2. HIV *and Other Secondary Immunodeficiencies*

Delane Shingadi, FRCPCH, MPH
Paul Kelly, MD, FRCP

Gastrointestinal symptoms are common manifestations of human immunodeficiency virus (HIV) infection in children because the digestive system represents an important point of contact with infectious organisms and an important reservoir of lymphocytes. Symptoms include diarrhea, failure to thrive, poor appetite, malabsorption, vomiting, and dysphagia. Alterations to gut morphology and function may be caused by a variety of infectious and noninfectious processes that become increasingly severe as immunosuppression deepens. Children with HIV become susceptible to infection with opportunistic organisms and with virulent pathogens that also infect immunocompetent children (eg, cryptosporidiosis). These virulent infections often have a worse outcome in HIV-infected children. Treatment of gastrointestinal disease in children with HIV infection may often be complex and difficult and require a multidisciplinary approach because nutritional consequences can be severe. However, recent advances in antiviral therapies have resulted in marked improvements in survival and morbidity, mainly owing to preservation and improvement of immunologic function. As a result, in industrialized countries, there has been a decrease in the number and severity of opportunistic infections caused by enteropathogens. This chapter discusses disease of the gastrointestinal tract in children with HIV infection.

HISTORY OF HIV INFECTION

The first indication that a new disease was emerging appeared in the *Morbidity and Mortality Weekly Report* in 1981 with a report of an increase of unusual opportunistic infection in young men in San Francisco, California.[1] This report indicated that *Pneumocystis carinii* pneumonia, which until then had been found only in severely immunocompromised people undergoing chemotherapy, had been diagnosed in apparently healthy men. Further investigation revealed that this unexplained breakdown of the immune system was occurring in homosexual men who had had contact with each other. The affected individuals were found to have depletion of CD4 cells, the cells that control and direct adaptive immune responses. It was not until 1984 that the virus responsible for this immune problem was identified and called human T lymphotropic virus type III, later renamed HIV. By 1985, it was also apparent that other problems related to immunodeficiency were emerging in Africa. Molecular epidemiologic analysis now suggests that HIV developed as a mutant form of simian immunodeficiency virus (SIV), which had crossed from monkeys to humans several decades previously. Its successful spread in human populations is attributable to several features, including that it destroys lymphocytes and disturbs their control, thus reducing the host's potential for controlling HIV itself, its potential for sexual spread, and the fact that infected individuals apparently remain well for many years before the immune failure leads to opportunistic infections. This stage of advanced immune failure is called the acquired immune deficiency syndrome (AIDS), but it is important to emphasize that defining this stage in children is often difficult.[2]

EPIDEMIOLOGY OF HIV

Since the first descriptions of the virus in the early 1980s, HIV has been detected in every continent and has caused millions of deaths. In sub-Saharan Africa, HIV has reshaped whole populations, cutting swaths through the middle years of the population and leaving the elderly and the children. Adults in middle life constitute the most economically active sector of society, and their loss leads to breakdown of families and negative effects on development.

The impact on children is twofold.[3] First, children themselves become infected by vertical transmission from their mothers. This accounts for the great majority of HIV infection in children, although some cases arise by transmission through blood transfusion or through use of unsterile hypodermic needles. Second, children suffer through the subsequent death of their parents, and in many less developed countries, there are difficulties in caring appropriately for these orphaned children. The HIV epidemic has been most severe in sub-Saharan Africa,[4] and it has been estimated that 90% of HIV-infected children live in Africa.[5] It is not yet clear how many children will become infected with HIV in the emerging epidemics in Asia or Eastern Europe.[6]

Transmission from mother to child may occur through transplacental infection, exposure at the time of birth, or breastfeeding. Statistical modeling, based on viral load studies, suggests that the majority of infections, at least in industrialized countries, occur during or soon after birth.[7] However, there is no doubt that in less developed coun-

tries, a high proportion of infections in children are attributable to breastfeeding, implying that the gastrointestinal tract is permeable to HIV in neonates, although the precise mechanism is still to be elucidated. In Africa, the risk of mother-to-child transmission has been estimated at 25 to 45%, whereas in industrialized countries, the risk is probably 10 to 39%. The majority of this excess risk is probably attributable to breastfeeding in populations where breastfeeding is the norm,[5] although there is evidence that exclusive breastfeeding is less likely to be associated with transmission.[8] Recent trials indicate that transmission can be reduced by short-course antiretroviral therapy; currently, the most widely used drug is nevirapine.[9]

HIV-1 VIROLOGY AND IMMUNOPATHOGENESIS

HIV-1 is a retrovirus that is closely related to primate retroviruses, such as SIV, and another human lymphotropic virus, HIV-2. HIV-1 is a ribonucleic acid (RNA) virus that is composed of a cylindrical virion core containing two copies of single-stranded RNA, together with integrase, protease, and reverse transcriptase enzymes. The core is surrounded by a spherical envelope, which is also studded with glycoprotein spikes (p120, p41) and coreceptors (chemokine receptors), which are important for viral attachment and entry into cells. The HIV-1 genome contains structural (*gag*, *pol*) and viral enzyme genes together with other genes (*rev*, *vpr*, *vpu*, *vif*, and *nef*) that are implicated in viral replication and pathogenesis.

