is generally reported that the diagnostic accuracy at that age varies from 70 to 80%.[86,104,105] Recently, a study in which 64 newborns (6 premature infants) with meconium delay or obstruction in whom repeated manometries were performed weekly for the first month of life was reported. There were 5 children with Hirschsprung disease in whom repeated manometries did not show a RAIR. There were, however, 3 newborns in whom the initial manometry did not show the RAIR, but when the study was repeated a few weeks later, it showed normal relaxation.[89] The opposite has been shown by other authors[106]: the manometry performed in the first 10 days of life may also give false-negative results (normal RAIR). In one report of 26 children with Hirschsprung disease, 3 initially had normal manometries that, when repeated later because of the persistence of symptoms, did not show a RAIR, and histology subsequently diagnosed Hirschsprung disease.[107] Therefore, anorectal manometry in the newborn may show more false-positive and false-negative results.

The false-negative results during anorectal manometry probably represent artifacts, such as movements of the probe, passage of flatus or feces, or relaxation of the EAS.[101] To avoid technical mistakes, it is necessary to have an empty rectum and correct position of the probe and to watch closely for movement (which could produce an artificial relaxation).

The false-positive manometries could be explained by different factors. First, there could be immaturity of the ganglion cells, particularly in premature infants and neonates. Other factors could include the following: some children have a high relaxation threshold, there could be technical errors in which the relaxation zone may be missed, and, finally, the presence of feces in the anorectum could interfere.[101]

Before a patient who has a nonrelaxing IAS and obstructive symptoms with normal biopsies is categorized as having a false-positive manometry, one has to decide if the patient suffers from IAS achalasia, or ultrashort-segment Hirschprung disease.[102,108–110] Anorectal manometry is the only way to diagnose this entity. In IAS achalasia, there is a nonrelaxing IAS, but the biopsies show normal ganglion cells and normal acetylcholinesterase.[102,108–110]

Another important use of anorectal manometry in children with constipation, after Hirschsprung disease has been excluded, is to detect those who have pelvic floor dyssynergia (see Table 70-2 and Figures 70-11 and 70-12).[92] Pelvic floor dyssynergia has been found in 30 to 53% of patients with constipation who have undergone manometry. The significance of this finding has been controversial, but it has been suggested that it may be associated with lower recovery rates. [91,111,112] Attempts to normalize defecation dynamics have been undertaken with biofeedback therapy.[93,113–115] In multiple open-label studies, biofeedback was shown to be effective, but the results of recent randomized trials have not demonstrated long-term efficacy.[93,113–115]

Changes in resting and squeeze pressure, as well as abnormal sensation, have been found inconsistently in patients with constipation by different authors and do not seem to have any major clinical implications.[1,88,111,116–118] Abnormal sensation has also been described in children with constipation,[88,92,112] and it is not known if the abnormality represents a primary problem or if it is secondary to the megarectum.

Manometry is useful in the evaluation of patients who have undergone surgery for Hirschsprung disease and continue to have incontinence or obstructive symptoms (see Table 70-2).[1] The presence of the RAIR in postoperative patients has been variable and in most studies does not seem to be correlated with outcome.[119–121] In a long-term follow-up study of adults, there was a positive correlation between functional outcome and anal resting pressure.[122] It has recently been suggested that those with obstructive symptoms and a high-pressure, nonrelaxing sphincter may benefit from procedures designed to decrease sphincter pressure. IAS myectomy[123] or, recently, botulinum toxin injection has been used.[102,124] Anorectal manometry is therefore a technique that allows detection of the nonrelaxing sphincter and may be useful to decide if the patient is a candidate for botulinum toxin or to evaluate patients after it has been applied.

The utility of anorectal manometry in diagnosing neuronal intestinal dysplasia is controversial.[125,126] The first difficulty arises because there is no consensus regarding the histologic diagnosis.[126] However, even in those reports in which a diagnosis of neuronal intestinal dysplasia has been made, the anorectal manometry has not been able to discriminate abnormal from normal cases.[125,127,128]

Anorectal manometry has been shown to allow some discrimination between patients with or without fecal incontinence (see Table 70-2).[1,129–132] In a study of 350 patients, 178 of whom were incontinent by history, it was found that squeeze pressure had the greatest sensitivity (60%) and specificity (78%) if a cutoff value of 60 mm Hg was used.[129] The measurement of the resting anal canal pressure was less sensitive and specific. In another study comparing 302 patients with fecal incontinence and 65 controls, it was found that by taking the mean – 2 SD for controls as the cutoff, the sensitivity of the maximum squeeze pressure to predict incontinence was 92% and the specificity was 97%. Basal anal resting tone had a sensitivity of only 37%.[130] An abnormal sensation has also been reported in patients with fecal incontinence,[131] and it has been suggested that the most important component of

biofeedback training for fecal incontinence is an improved ability to detect rectal distention.

In patients with imperforate anus, anorectal manometry is a useful technique to evaluate the state of intrarectal pressure and sensation, as well as of the voluntary muscles.[1,131,133–135] Some studies have found that patients with a repaired imperforate anus have significant abnormalities in anorectal function.[131,134,135] It has been shown that patients with more incontinence have lower squeeze pressures and sensation abnormalities.[131,133] In postoperative patients with fecal incontinence, the measurement of intraanal pressure is important, particularly when a reoperation is being considered. Also, a manometric evaluation may allow the detection of abnormalities that may be amenable to biofeedback training.[2,131,135,136]

Indications. The main indication is in the evaluation of children with constipation to exclude the presence of a nonrelaxing IAS (see Table 70-2).[1] Hirschsprung disease also has to be considered in older patients (including adults) with intractable constipation.[137] It is indicated in the evaluation of patients with fecal incontinence to evaluate sphincter function and weakness, as well as sensation.[1] In patients with imperforate anus repair or neurogenic problems, it may be useful to decide if the patient is a candidate for biofeedback.[1] It is also indicated in the evaluation of children with Hirschsprung disease who have postoperative obstructive symptoms to determine if they are candidates for botulinum toxin or after botulinum toxin has been applied and the symptoms recur (see Table 70-2).[1]

The study of defecation dynamics is also important, although the use of biofeedback in children has not been shown to be effective.[1,113]

Other Tests to Evaluate Anorectal Function. EMG of the pelvic muscles can be performed using either a needle electrode, a surface electrode, or an anal plug. This test allows the identification of areas of injury, establishes if the muscle contracts or relaxes, and identifies evidence of denervation-reinnervation. The needle electrodes that are used study the activity of a large number of motor units (concentric) or a single fiber. This requires the insertion of the needle in the perineum into the sphincter muscle, so it is painful, and its utility in children is limited. In children, it is most useful in the evaluation of postoperative patients of imperforate anus, in which it may be used to show the presence or absence of striated muscle around the anal opening. It is also useful in the establishment of nerve damage from spinal lesions. Because of its invasiveness and its limited usefulness, needle EMG is not routinely used in pediatrics. On the other hand, superficial EMG electrodes can be useful, particularly to evaluate for the presence of pelvic floor dyssynergia.[88,91] This causes less discomfort to the patient. It has also been shown that the number of motor units recruited during squeeze correlates with squeeze pressure. Therefore, surface electrodes have been successfully used in the assessment of defecation dynamics and squeeze pressure and can also be used to provide biofeedback training.[113]

Other tests, such as balloon expulsion and pudendal nerve terminal motor latency, have not been shown to have a clinical role in the evaluation of children.