HIV-1 entry into cells is mediated through the attachment of virus to CD4 molecules, which are present on the surfaces of certain cells (CD4+ T cells or T helper cells, some monocytes and macrophages).[10] The process of attachment and entry is aided by chemokine receptors such as CCR5 and CXCR4. Once attachment has occurred, fusion of the viral envelope and cell wall occurs with incorporation of virus into the host cell. The viral cycle begins with the generation of a deoxyribonucleic acid (DNA) transcript of viral RNA genome mediated by viral reverse transcriptase. Double-stranded proviral DNA is incorporated into the host genome assisted by viral integrase. Incorporated viral DNA is then "read" as part of the process of protein synthesis within the host cell. Viral products are subsequently assembled and cleaved by viral proteases into individual virions. Viral budding occurs at the cell surface, where the cell wall lipid bilayer contributes to the formation of the viral envelope together with viral envelope proteins. Budding and formation of virions often result in host cell death.

The hallmark of HIV-1 infection is the loss of cell-mediated immunity, predominantly CD4+ T cells or T helper cells.[11] T helper cells are key orchestrators of the immune response and are responsible directly or indirectly for the induction of a wide array of immune functions. A decrease in CD4 cells results in an inverted CD4-to-CD8 ratio, which is usually less than 1.0. The degree of immunosuppression in children with HIV is determined by the age-specific CD4 T-lymphocyte count and percentage (Table 39.2-1). T-lymphocyte function may also be impaired with loss of mitogen responses and cutaneous anergy to antigens. Cytotoxic T-cell and natural killer cell function has also been shown to be diminished with HIV infection.

In addition to T-lymphocyte dysfunction, B-cell dysfunction may occur with polyclonal B-cell activation, hypergammaglobulinemia, and circulating immune complexes.[12] B-cell activation or dysregulation may actually precede CD4 depletion, with dramatic rises in immunoglobulins G, A, and M. Despite polyclonal activation and elevated immunoglobulins, specific antibody production is inadequate for host protection. This "functional hypogammaglobulinemia" underlies the 10- to 50-fold increase in the risk of bacteremia and bacterial infection in adults and children.[13]

Decline of T helper cells over time results in progressive immunoparesis and subsequent risk of opportunistic infections, such as intracellular bacteria and parasitic infections. In addition to opportunistic infections, there is also an increased risk of malignancies such as non-Hodgkin lymphoma (NHL), Kaposi sarcoma (KS), and leiomyosarcoma, although these conditions are less commonly seen in children compared with adults. Table 39.2-2 summarizes the AIDS-defining conditions.[14]

CLINICAL FEATURES IN RELATION TO PATHOLOGY

The clinical manifestations of HIV infection related to the gastrointestinal tract in children can usually be attributed to infections (opportunistic or virulent; see above) or malignancy. Because nutritional failure (failure to thrive) is so important in children, we consider this alongside the clinical features of these other processes.

Infections of the Gastrointestinal Tract

Infectious causes of gastrointestinal tract disease can be divided into major categories based on microbiologic classification. Several different parts of the gastrointestinal tract may be affected, often simultaneously, and often multiple infectious agents may be present. Eight organisms that infect the gastrointestinal tract are classified as AIDS-

TABLE 39.2-1 AGE-SPECIFIC CD4+ T-LYMPHOCYTE COUNT AND PERCENTAGE OF TOTAL LYMPHOCYTES

DEGREE OF IMMUNOSUPPRESSION	AGE < 12 MO		AGE 1–5 YR		AGE 6–12 YR	
	CELLS/μL	%	CELLS/μL	%	CELLS/μL	%
No suppression	≥ 1,500	≥ 25	≥ 1,000	≥ 25	≥ 500	≥ 25
Moderate suppression	750–1,499	15–24	500–999	15–24	200–499	15–24
Severe suppression	< 750	< 15	< 500	< 15	< 200	< 15

defining conditions, including cytomegalovirus (CMV), herpes simplex virus, *Histoplasma capsulatum*, *Isospora belli*, *Mycobacterium avium-intracellulare* complex (MAC), and *Salmonella* spp (see Table 39.2-2).[14] Many other organisms can produce gastrointestinal infection, and these can be broadly divided into the major classes of bacteria, viruses, fungi, and parasites. The clinical features and treatment of these infections are summarized in Table 39.2-3. Each class of infection is discussed below.