OTHER STUDIES TO EVALUATE GASTROINTESTINAL NEUROMUSCULAR FUNCTION

Electrogastrography

Electrogastrography (EGG) is a technique in which the electrical activity generated by gastric smooth muscles is measured.[138–140] It is a noninvasive method of assessing the gastric myoelectrical activity that controls gastric motility.[140–144] This is now done by using surface cutaneous electrodes placed on the abdomen overlying the stomach.[138,141,142] Because of its noninvasive nature, it represents an attractive tool for the diagnosis of gastric motility problems in children.[138,139,141–143]

The cutaneous EGG usually uses three to four electrodes that are placed on the abdominal wall close to the antral region to reduce interference and to obtain a high signal-to-noise ratio.[138,144] Ideally, the electrodes are placed either with ultrasound or fluoroscopic guidance to identify the gastric contour.[140–144] In adults, it has been advocated that a standard configuration can be used without the need for imaging studies.[138,140,144] The first electrode is set above the antrum (located 1 to 3 cm right of the midline, between the xiphoid process and the umbilicus), the second 45° and 3 to 6 cm above and left of the first electrode (based on the size of the subject), and the third (reference) at the left flank, horizontal to the first electrode. In an effort to establish if it is possible to accurately place the electrodes without the use of ultrasonography in neonates, Patterson and colleagues compared the results obtained by both ultrasonography or blind placement of the skin electrodes and found no differences.[142] In another study in premature infants, the first electrode was located immediately below the left costal margin in the midclavicular line.[141] The third electrode was located between the umbilicus and the xiphoid process and the second electrode between the first and third electrodes.

The duration of an EGG recording session may vary depending on the center or the working diagnosis.[138,140,144] Most commonly, the test is performed with 1-hour fasting, then a standardized meal is given, and the activity is recorded for another 1 to 2 hours postprandially.[138,140–144] It has been suggested that for the major EGG parameters, 30 minutes in the fasting state is sufficient to produce reliable results, and in the postprandial period, recordings from 30 to 60 minutes adequately represent the change after meal ingestion.[140] The recordings are analyzed by computer using specialized software, and usually the fast Fourier transform is used to detect the dominant frequencies.[42,138,139,141,143]

The major EGG parameters that are analyzed include the following: the dominant frequency, the dominant power, the percentage of normal slow waves, the percentage of gastric dysrhythmias, and, in some centers, the dominant frequency instability coefficient (DFIC).[138,139,141,143]

Many studies have documented that the dominant frequency of the cutaneous EGG corresponds to the basal gastric rhythm or frequency of the gastric slow wave.[138,140,144] It is thought that the electrical activity reflects the gastric slow wave generated by the stomach's pacemaker, the interstitial cells of Cajal of the greater curvature.[55,140,143] The normal gastric slow-wave frequency is about 3 cycles per minute (cpm) (normal range 2–4 cpm).[138] The computer also determines the "power" for each of the signal frequencies. Power is a reflection of both the amplitude and the regularity of the EGG.[140,144] It has been shown that the EGG amplitude does not always correlate with the force of the gastric contractions,[144] and the absolute value is influenced by electrode placement, skin/fat thickness (distance between stomach and skin), and movement of the stomach.[140,144] Therefore, only relative changes are considered by comparing in the same individual the change of the power after a meal.[138,140,144] This can be calculated from the ratio of the postprandial power of the dominant frequency to the preprandial power of the dominant frequency.[139,143,144] Usually, the postprandial-to-fasting power ratio value is more than 1.[55,144] It has been suggested that a diminished or absent increase in the power ratio correlates to delayed gastric emptying and antral hypomotility.[144]

The percentage of normal slow waves reflects the regularity of the EGG.[140] It is defined as the percentage of time during which 2 to 4 cpm slow waves are present across the entire recording. Studies suggest that most healthy individuals display a value above 70% in fasting and postprandial states.[140]

A dysrhythmic index (percentage of dysrhythmic time during the recording) is usually reported.[138] It measures the percentage of time during the recording in which 2 to 4 cpm slow waves are absent. It has been suggested that abnormal rhythms of gastric myoelectrical activity may be detected. They are classified as tachygastria (rapid) usually > 4 cpm, bradygastria (slow) < 2 cycles/min; bradytachyarrhythmia (mixed), or absent activity.[139,143,144] Antral hypomotility has been associated with both brady- or tachyarrhythmia.[139,144] Values for a 1-hour recording in both fasting and fed states have been reported in 10 asymptomatic children and in 14 children with dyspepsia.[145] The fasting dysrhythmic index was 1.6% (range 1.6–33.3) in the controls versus 33.3% (range 10–48) in the dyspeptic patients. The fed dysrhythmic index was 2.7% (range 1.6–5.5) in controls and 15% (range 11–66) in patients.[145]

The DFIC specifies the stability of the gastric electrical peak visible on the running spectra plot and calculated as the percentage ratio of the frequency standard deviation to mean gastric frequency.[138] The DFIC reflects subtle changes in gastric slow waves.

In children, the validation of the technique is limited, but the use of EGG is growing. One of the biggest problems so far has been the fact that there is almost no information about the normal EGG patterns in healthy children, including a lack of information on developmental aspects.

A study in 114 normal children (6–12 years) found in the preprandial state a dominant frequency of 3.0 cpm (2.1–3.5), a DFIC of 26% (6.7–54.5), normal slow waves of 81.5% (59.3–100), bradygastria of 3.7% (0–22.2), and tachygastria of 9.4% (0–38.7).[146] The dominant frequency postprandially was 3.0 cpm (2.1–3.7), the DFIC was 30% (11–67; $p < .05$), normal slow waves were 76.9% (54.4–97.2), bradygastria was 4.9% (0–29.3), and tachygastria was 11.8 (0–35). The EGG power increased postprandially to a power ratio of 3.6 (0.8–19.7). The researchers found no age differences or effects of age, gender, and body mass index.[146]

In another study of 24 normal boys ranging from 1 to 11 years (mean 6 years), Cheng and Tam found that the percentage of bradygastria was higher in younger children, accounting for 34% of the recording.[147] The normal 3 cpm increased with age, whereas the bradygastria decreased. They suggested that by the end of the first decade, the EGG patterns are similar to those in the adult,

A recent study of 50 healthy volunteers ranging in age from 6 to 18 years described a mean dominant frequency of 2.9 ± 0.4 cpm preprandially and 3.1 ± 0.35 postprandially, with 80% ± 13% of test time spent in the normogastric range (2–4 cpm) before and 85% ± 11% after the test meal.[143] The authors concluded that there was a postprandial increase in rhythmicity and amplitude of the gastric slow waves and that key normative values are not dependent on age, gender, or body mass index.[143]

Development. Different authors have found that both preterm and newborn infants have a low percentage of gastric slow waves.[148,149] Chen and colleagues studied EGG in five different groups: premature infants, newborns, infants 2 to 6 months, children 4 to 11 years, and adults.[149] Children and adults showed similar activity.[149] Infants showed a percentage of normal slow wave that was significantly lower than that in adults but higher than in newborn and premature infants. The percentage of 2 to 4 cpm slow waves was 26 ± 4% in premature infants, 30 ± 4% in full-term infants, 70 ± 6 in 2- to 6-month-old infants, 85 ± 3% in children 4 to 11 years, and 89 ± 2% in adults.[149] As in other studies, both newborns and premature infants showed an absence or a decrease in normal slow waves.[148–150] The biggest limitation of the study is the small number of patients. Koch and colleagues also showed that in premature infants and newborns, there were no significant differences in activity after gavage feeding.[150] Bradygastria, 3 cpm, and tachygastria comprised 49%, 17%, and 29% of the preprandial recording and 51%, 15%, and 27% of the postprandial EGG.[150]

The developmental maturation of the gastric slow waves has recently been analyzed in a longitudinal study of 19 preterm infants followed from birth to 6 months. It was shown that the percentage of 2 to 4 cpm slow waves increased gradually over time to a value slightly lower than that in adults.[151] The rate of development was twice as fast in the first 2 months, and dominant peaks and an increase in power were not observed at birth in any of the infants but could be identified in 70% of the children at 6 months of age.[151] Patterson and colleagues studied 9 healthy neonates born at 34 weeks gestation and showed that their EGG dif-

fered from that of adults.[141] Tachygastria and bradygastria were seen more frequently, with fewer episodes of 3 cpm. There was an increase in 3 cpm episodes over time.[141]

Clinical Significance. Interest in EGG has been generated not only because it is a noninvasive technique but also because, in recent years, a correlation between disorders in gastric electrical rhythm and certain clinical syndromes characterized by alterations in gastrointestinal motility has been described.[138,140,146] Because normal motility of the stomach requires integrity of the enteric and extrinsic nerves and smooth muscle, any abnormality in them may result in dysfunction.[140] Therefore, there are some diseases in which EGG may be theoretically useful, and it is possible that it may be used as a noninvasive screening technique[140] or, most importantly, as a way to evaluate follow-up or the results of therapy, particularly when invasive techniques are the only other alternative. To date, however, no therapies have convincingly demonstrated in controlled studies that correcting abnormalities detected by EGG improves upper gastrointestinal symptoms.[138] Ideally, EGG could be used as a screening tool to detect those patients who may have underlying motility disorders. It may provide evidence that upper gastrointestinal symptoms are associated with gastric dysmotility. However, studies have shown that there are patients with gastric dysrhythmias who do not have abnormal motility or that not all patients with abnormal motility have dysrhythmias. In children, limited data have tried to validate the specificity and sensitivity of EGG to detect motility disorders in children. In a study in which simultaneous EGG was performed together with antroduodenal motility in 25 children, the authors found that EGG differentiated groups of children with normal manometry from others with neuropathic or myopathic change, but in some patients, there was an overlap of EGG results between children with normal and abnormal manometry.[55] The percentage of tachygastria time was higher in patients with mild (44 ± 16%) and severe neuropathy (48 ± 19%) compared with those with myopathy (20 ± 16%) or normal motility (23 ± 13%). There was considerable overlap in the percentage of tachygastria and total arrhythmia time among the different groups. Every child with a total arrhythmia time < 35% and a ratio of postprandial-to-preprandial power > 2.4 had normal motility.[55]

In children, EGG has also been used as a method to understand the physiopathology of upper gastrointestinal symptoms in patients with different medical problems, such as pseudo-obstruction,[152] GER after fundoplication,[153,154] with functional dyspepsia[139,140,145] or in children with systemic or generalized problems. Gastric dysrhythmias have been described in children with renal failure,[155] Noonan syndrome,[156] cyclic vomiting,[157] cystic fibrosis,[139] or neurologic handicaps.[154,158]

EGG has also been suggested as a noninvasive way in which to evaluate the effects of therapy for motor disorders. In a study to evaluate the effects of cisapride, Cucchiara and colleagues showed that after 8 weeks of therapy, the medication reversed the abnormal myoelectric activity in three children with nonulcer dyspepsia.[159]

Indications. Even though, at present, the use of EGG in children is still considered a research tool and future studies will be needed to continue to validate its usefulness, it is very likely that EGG will become a useful test in the evaluation and treatment of children with gastrointestinal motility disorders. The most likely indication will be in the evaluation of children with unexplained nausea, vomiting, and postprandial abdominal bloating or distention. It may also become a screening test to predict gastroparesis, to assess for gastric motor dysfunction in patients with other gastrointestinal symptoms (eg, constipation), to try to predict who will develop symptoms after fundoplication, or to follow the response to medications.[42,55,140,153,154,159] For now, however, the proposed clinical indications for the performance of the EGG in adult and pediatric patients with unexplained nausea, vomiting, and dyspeptic symptoms must be validated by prospective controlled investigations.[138]

Other Future Techniques

Other gastrointestinal motility studies are currently being performed mostly in adult units or research laboratories that have the potential to become clinically useful in pediatrics. Therefore, a brief description follows, although, at present, there is very limited information in children, and these studies have no role in the routine treatment of children with motility problems.