Viruses. Acute viral intestinal infections of childhood cause a similar spectrum of disease in HIV infection and are usually self-limited illnesses with no increase in severity associated with immunosuppression (eg, rotavirus[15]). Acute diarrhea is the most common presentation and can be due to any of several viral agents, including rotavirus, adenovirus, astrovirus, calicivirus, and small round-structured viruses.[16] CMV is a common coinfection with HIV; however, its significance in pediatric gastrointestinal tract disease is unclear. Esophageal, hepatic, and large bowel involvement have all been described with CMV infection.[17] Herpes simplex virus has also been associated with erosive esophagitis, indistinguishable from CMV esophagitis.

As the gastrointestinal tract constitutes a major component of the total lymphocyte population, this region is also an important target for HIV infection. Lymphocyte populations in the gastrointestinal tract show similar depletion of CD4 lymphocytes, particularly in the lamina propria. An enteropathy, with partial villous atrophy and crypt hyperplasia, associated with HIV has also been described in the absence of opportunistic infection, but there is controversy as to whether this is due to HIV itself or to undetected opportunistic agents.[18] The consequences of this enteropathy are variable: in some instances, these findings are associated with severe malabsorption, but in other cases, there may be no symptoms associated with these findings.

Bacteria. Several bacterial enteric pathogens associated with acute infectious diarrhea in immunocompetent children also cause disease in HIV-infected children, notably *Campylobacter* spp, *Shigella* spp, and *Salmonella* spp.[19,20] Intestinal MAC infection, however, usually occurs in the more severely immunosuppressed children and is characterized by severe chronic diarrhea, malabsorption, and wasting. Infection with these agents is most often through

TABLE 39.2-3 INFECTIONS OF THE GASTROINTESTINAL TRACT IN CHILDREN WITH HIV INFECTION

INFECTION TYPE	CLINICAL PRESENTATION	TREATMENT
BACTERIA		
Shigella spp	Acute/persistent diarrhea	TMP-SMX, fluoroquinolone, ceftriaxone, cefotaxime
Nontyphi *Salmonella*	Acute/persistent diarrhea, septicemia	TMP-SMX, ampicillin, fluoroquinolone, ceftriaxone
Campylobacter spp	Acute/persistent diarrhea	Erythromycin, fluoroquinolone
MAC	Persistent diarrhea, malabsorption	Macrolide, ethambutol, rifabutin
VIRUSES		
Rotavirus	Acute diarrhea	—
Adenovirus	? Ribavirin/cidofovir	
CMV	Esophagitis, colitis	Ganciclovir, foscarnet, cidofovir
HSV	Esophagitis, perianal disease	Acyclovir
PARASITES		
Cryptosporidium parvum	Acute/persistent diarrhea	Paromomycin, immunoglobulin*
Isospora belli	Acute/persistent diarrhea	TMP-SMX
Giardia intestinalis	Acute/persistent diarrhea	Metronidazole, albendazole
Microsporidia	Acute/persistent diarrhea	Albendazole
Cyclospora cayetanensis	Acute/persistent diarrhea	TMP-SMX
Strongyloides stercoralis	Acute/persistent diarrhea; hyperinfection syndrome	Thiabendazole, albendazole
FUNGI		
Candida albicans	Esophagitis	Fluconazole, itraconazole, amphotericin

CMV = cytomegalovirus; HSV = herpes simplex virus; MAC = *Mycobacterium avium-intracellulare* complex; TMP-SMX = trimethoprim-sulfamethoxazole.
These anti-infective agents should be used in standard pediatric doses except for TMP-SMX for isosporiasis or cyclosporiasis, when double the usual dose should be given, and albendazole, which should be given for 4 weeks. Only one species of microsporidian (*Encephalitozoon intestinalis*) is likely to respond well to albendazole, and very little information is available to confirm its efficacy in children.
*Anti-*Cryptosporidium* immunoglobulin is unlikely to be available outside a research setting.

contaminated food or water, contact with infected animals, or person-to-person transmission through the fecal-oral route. Infection with these enteropathogens can result in prolonged diarrhea, malnutrition, recurrence after apparently successful treatment, and extraintestinal infections.[21]

Parasites. Cryptosporidial infection is associated with protracted watery diarrhea in immunocompetent children,[22,23] and in HIV-infected children, there is more severe anorexia and weight loss and higher mortality.[24] Infection may be acquired by person-to-person contact or through contaminated water supply or food. *Isospora belli* and *Cyclospora cayetanensis* infections may also cause a similar clinical picture, but these appear to be less common in HIV-infected children[24] than in HIV-infected adults in the same setting.[25] Acquisition of infection may take place from person to person or by contaminated food or water. Giardiasis may present with an acute diarrheal illness characterized by abdominal cramps and bloating or a more chronic protracted diarrheal illness leading to malabsorption and failure to thrive, but there is little evidence that giardiasis is more common or more severe in HIV infection. Again, transmission usually occurs by person-to-person transmission through the fecal-oral route or through ingestion of contaminated food or water. There is uncertainty surrounding the importance of microsporidia in HIV-related intestinal disease in children. A study in Thailand suggested that microsporidiosis was more common in HIV-related diarrhea than in HIV-unrelated diarrhea,[26] but in Uganda, the prevalence of microsporidiosis was the same in children with and without diarrhea,[27] and similar observations were made in Tanzania.[28] It is important to realize that diagnosis of microsporidiosis is difficult, and no consensus yet exists as to its epidemiology.

Strongyloides stercoralis infection may be asymptomatic in HIV-infected individuals but may also cause a severe hyperinfection syndrome characterized by a Löffler-like syndrome with eosinophilia, pulmonary infiltrates, rash, and diarrhea.[29] This is uncommon. Other helminths are not associated with disease in HIV.

Fungi. Oral thrush owing to *Candida albicans* is a common presentation in children with HIV infection, sometimes causing feeding difficulty. More troublesome symptoms of dysphagia and retrosternal chest pain are associated with *Candida* esophagitis, which may be clinically indistinguishable from CMV and HSV esophagitis without endoscopic clarification.[30]

Failure to Thrive and Nutritional Problems

Many children with HIV/AIDS experience wasting and/or failure to thrive during the course of their disease.[31] In developing countries, weight loss is one of the most common presentations of HIV infection and is often associated with diarrhea.[32] The etiology of failure to thrive in this population may often be unclear and, in many cases, multifactorial. The most important factors include reduced oral intake, malabsorption in the gastrointestinal tract, increased energy use with HIV infection, and psychosocial stressors. In many instances, more than one factor may be responsible but may also exacerbate other factors. Poor energy intake is an important cause of failure to thrive, particularly when owing to infections of the upper gastrointestinal tract, which limit oral intake (eg, esophagitis), and poor energy intake is often a consequence of anorexia related to intestinal infection. HIV encephalopathy may also cause neurologic disease, resulting in difficulty in swallowing or incoordination and therefore a reduction in oral intake. More recently, newer HIV therapies have been associated with significant gastrointestinal toxicities, including severe taste aversion, which has resulted in nutritional problems in some children. Malabsorption is another important factor in children who fail to thrive, either directly owing to HIV enteropathy or secondary to enteropathogen infection (see above). Increased energy use may also play an important role in failure to thrive, mainly through increased metabolic rate and high cellular turnover/inflammation owing to HIV infection and other coinfections; however, the exact importance of this factor has been difficulty to measure, and further research is needed in this field. Psychosocial factors are important causes of failure to thrive in children with HIV infection, particularly in the setting of perinatally acquired infection, where other family members may also be infected. Illness of both a child and his/her parent may have profound influences on the individual. HIV infection in this setting may also be associated with other social factors, such as poverty and intravenous drug use, that may impact on the HIV-infected child.

Malnutrition was a serious health problem in children in tropical populations long before the HIV pandemic, but the interaction of intestinal infection, nutritional impairment, and HIV has escalated the problem. HIV appears to induce changes in small intestinal mucosal function, and these changes are exacerbated in the presence of opportunistic infection. Whether these changes explain the increased severity of malnutrition in HIV-infected children remains to be elucidated. These children have severe malnutrition and high mortality rates, particularly in the presence of specific infections, such as cryptosporidiosis.[24] Treatment of the most severely affected children can be very challenging.

Gastrointestinal Malignancy

There is an increased risk for the development of malignancies in HIV infection, including KS, NHL, and leiomyosarcoma.[33] However, there are clear differences between malignancies in children and adults with HIV infection. For example, KS is relatively unusual in children and leiomyoma/myosarcoma is relatively more common.[34] All of these malignancies can affect the gastrointestinal tract and may occur without severe immunosuppression. The most common tumors seen are NHL, which may affect extranodal sites such as the gastrointestinal tract, liver, and central nervous system. NHL may behave aggressively and present with nonspecific symptoms such as weight loss, fever, and fatigue, which are not dissimilar to symptoms seen with other opportunistic infections.[35] Lymphoprolif-