Manometry of the SO. The evaluation of manometry of the SO has been used mainly to evaluate patients for SO dysfunction. The intraluminal pressure recording from the billiary tree requires intubation with the use of endoscopic retrograde cholangiopancreatography (ERCP), which makes the technique very invasive. Also, the effects of anesthesia or sedation on manometric results have not been well established. In addition to the technical difficulties involved, the performance of SO manometry increases the incidence of post-ERCP pancreatitis and may result in pancreatitis in up to 15 to 20% of patients.[160]

When SO manometry is performed, a perfused system is usually used. A catheter with three lumens of 0.5 mm internal diameter making up a catheter of 1.7 mm or a tapering catheter of 1.5 outer diameter is usually introduced using the biopsy channel of the duodenoscope through the papilla and into either the bile duct or the pancreatic duct. The catheter is then withdrawn until all three recording ports are situated in the SO. The SO is characterized by a basal pressure on which prominent pressure peaks representing phasic contractions are superimposed. Usually, the basal SO pressure ranges from 3 to 35, with a median of 15 mm Hg.[161,162]

Over the past decade, different abnormalities of the SO have been described,[160,161] and abnormal pressure is the parameter most often employed.[161] The clinical significance of SO manometric findings is still debated. Some authors recommend SO manometry for the evaluation of recurrent pancreatitis or unexplained biliary pain and for the selection of those patients who may benefit from endoscopic therapy (eg, sphincterotomy).[160,161] In children, there is very limited information,[162] and there are no nor-

mal controls or validation of its clinical utility. Because of those limitations and the high incidence of pancreatitis associated with its performance, SO manometry should still be considered only a research tool, although it is possible that, in the future, it may have a role in the evaluation and treatment of children with unexplained right upper quadrant pain or recurrent pancreatitis.[162]

Barostat. This technique allows the study of a component of motor activity that cannot be evaluated by conventional manometry or EMG. The barostat is mainly used to measure intraluminal volume or pressure relationships and helps to establish sensory thresholds.[163,164] The instrument requires a high-compliance balloon, and it measures tone by monitoring the volume of air required to maintain a constant preselected pressure level in a flaccid bag. The system uses an electronically regulated air injection/aspiration device. The volume of the bag increases or decreases depending on intraluminal pressure, which is determined by the motor activity of the organ being studied. When used in the stomach, it uses a balloon designed for the fundus/body, in which relaxations and contractions are relatively slow.

The barostat also allows the quantification of sensory thresholds triggered by intraluminal distention. In children, the use of the barostat has allowed some insight into the pathophysiology of irritable bowel syndrome and abdominal pain.[163,164] At this point, the barostat remains a research tool that is being used to understand the physiopathology of irritable bowel syndrome or other gastrointestinal disorders and to evaluate the effects of therapy, and it is difficult to predict what role it will play in the routine evaluation and treatment of patients with gastrointestinal motility disorders.

TRAINING IN GASTROINTESTINAL MANOMETRY

The North American Society for Pediatric Gastroenterology Hepatology and Nutrition (NASPGHAN) has approved and published guidelines for training in gastrointestinal motility.[165] The guidelines recommend two levels of training. Level 1, or basic training, is expected from all trainees and includes understanding the pathophysiology of motility disorders, treatment of an adequate number of patients with these problems, and understanding of the rationale, usefulness, and limitations of the common tests used in the evaluation of the patient. Level 2, or advanced training, is recommended for those who are planning to perform specialized motility studies or act as consultants to other gastroenterologists. Table 70-4 shows the number of procedures recommended to achieve proficiency in the performance of the common gastrointestinal manometry studies.[165]

TABLE 70-4 NUMBER OF PROCEDURES TO ACHIEVE COMPETENCE IN GASTROINTESTINAL MANOMETRY*

STUDY TYPE	THRESHOLD FOR COMPETENCE
Esophageal manometry	20
Anorectal manometry	20
Antroduodenal manometry	25
Colonic manometry	25
Electrogastrography	25

SUMMARY

The study of gastrointestinal motility in children continues to evolve and has changed from being a research technique to becoming a useful diagnostic tool. There continues to be a dichotomy between the use of manometry as an investigation technique or as a useful clinical test, and as new techniques are being developed and validated, the clinical indications are becoming better defined. The performance of gastrointestinal manometry in children is more challenging, and recent technical advances have allowed the study of younger and smaller babies, which has allowed the understanding of some developmental aspects.

The role of gastrointestinal manometry has been defined more clearly for anorectal and esophageal manometry, although small bowel motility is becoming clinically more accepted. Other studies are mainly performed in research laboratories and have still not been fully validated. Manometry is mainly useful for the diagnosis of primary motility disorders and can be useful in some cases in which the motility alterations are secondary to other illness. In general, the manometric evaluation may detect aberrations that may be clinically insignificant, so care needs to be exerted to avoid overinterpretation.

CHAPTER 71

pH MEASUREMENT

Yvan Vandenplas, MD, PhD

WHY MONITOR THE PH IN THE ESOPHAGUS?

The idea that the measurement of the pH in the esophagus may be of great clinical importance started with the observation that acid perfusion–induced heartburn coincides with the fall of intraesophageal pH below 4.0.[1] Esophageal pH monitoring is often considered an investigation technique studying esophageal motility, which it obviously does not do because it does even not measure gastroesophageal reflux (GER). This being said, the major shortcoming of esophageal pH monitoring is obvious: the technique measures changes in esophageal pH, not GER. The first clinical tests were performed in the early 1960s by Miller.[2] Modern electronic technology has profoundly changed the practice of medicine, principally through its ability to monitor, record, and analyze large volumes of data. The introduction of computers has provided physicians with powerful tools to identify elusive and intermittent disorders, such as gastroesophageal reflux disease (GERD). Although a continuous investigation technique such as pH monitoring is extremely suitable for ambulatory outpatient application, many centers still hospitalize patients.

Major areas of indications for esophageal pH monitoring are (1) in clinical and laboratory research, (2) as a routine clinical procedure in the diagnosis of GERD, especially in children presenting with atypical GER manifestations (Table 71-1), and (3) in the evaluation of the efficacy of treatment of GERD on the frequency and duration of the presence of acid in the esophagus.[3,4]

HARDWARE AND SOFTWARE: PEDIATRIC NEEDS

Device

Purchase costs, system abilities, costs in use, number of measurements, and durability of the material are factors to consider before purchasing equipment. Of importance for pediatric use are a time indication on the display (ie, the number of data recorded, the real time, the duration of the investigation) and the protection of the event marker(s) to avoid erroneous use by the child.[4] A system should refuse to work if it has not been calibrated properly.

One of the advantages of pH monitoring is the possibility of realizing an ambulatory recording, even in young children. Therefore, the device should be small and light. Devices not larger than a credit card, although of course a little thicker, are commercially available.

Electrode

pH sensors or "electrodes" exist in several forms, of which the two most popular are glass and antimony. Ion-sensitive field effect pH electrodes are modified field effect transistors. Glass electrodes are generally considered to be the most accurate.[5,6] Clinical studies require a pH sensor that is both economical and reliable. Glass electrodes with an internal reference are "the best" but are expensive and have a rather large diameter (3.0–4.5 mm). Although the passage of such an electrode through the nostrils of a young baby is, most of the time, technically possible, it does not mean that it is well

TABLE 71-1 SYMPTOMS OF GASTROESOPHAGEAL REFLUX DISEASE

ESOPHAGEAL MANIFESTATIONS
Specific symptoms
Regurgitation
Nausea
Vomiting
Symptoms possibly related to reflux esophagitis
Symptoms related to anemia (iron deficiency anemia)
Hematemesis, melena
Dysphagia (as a symptom of esophagitis and/or due to stricture formation)
Weight loss and/or failure to thrive
Epigastric or retrosternal pain
"Noncardia angina-like" chest pain
Pyrosis or heartburn, pharyngeal burning
Belching, postprandial fullness
Irritable esophagus
General irritability in infants ("colic")

GER = gastroesophageal reflux.

tolerated and that it is the best option. From recent experience with combined pressure-pH recordings, it became clear that the larger the diameter of the electrode(s), the more the patient had to swallow (personal data). Thus, the pharyngeal presence of an (large size) electrode has a decreasing effect on GER episodes because the more the patient has to swallow, the more primary peristalsis is induced, and the better esophageal clearance becomes.

Because of their smaller diameter, antimony (2.1 mm) (Synectics Medical, Queluz, Portugal) or glass microelectrodes (1.2 mm) are preferable in infants. Antimony electrodes also exist with a diameter of about 1.5 mm for use in premature babies; these electrodes are too flexible for older babies. Single esophageal pH monitoring cannot detect alkaline reflux.[7] Glass electrodes have only one pH sensor. Antimony electrodes with multiple pH sensors may help to detect alkaline reflux episodes. Antimony electrodes with two sensors can also be helpful to evaluate the therapeutic efficacy of acid-reducing medication: the esophageal sensor measures the incidence of acid GER, whereas a gastric sensor measures the efficacy of the medication. Antimony is only poorly resistant to gastric acid, but the fact that acid should be reduced or minimalized in these patients minimizes the impact of this shortcoming.

Most antimony and all glass microelectrodes need an external cutaneous reference electrode, which is a possible cause of erroneous measurement resulting from transmucosal potential differences. If the environmental temperature is high or the patient sweats a lot, the conductivity of the contact gel will change, resulting in a less accurate conduction of the electric potential. Antimony electrodes with a diameter of about 2.0 mm with an internal reference electrode have been developed, providing comparable results (personal data, 1997; Table 71-2). This electrode is accurate, thin, flexible, and easy to place in the esophagus, and there is no longer need for a cutaneous reference electrode. However, in clinical reality, the purchase cost of the electrode and income of the pH monitoring will substantially influence the type of electrode used. Whatever the type of electrode chosen, each center should preferentially use one type or a limited number of electrodes.

Prior to each study, an in vitro two-point calibration must be carried out. The electrode and reference are placed in two buffer solutions (usually pH 1.0 and 7.0) at either room or body temperature until stabilization is reached. This calibration should be repeated on return of the patient to rule out electrode failure and to check for slow pH drift. A drift of less than 0.5 pH over the 24-hour period is acceptable. Calibration needs to be corrected according to room and body temperature.

LOCATION OF THE ELECTRODE

There is abundant evidence in the literature that the esophageal location of the electrode is of critical importance regarding the number and duration of acid reflux episodes recorded. It seems logical that the closer the electrode is located to the lower esophageal sphincter (LES), the more acid reflux episodes will be detected.[8,9] In adults, the electrode is, by consensus, positioned 5 cm above the proximal border of the LES. Also in adults, determination of the position of the LES by means of a standard stationary esophageal manometry study is generally regarded as the optimum method for pH probe localization.[6] In children, several methods have been proposed to determine the location of the electrode: fluoroscopy, calculation of the esophageal length according to the Strobel formula (distance from the nose to the cardia = 5 + 0.252 [length in cm]), manometry, and endoscopy. Ideally, as in adults, the electrode should be sited in reference to the manometrically determined LES. However, this has several inconveniences: (1) manometry in infants and children is time consuming, rather invasive, or at least unpleasant, and (2) this method would have the inconvenience that the electrode is located at a fixed distance to the LES, whereas the length of the esophagus increases from less than 10 cm in a newborn to over 25 cm in an adult. Moreover, manometry cannot be performed in all centers. Therefore, the European Society for Paediatric Gastroenterology, Hepatology, and Nutrition Working Group on GER recommended the use of fluoroscopy to locate the electrode.[4] The radiation involved is minimal, and the method can be applied in each center. As the tip of the electrode moves with and during respiration, the tip should be positioned in such a way that it overlies the third vertebral body above the diaphragm throughout the respiration cycle (Figure 71-1). Dislocation by a curled electrode is also

TABLE 71-2 ADVANTAGES AND DISADVANTAGES OF PH MONITORING TO DIAGNOSE GASTROESOPHAGEAL REFLUX DISEASE

	ADVANTAGES	DISADVANTAGES
Technique	Physiologic conditions Normal ranges Good reproducibility Long duration (24 h)	Physiologic conditions Social discomfort (electrode)

GER = gastroesophageal reflux; PPI = proton pump inhibitor.

prevented with fluoroscopy. If the pH device is exposed to x-rays, the data and calibration may be erased.

PATIENT PREPARATION

No special patient preparation is required for pH monitoring, except for fasting. The patient should fast for at least 3 to 5 hours before the study, depending on the age, to avoid nausea and vomiting. If the child is able to communicate, it is important to reassure the child at the beginning of the study and explain what will happen. The child should understand that the passage of the catheter through the throat is uncomfortable, but after the first few swallows, it will feel better. To facilitate insertion, a silicone spray (eg, Silicone-spray, Alphamed, Brussels, Belgium) can be placed on the electrode (but not on the pH sensor!) and/or local anesthesia of the mucosa of the nostrils can be done. Sedation should not be used because the sedative may interfere with swallowing and influence pressures.

Histamine$_2$ (H_2) blockers or proton pump inhibitors should be stopped at least 3 or 7 days, respectively, before a diagnostic pH monitoring (on the condition that the investigation is not performed to evaluate the acid-buffering effect of the drug). Antacids are permitted up to 6 hours prior to the start of the recording. Prokinetics should be stopped at least 48 hours before the pH monitoring.[8] The continuation or discontinuation of drugs depends on the indication for the pH study: diagnosis of reflux or evaluation of efficacy of treatment.

It is best not to start a pH metry the same day an upper gastrointestinal tract endoscopy was performed because of the sedation, fasting, and inflated air. It is best to start pH metry at least 3 hours after a barium swallow or radionuclide gastric or esophageal studies.

PATIENT-RELATED INFLUENCING FACTORS: RECORDING CONDITIONS

Feeding, position, and physical activity are examples of patient-related factors influencing pH monitoring data. Patient-related factors that possibly influence the results of pH monitoring are a controversial topic.[4,8] The answer to the fundamental question if patient-related factors should be minimized and standardized is difficult and necessarily ambiguous. If the pH monitoring is performed as part of a diagnostic workup in a patient, it is interesting to study the patient during normal daily life, noting what is enhanced by unrestricted recording conditions. But if the pH monitoring is performed as part of a (clinical) research project, recording conditions should be standardized. Standardization of recording conditions inevitably causes a loss of patient-specific information.