erative disorders represent a spectrum of disease, of which NHL is the most malignant and aggressive form of disease. At the benign end of the spectrum of lymphoproliferative disorders are mucosa-associated lymphoid tissue (MALT) tumors. Several different agents have been implicated in the pathogenesis of lymphoproliferative disorders, including Epstein-Barr virus and *Helicobacter pylori* infection.[36,37] MALT tumors may occur in the lung, stomach, and salivary glands and may be slow-growing, indolent tumors. KS is a hemangiosarcoma that has been associated with human herpesvirus 8 infection.[38] KS is reasonably uncommon in children, although there has been an increased incidence in children with HIV in sub-Saharan Africa.[39] Typically, KS causes mucocutaneous lesions, including lesions in the mouth and gastrointestinal tract. Lymphadenopathic KS may also occur, affecting specific regional lymph nodes such as the inguinal areas. Less common forms of KS include visceral organ involvement such as the spleen and lungs.[40] Smooth muscle tumors (leiomyoma and leiomyosarcoma) are rare in children, although the risk is estimated to be 10,000 times higher in children with HIV infection. Smooth muscle tumors are not classified as AIDS-defining conditions (unlike NHL and KS). Epstein-Barr virus infection has been associated with smooth muscle tumors and may have a pathogenic role. After NHL, smooth muscle tumors are the second most common malignancy in children with HIV and in some surveys represent 17% of all reported tumors.[41] Leiomyosarcomas may occur in the gastrointestinal tract, spleen, retroperitoneal space, adrenal glands, and lungs.

INVESTIGATION

Children presenting with chronic gastrointestinal symptoms need to be thoroughly evaluated to determine the etiologic agent and institute appropriate therapy and symptom relief. Stepwise diagnostic testing is essential to exclude common pathogens initially and search for more unusual pathogens, using, in some cases, more invasive testing modalities. Initial investigation involves obtaining at least two stool samples for bacterial culture to exclude bacterial enteropathogens. Microscopy using specific stains (saline, iodine, trichrome, acid-fast, and fluorescein-conjugated stains) should be performed to detect specific parasites. *S. stercoralis* infection usually requires identification of the rhabditiform larvae in feces or duodenal fluid. Serodiagnosis may be less useful due to cross-reactivity with other filaria and reduced antibody responses, particularly in more immunocompromised individuals. Stool samples should also be analyzed by acid-fast staining to detect MAC infection. In children who have diarrhea and fever, blood for bacterial culture, mycobacterial culture, and CMV culture/polymerase chain reaction may be useful. Often repeated blood sampling may be necessary to identify bacteremia or viremia. If a diagnosis is not established using standard culture and microscopic techniques, then upper and lower gastrointestinal endoscopy may need to be performed to obtain biopsy specimens. This may be particularly important to detect MAC and CMV infection because stool examination is relatively insensitive. Samples obtained by endoscopy need to be sent for histology, mycobacterial culture, and virologic examination using immunohistochemistry and/or electron microscopy if available. Radiologic investigations may be useful in determining the anatomic site and extent of disease. Barium swallow studies may be useful in supporting the diagnosis of *Candida* esophagitis in patients with dysphagia. Barium radiographs may also demonstrate large intestinal changes, such as mucosal thickening and ulceration, as seen in CMV colitis; however, endoscopic investigation may need to be performed to confirm the diagnosis. Computed tomography may be useful in demonstrating bowel wall thickening and luminal narrowing, as well as intra-abdominal masses, such as lymphadenopathy or malignancies. Major intra-abdominal lymphadenopathy should be investigated further and may require biopsy at laparotomy or laparoscopy to detect tuberculosis, NHL, or MAC.[42] In children from tropical populations, tuberculosis should always be considered in a child with unexplained abdominal symptoms because treatment is so dramatically successful.

MANAGEMENT

Secondary and Supportive Treatment

Treatment for children with HIV infection includes the prompt and aggressive control of acute infections, including opportunistic infections. These are summarized in Table 39.2-3. In children with acute diarrhea, replacement of fluid and electrolytes is initially important. Nutritional support and supplementation are frequently required, especially in children with chronic diarrhea. Enteral support should be used whenever possible, although parenteral support may sometimes be required (see Chapter 76, "Drug Therapy"). In children with difficult or dysfunctional swallowing, a feeding gastrostomy may be a useful method of enteral support.[43]

Prophylactic therapy using trimethoprim-sulfamethoxazole is often given to prevent *P. carinii* pneumonia, but it may have the desirable effect of reducing infections with *I. belli* or *C. cayetanensis*. At a community level in tropical populations, the most important intervention is vitamin A supplementation, which has marked benefits for HIV-infected and HIV-uninfected children.[44]

Anti-HIV Treatment

Initial antiviral therapy for children with HIV infection involved the use of monotherapy or dual therapy with drugs such as zidovudine and didanosine that belonged to the nucleoside analog family (Table 39.2-4). These agents inhibit the viral enzyme reverse transcriptase and thereby reduce viral replication. Although this approach appeared to have an initial beneficial effect, it soon became apparent that specific viral mutations developed against these drugs, rendering them ineffective.[45] Improved monitoring of HIV infection by measurement of HIV-1 viral load made it apparent that viral replication was an important prognostic marker and complete viral suppression was a key goal in permitting immune reconstitution.[46] The development of

Lopinavir

newer antiviral agents, including the more potent protease inhibitor group, has meant that effective and prolonged viral suppression is now possible. Combination therapy or highly active antiretroviral therapy (HAART) has dramatically altered the outlook for many children with HIV infection who have access to this form of treatment.[47] Both mortality and morbidity have improved by HAART, and some have suggested that HIV is now another chronic treatable disease of childhood.[48] Combination therapy usually involves the use of at least three different drugs from different classes (eg, two nucleoside reverse transcriptase inhibitors plus a non-nucleoside reverse transcriptase inhibitor or a protease inhibitor (see Table 39.2-4 for drug classes). However, complete eradication of HIV is not possible with current drugs, and children will probably have to remain on some form of lifelong therapy. Furthermore, HAART requires high levels of compliance for sustained viral suppression and the prevention of viral resistance and treatment failure. Obstacles to long-term successful treatment and compliance include poor drug tolerability, particularly taste, and long-term adverse effects (including abnormal lipid and glucose metabolism).[48] Despite these problems, HAART has been used effectively and safely in children in North America and Europe, with dramatic improvements in long-term survival. Treatment of children in these settings has involved a multidisciplinary team, often in specialist centers that have the expertise and experience in managing the many complex physical, psychological, and social issues that affect children with HIV infection. Newer therapeutic strategies are also being developed to boost anti-HIV immune response, which may, in the future, provide more durable immune reconstitution.

The use of HAART in resource-limited countries, which have the highest burden of HIV infection, has sadly been very limited or nonexistent. This has been primarily due to high drug costs, which make HAART inaccessible to the vast majority of HIV-infected individuals globally. However, HAART has been demonstrated to be effective and safe when used in even the most resource-limited settings, and recent initiatives in reducing drug costs will mean that access to HAART will improve.[49] In addition to providing affordable drugs, infrastructural development will also be necessary if treatment programs are to be successful.

Prevention of vertical HIV transmission from mother to child has been an important initiative in resource-limited countries with a high HIV burden. Zidovudine and nevirapine have both been used, the latter drug used as a single dose to mother and child with effective interruption of HIV transmission.[9]

OTHER SECONDARY IMMUNODEFICIENCIES

Secondary immunodeficiency may occur with a variety of different conditions (and their treatments), including hematologic malignancies, transplant, malnutrition, and autoimmune disorders, such as inflammatory bowel disease. Gastrointestinal manifestations are common in these children, with an increase in opportunistic and enteric infections, which may cause chronic relapsing illness similar to that seen with HIV infection in children. Particularly at risk of infection because of enteric pathogens are children receiving chemotherapy for malignancies and those who are immunosuppressed following bone marrow or solid organ transplant. In those children receiving chemotherapy, the main problems occur with neutropenia and gram-negative bacilli infection, particularly *Escherichia coli*. In children receiving immunosuppressive therapy following transplant, viral (CMV, adenovirus) and fungal (*Candida, Aspergillus*) infection may be particularly problematic, especially when immunosuppressive therapy is maximal. In both groups of children, *Clostridium difficile* has also been recognized as a cause of pseudomembranous colitis. Antibiotic therapy is a key factor in pseudomembranous colitis, particularly through disruption of normal bowel flora and subsequent colonization with *C. difficile*. Parasitic infections, especially *Cryptosporidium* and *Strongyloides*, may be important causes of chronic diarrhea and gastrointestinal disease. Gastrointestinal syndromes associated with CMV are an increasingly important problem in bone marrow transplant recipients, causing ulceration of the esophagus, stomach, and small and large bowel. Graft-versus-host disease (GVHD) is also an important cause of gastrointestinal disease in children receiving bone marrow transplant and may be difficult to differentiate clinically from other opportunistic infections and the effects of chemoradiotherapy. Acute GVHD may affect the distal small bowel and colon, presenting with profuse diarrhea, intestinal bleeding, and abdominal pain. It should also be borne in mind that any gastrointestinal problem in a child receiving corticosteroids or another immunosuppressive treatment might be related to an opportunistic infection or malignancy, and due consideration should be given to this. The approach to a child with gastrointestinal symptoms and secondary immunodeficiency will be similar to that for HIV infection, in which stepwise diagnostic testing is important to identify infectious agents. Endoscopy and biopsy may be required in some children, especially when GVHD is suspected. Management of these

children will require treatment of the infectious agent (where identified) and supportive treatment, particularly nutritional support.