DURATION OF THE RECORDING

The duration of the recording should be "as close as possible to 24 hours" and at least 18 hours, including a day and a night period.[4,10,11] If the pH monitoring is performed for diagnostic purpose, there is no indication for short-duration pH tests (eg, Tuttle and Bernstein tests, 3-hour postprandial recording). The first reports on the clinical use of pH monitoring concerned esophageal tests of short duration. Tuttle and Grossman developed the "standard acid reflux test."[12] This test was modified by Skinner and Booth[13] and Kantrowitz and colleagues,[14] demonstrating that pH tests can contribute to define abnormal GER. The Tuttle test was reported to have a sensitivity of 70%.[15] After great initial enthusiasm for this test, criticism became more and more common. The test is unphysiologic in requiring intragastric instillation of acid and various artificial maneuvers to raise intragastric pressure. In the early 1980s, it was reported that the false-positive rate might be as high as 4 to 20% and the false-negative rate as high as 40%.[16–18] Bernstein and Baker demonstrated in 1958 that heartburn could be provoked by infusing diluted hydrochloric acid into the esophagus in susceptible individuals.[19] This test was shown to be 100% positive in reflux patients.[20] A modified Bernstein test was used to illustrate the relationship between GER and apnea and stridor and between nonspecific chest pain and GER.[21,22] Provocative testing can be used in particular conditions to demonstrate the relationship between GER and specific symptoms (bradycardia in relation to acid in the esophagus). However, provocative testing has always had the inconvenience that the investigation conditions are unphysiologic. The latter might explain some discrepancies in literature. Ramet and colleagues showed a prolongation of the R-R interval in infants during provocative testing with acid instillation in the esophagus,[23] whereas others could not reproduce these findings in 24-hour recordings in physiologic conditions.[24,25]

There is now substantial evidence that in controls and in the majority of infants and children with classic symp-

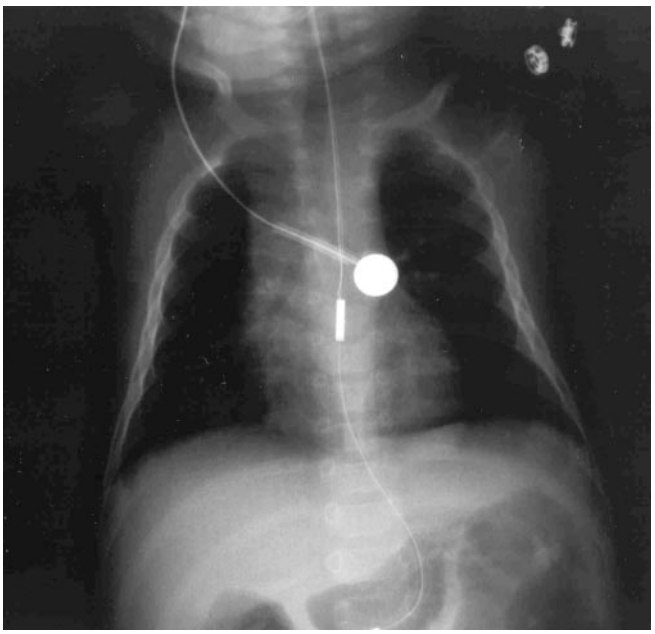

FIGURE 71-1 Radiograph of the thorax to show the localization of the pH electrode (third vertebra above the diaphragm). The radiograph shows a two-channel electrode with the distal electrode in the stomach and the proximal electrode at the third vertebra.

toms of GERD, esophageal acid exposure is highest during the day, probably because of provocation of GER by food ingestion and physical activity. Controls have more reflux upright than supine or more reflux awake than asleep.[26] The relationship between esophagitis and nocturnal reflux is far from clear.[27–29]

Feeding

Feeding during pH monitoring has been and still is an area of controversy. On the one hand, it seems logical to forbid the intake of acidic foods and drinks. However, many popular foods and beverages have a pH of < 5.0 (eg, cola drinks, fruit juice, tea, soup), resulting in a quite restricted diet. A too restricted diet might alter the patient's normal daily habits in such a way that the investigation is no longer performed in physiologic conditions. Electrodes are temperature sensitive; therefore, very hot and ice cold beverages and food (eg, coffee, tea, ice cream) should be avoided.[4] Ask the older child not to chew gum or eat hard candy because these will increase saliva production and thus will induce swallowing and peristalsis and tend to normalize the test results. In older children, alcohol intake and smoking should be recorded on the diary.

In infants, it has been suggested to replace one or several feedings during pH monitoring with apple juice.[30] This would solve the problem of gastric anacidity after a milk feeding, but apple juice has a pH of about 4.0 and a very rapid gastric emptying and is not part of normal infant feeding. In our unit, feeding is free, but parents and children are asked not to exaggerate "acid" ingestion and to avoid very hot and cold food and beverages and chewing gum. Although the ingestion of acid such as a cola drink might simulate a reflux episode, the duration of ingestion is limited to a few minutes and most of the time is irrelevant to the total 24-hour data. To minimize this effect, it is possible to eliminate these false reflux episodes with the help of a diary.

All of the above is true for diagnostic investigations. However, in research, the opposite might be valid: all factors possibly influencing the pH data should be controlled and standardized as much as possible.

The influence of a particular food on the incidence of acid GER episodes detected by pH monitoring might be opposite to its influence on the incidence of reflux episodes: a fat meal is known to provoke GER because of its delayed gastric emptying. Because the duration of postprandial gastric anacidity after a fat meal is prolonged, a meal with a high fat content will result in delayed gastric emptying and thus less acid reflux episodes detected by pH monitoring.[31,32] Some drugs influencing gastric emptying (eg, prokinetic agents) have a comparable effect on pH monitoring data: prokinetic drugs enhance gastric emptying, shorten the period of postprandial gastric anacidity, and prolong the periods during which acid GER can be detected.

Position

Different patterns of GER (upright, supine, combined) have been reported in adults and older children.[33] Orenstein and colleagues. demonstrated that the prone sleeping position is the preferred position for infants as far as GER is concerned because crying time is decreased if compared with the supine position.[34–36] There is evidence that the prone anti-Trendelenburg 30° sleeping position reduces GER in normal subjects and patients, although the position is difficult to apply and maintain correctly (infants have to be tied up in their bed). Meanwhile, the literature on sudden infant death syndrome (SIDS) in infants shows that infant mortality decreases if infants are put to sleep in the supine position. Accordingly, the prone anti-Trendelenburg position is no longer recommended in infants at risk for SIDS.[37,38] Thus, the position of the infant should be recorded on the diary during pH monitoring.