CHAPTER 40

INTESTINAL FAILURE

1. *Short-Bowel Syndrome and Intestinal Adaptation*

Jon A. Vanderhoof, MD

Short-bowel syndrome constitutes a major clinical challenge for the pediatric gastroenterologist. It represents a complex disorder characterized by multiple disruptions of normal intestinal anatomy and physiology, complicated by a variety of nutritional, infectious, and metabolic alterations that challenge the art and science of medicine. There have been numerous attempts to anatomically define short-bowel syndrome. Most of these definitions related poorly to infants and children, who may develop short-bowel syndrome at any age, with different lengths of small intestine and different anatomic causes. Consequently, the functional definition of short-bowel syndrome is generally accepted.[1] Short-bowel syndrome is therefore defined by malabsorption in the presence of shortened small intestine. Malabsorption may include nutrients, fluid, or electrolytes, but nutrients appear to play the most important role in determining the presence of short-bowel syndrome and its consequences.

Great strides have been made over the last 30 years in the treatment of short-bowel syndrome. The development of parenteral nutrition; the continuing refinement of parenteral solutions, techniques, and catheters; the introduction of improved enteral feeding formulas; and the use of trophic factors have all greatly impacted on the prognosis of short-bowel syndrome.[2,3] This formerly fatal disorder is now often compatible with long-term and even normal life span, often with good quality of life.[4] Advances in intestinal transplant are currently changing the perspective of short-bowel syndrome. This chapter discusses the abnormal pathophysiology and the sequence of interventional steps the clinician must negotiate to allow patients with short-bowel syndrome to achieve full potential.

ETIOLOGY

In pediatrics, most patients with short-bowel syndrome present at or near birth. A few remaining patients may present at any age from a variety of causes. The patients can often be subdivided into those who were intially anatomically normal and those who were not.

Patients who begin with normal gastrointestinal anatomy constitute a large number of neonates with short-bowel syndrome. The majority of cases occur as a result of intestinal resection in infants, especially premature infants, who develop necrotizing enterocolitis (see Chapter 42, "Necrotizing Enterocolitis").[2,3,5–7] The actual cause of this condition is hotly debated, but it appears that ischemic injury of the small intestine results in nonviable bowel, which must often be resected. Ileal or proximal colonic resections are most common, and patients are frequently left with compromised intestinal function. Later in life, Crohn disease (see Chapter 41.1, "Crohn Disease"), volvulus with intestinal ischemia, tumors (see Chapter 45, "Intestinal Tumors"), and radiation enteritis secondary to radiation therapy for neoplastic diseases (see Chapter 8.2, "Radiation Enteritis") may result in short-bowel syndrome. Occasionally, Hirschsprung disease may involve the small bowel as well as the colon, and extensive resection may result in short-bowel syndrome (see Chapter 46.4, "Chronic Intestinal Pseudo-obstruction").

A number of patients have short-bowel syndrome owing to congenital anomalies (see Chapter 32, "Congenital Anomalies"). Atresia may occur anywhere in the small intestine and may be either isolated or multiple. Frequently, multiple atresias result from anomalies in the superior mesenteric artery and are known as "apple peel" or "Christmas tree" deformities of the small intestine. Some children are born with shortened small bowel, and a number of patients with gastroschisis will have short bowel either congenitally or as a result of resection for ischemia or bowel injury.

From a functional perspective, there is little difference between these two groups of patients. However, certain anatomic considerations, to be discussed later, may greatly impact on the patient's long-term prognosis and may affect the interventional steps required.

PHYSIOLOGIC ABNORMALITIES

Before one can begin to assess the functional abnormalities that occur as a result of short-bowel syndrome, it is impor-