DATA ANALYSIS

Interpretation and Parameters

Interpretation starts with a visual appreciation of the pH tracing, what is subjective and difficult to standardize (Figure 71-2). Nevertheless, it is of the utmost importance "to have a look" at the tracing. The parameters that are classically analyzed are the total number of reflux episodes, the number of reflux episodes lasting more than 5 minutes, the duration of the longest reflux episode, and the reflux index that is the percentage of time of the entire duration of the investigation during which the pH is less than 4.0. From all "classic" parameters, the acid exposure time or reflux index is the most relevant. The correlation between all four parameters is good, and they are closely related to the reflux index.[39] Results should also be (automatically) calculated for periods of interest, such as sleep, wakefulness, feeding, postprandial fasting, and body position. A time relation between atypical manifestations (eg, cough, bradycardia, desaturation) and "changes" in pH (not necessarily a drop in pH below 4.0) should be searched for. The duration of reflux during sleep has been suggested to be a good selection criterion for reflux related to apnea in infancy (the "ZMD-score").[40] However, one should not forget that the response time of an electrode (the time needed to reach 95% of the exact pH) is at least about 5 seconds. The "area below pH 4.0" is a parameter considering the acidity of the reflux episodes,[41] which has been shown to correlate better with the presence of reflux esophagitis than with the reflux index.

Various complex reflux scoring systems (Johnson-Demeester Composite Score, Jolley, Branicki, Kaye, Boix-Ochoa scoring systems) have been developed. The majority of all of the parameters have been developed for assessing reflux esophagitis in adults. In marked contrast to these complex scoring systems is the simple recommendation by some investigators that the reflux index or total acid exposure time should be regarded as the most important, if not the only, variable in clinical practice.[39,41] Jolley and colleagues proposed a score for children.[42] Scores based on symptom indices are not applicable in infants and young children.

A major interfering factor in the interpretation of pH monitoring data is the "yes" or "no" interpretation of the data by computer software: a pH of 4.01 will be regarded as normal, whereas a pH of 3.99 will be considered as acid

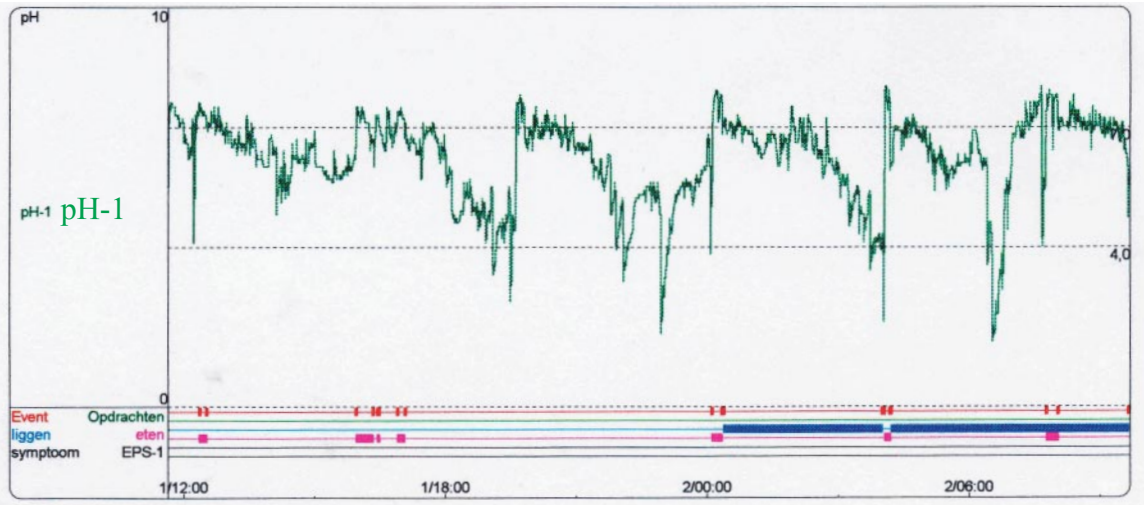

FIGURE 71-2 A 24-hour pH tracing, showing different acid and nonacid reflux episodes, during periods of wakefulness and sleep (*dark line*). Events (coughing) are either nonrelated or occur just after a reflux episode.

reflux. Minimal changes in esophageal pH around pH 4.0 can be at the origin of different software interpretations, although without difference in clinical meaning. The oscillatory index, a parameter measuring the time the pH oscillates around pH 4.0, was developed to evaluate this risk for erroneous computer interpretation.[43]

Normal Ranges

As for any measurement, normal ranges are mandatory. However, because there is a continuum between physiologic and pathologic GER, normal ranges should be regarded as a guideline for interpretation. Because GER is a naturally occurring phenomenon, there will inevitably be an overlap between "normal" and "abnormal" data. Excellent reproducibility has been shown for various parameters. Intrasubject reproducibility supports the diagnostic use of continuous pH monitoring. In general, it can be stated that a reflux index above 10% should be considered as abnormal, a reflux index below 5% as normal, and a reflux index between 5 and 10% as between normal and abnormal. However, normal ranges are developed to separate patients at risk for esophagitis from those not at risk, which is not the major indication of the procedure. Normal ranges proposed by one group can be used by another group only if the investigations are performed and interpreted in a comparable way. This means that materials and methodology should be identical (Tables 71-3 and 71-4). For some individuals and in some clinical situations, it may be more important to relate "events" (eg, coughing, wheezing, apnea) to pH changes rather than to know if the data are within the normal range. It should be borne in mind that normal ranges for a group are not always applicable to an individual.

pH MONITORING AND OTHER INVESTIGATIONS

Many different techniques to evaluate GER do exist, focusing on different aspects, such as postprandial reflux (scintiscan, barium swallow, ultrasonography), histologic abnormalities (endoscopy), continuous measurements that are pH dependent (pH monitoring) or not (impedance), and pathophysiology by measuring the relaxations of the LES (manometry). Because there is no one investigation for GER that is accepted to provide a clear-cut discrimination between normal and abnormal, there is no reason why pH monitoring should do so. Abnormal pH monitoring does not accurately predict the risk for esophagitis.[30,44] In a group of reflux patients with esophagitis, the sensitivity of pH metry is 88% and of scintigraphy is 36%.[45] In a group of patients with abnormal scintigraphy, the sensitivity of pH monitoring is 82%, of endoscopy is 64%, and of manometry of the LES is 33%.[46] Nonacid reflux my be inoffensive (postprandial) reflux at a neutral pH but may also contain bile, which is also toxic for the esophageal mucosa.[46] There is little experience with esophageal bile monitoring in children. The overall correlation between scintiscanning and pH monitoring is acceptable ($r = .78$).[47] However, during simultaneous pH recording and scintiscanning, only 6 of 123 reflux episodes were recorded simultaneously.[48] There is no correlation between the number of reflux episodes detected with scintigraphy and pH monitoring.[49] Barium studies seem to have a much lower sensitivity to pick up reflux episodes if pH monitor-

ing is regarded as the "gold standard."[48] According to many authors, there is a high incidence of false-positive and false-negative studies with barium studies that is related to the short investigation time on the one hand and the intensity of reflux-provoking maneuvers on the other hand. Fifteen-minute postprandial period color Doppler ultrasonography was compared with 24-hour pH monitoring, showing agreement in 81.5%.[50] However, if pH monitoring was considered the "gold standard," the specificity of the color Doppler ultrasonography was as low as 11%, and there was no correlation between the incidence of reflux episodes measured with both techniques.[50] A far higher number of reflux episodes is detected with impedance in comparison with pH monitoring because only 14.9% of all reflux episodes are acid.[52] But only 57% of acid reflux episodes are detected with impedance.[51]

CONCLUSION

Esophageal pH monitoring measures pH in the esophagus, not GER. The miniaturization of devices and electrodes has made pH monitoring a procedure that is easy to perform, even in the youngest children. Patient-related factors such as feeding and physical activity influence pH monitoring results. Hardware- and software-related factors, as well as patient-related factors and recording conditions, determine the results. In clinical practice, pH monitoring is of interest in those patients in whom GERD is suspected who present without clear regurgitation or emesis and to measure the efficacy of treatment.

CHAPTER 72

PANCREATIC FUNCTION TESTS

Richard T. Lee Couper, MD
Mark R. Oliver, MBBS, MD, FRACP

Exocrine pancreatic function is notoriously difficult to assess. In practical terms, the organ and its secretions are relatively inaccessible, and direct assessment requires duodenal intubation to collect pancreatic secretions. The other obstacle rendering assessment difficult is the enormous functional reserve capacity of the exocrine pancreas. Digestive enzymes are synthesized and secreted by the pancreatic acini in considerable excess. Marked reduction of exocrine pancreatic function must occur before nutrients are malassimilated and the functional loss becomes a homeostatic threat. In pediatric patients with cystic fibrosis and Shwachman-Diamond syndrome, Gaskin and colleagues found that lipase and colipase outputs had to be less than 2% and 1% of normal values, respectively, before steatorrhea was apparent.[1] The corollary is that between 98 and 99% of pancreatic reserve for lipase and colipase must be lost before fat maldigestion occurs.

Steatorrhea is a useful indicator of pancreatic function. Steatorrhea is defined as a fecal fat output in excess of 7% of ingested fat in patients over 6 months of age and in excess of 15% in patients under 6 months of age. Patients are pancreatic insufficient if steatorrhea is present. Patients are pancreatic sufficient if steatorrhea is absent and may have pancreatic function in excess of 2% of normal. Pancreatic-insufficient subjects can be detected reliably by a variety of tests. The challenge has been to develop a test that evaluates the range of function in pancreatic-sufficient subjects.

TESTS OF EXOCRINE PANCREATIC FUNCTION

Test Categories

There are three categories of exocrine pancreatic function tests (Table 72-1). Direct tests assess the secretory capacity of the exocrine pancreas. Pancreatic secretions are collected via intubation of the small intestine, usually under stimulated conditions, and are analyzed for the output of water, ions, and enzymes. Stimulation of the pancreas allows the pancreatic functional reserve to be assessed. Collection of unstimulated secretions from a rested organ provides little information.

Indirect tests detect abnormalities secondary to loss of pancreatic function, such as the maldigestion and consequent malabsorption of fat and/or nitrogen. Alternatively, these tests depend on the ability of pancreatic enzymes to cleave specific synthetic substrates, generating absorbable, measurable end products that are detectable in breath, serum, or urine. Additionally, pancreatic enzymes such as chymotrypsin and elastase 1 are relatively biostable and can be detected in the stool.

Blood tests rely on the fact that small but significant amounts of the enzymes and enteroendocrine hormones synthesized by the pancreas are normally present in the systemic circulation. In certain circumstances, the serum concentration of specific pancreatic enzymes (such as immunoreactive trypsinogen) and specific hormones (such as pancreatic polypeptide) may reflect residual exocrine pancreatic function.

The criteria for an ideal pancreatic function test are listed in Table 72-2. All currently available tests have one drawback, and many have several. Direct tests provide the most sensitive and specific measurements of exocrine pancreatic function and are useful in the detection of mild to moderate dysfunction. However, these tests are invasive and expensive, and the results are poorly reproducible between laboratories owing to different study protocols. Indirect and blood tests, although cheaper and easier to administer, are less sensitive and specific and, as a whole, lack an ability to differentiate between mild and moderate exocrine dysfunction.

Indications for Pancreatic Function Tests

1. Differentiate pancreatogenous malabsorption from other causes of malabsorption.
2. Diagnose and study the natural history of disorders affecting exocrine pancreatic function.
3. Assess the efficacy of pancreatic enzyme replacement in children with malabsorption secondary to exocrine pancreatic dysfunction.

DIRECT TESTS

The exocrine pancreas secretes fluid and ions in response to endogenous secretin and enzymes in response to endogenous cholecystokinin (CCK). Endogenous secretin and CCK are released from small intestinal mucosa in response to nutrients and/or gastric acid. The pancreas is also stimulated by neural pathways. It is supplied by vagal efferents that act on muscarinic receptors. Intestinal nutrients provoke stimulation of enzyme secretion via this pathway as well as by CCK release. Stimulation of the exocrine

TABLE 72-1 TESTS OF EXOCRINE PANCREATIC FUNCTION

DIRECT TESTS
Exogenous hormonal stimulants
Cholecystokinin*†
Cerulein*
Bombesin*
Secretin†
Nutrient stimulants
Lundh test meal
Fatty acids
Amino acids
Other
Selenium 75 methionine incorporation and release
Pure pancreatic juice
INDIRECT TESTS
Stool
Microscopy—fat, meat fibers†
Acid steatocrit†
Fecal balance†
Iodine 131 triolein excretion
Dual-radiolabeled fat
Trypsin,† chymotrypsin,† lipase, elastase†
Breath tests
Carbon 14 lipids
Carbon 13 lipids†
Carbon 14 cholesterol octanoate
Starch breath hydrogen
Urinary/plasma markers
Bentiromide†
Fluorescein dilaurate (pancreolauryl)†
Oral tolerance (fat and vitamins)
Dual-label Schilling
Urinary lactulose
BLOOD TESTS
Total amylase or lipase
Isomylase
Cationic/anionic trypsinogen†
Pancreatic polypeptide
Amino acids

*Used in various dose combinations with or without secretin.
†Test currently used in pediatric practice.

pancreas is undertaken by using one or both of these pathways by supplying either exogenous hormones or intestinal nutrients.

Successful quantitation of human pancreatic exocrine function is contingent on the following conditions:

1. The development of appropriate intravenously administered hormonal stimuli or appropriate nutrient delivery to the small intestine