tant to consider the differences in function of the proximal versus the distal small intestine. The jejunum is characterized by long villi, a large absorptive surface area, a high concentration of enzymes and transport carrier proteins, and an epithelium in which the tight junctions are relatively large, rendering the epithelium more porous to larger molecules. Consequently, the jejunum is the site for the greatest nutrient absorption in the small intestine. It is also relatively leaky, allowing free and rapid flux of water and electrolytes from the vascular to the intraluminal space. The ileum, on the other hand, is characterized by shorter villi, more lymphoid tissue, less absorptive capacity, and a tighter epithelium. The tight junctions are smaller, permitting less flux of fluid from the vascular space to the lumen; consequently, the ileum is a more efficient epithelium for the absorption of fluid and electrolytes. Nutrients are absorbed less rapidly than in the jejunum. The ileum also has certain capabilities that are not present in the jejunum, namely, the absorption of vitamin B_{12} and bile salts through site-specific receptors. In the normal small intestine, fluid and electrolytes flow from the plasma into the lumen to dilute the highly concentrated nutrients delivered into the duodenum. Rapid mixing, digestion, and subsequent carrier-mediated transport of monosaccharides, amino acids, and dipeptides occur predominantly in the jejunum. Although some of these functions occur in the ileum as well, its tighter epithelium is better suited to the reabsorption of the water and electrolytes. Consequently, the patient with a jejunostomy and major ileal resection will be extremely susceptible to fluid losses from osmotic diarrhea associated with high-carbohydrate feedings, whereas a patient with a jejunal resection may tolerate such feedings better with less fluid loss. Likewise, following an ileal resection, the patient may initially be able to absorb more nutrients, although absorption will adapt rapidly following jejunal resection as the ileum assumes jejunal function. The jejunum cannot develop site-specific carrier-mediated transport of vitamin B_{12} and bile salts; consequently, these will be malabsorbed permanently following ileal resection. The ileum is also the site of synthesis for many gastrointestinal hormones, especially those that affect small intestinal motility such as enteroglucagon and peptide YY. Resection of the ileum may impair regulation of gut motility by nutrients, especially fat (ie, the ileal brake). Also, the normal negative feedback mechanism for gastrin is lost, and hypergastrinemia is common. This may partially explain why acid-peptic disease and esophagitis are common in patients with short-bowel syndrome.

Resection of the ileocecal valve may have major effects on physiology following small bowel resection.[2,3] The ileocecal valve appears to have two functions. It serves as a barrier for reflux of colonic bacteria from the colon into the small intestine and may also play a role in regulating the exit of fluid and nutrients from the small intestine. Consequently, resection of the ileocecal valve will permit greater reflux of bacteria into the small intestine, resulting in bacterial overgrowth. The consequences of this functional abnormality are discussed later. In addition, following resection of the ileocecal valve, rapid transit of nutrients from the small intestine into the colon may exacerbate malabsorption and increase sensitivity to osmotic loads in the small intestine. The importance of the ileocecal valve has been questioned, and its perceived importance may actually be related to the value of the adjacent ileum.

The major consequence of resection of the small intestine is malabsorption, and at least initially, this is primarily due to reduction in the absorptive surface area, with a concomitant loss of digestive enzymes and transporters.[8] The normal consequences of malabsorption become more pronounced in patients with short-bowel syndrome. Malabsorption of rapidly digested carbohydrate, for example, produces tremendous osmotic diarrhea following resection of the ileum because reabsorption of water is impaired. Proteins are larger molecules and are generally ingested in smaller quantities, creating less osmotic diarrhea. Fats are extremely large molecules, and although they may be less well absorbed, their malabsorption produces little additional osmotic fluid loss from the small intestine. However, fat generally requires a greater mucosal surface area for absorption, and the coefficient of fat absorption may be less than that for proteins and carbohydrates. Fat-soluble vitamins are also malabsorbed in large quantities in short-bowel syndrome. In patients with extensive ileal resections, reabsorption of bile salts may be impaired to such a degree that the patient will become bile salt depleted. This will result in bile salt concentrations falling below the critical micellar concentration, preventing solubilization of fats and fat-soluble vitamins and exacerbating malabsorption. Because fat is not thought to be absorbed by a carrier-mediated saturable process, additional total fat absorption may take place by increasing dietary fat content, even though the coefficient of absorption is already relatively low and substantial fat is being malabsorbed. To state it another way, as fat intake increases, the percentage of fat absorption decreases, but the total fat calories absorbed increases. Conversely, additional calories in the form of carbohydrate and protein cannot be absorbed once transport carriers are saturated. The exception is the fermentation of some malabsorbed carbohydrate to short-chain fatty acids in the colon. Colonic absorption of these substances may result in the capture of some additional calories; consequently, preservation of the colon may be important for reasons other than control of fluid and electrolyte losses.[9] These advantages are perhaps of greater benefit to older children and adults than to infants.

Abnormalities in motility also occur following resection. Following ileal resection, transit time is faster through the jejunum. Gastric emptying is also more rapid following ileal resection but can be normalized if the colon can be retained.[10] Additional functional abnormalities may develop with time. Many of these result because of compensatory changes that occur within the small intestine. For example, motility may decrease and small intestinal transit time may increase as the intestine tries to increase nutrient contact time with the small bowel mucosa. The small intestine will dilate in an attempt to increase mucosal surface area. This will result in an increased bacterial content in the small intestine, which may result in a variety of problems, which are addressed later.

INTESTINAL ADAPTATION

Ultimately, successful medical management of short-bowel syndrome is dependent on stimulation of the process of intestinal adaptation. Adaptation is the process by which the small intestine functionally adapts to increased nutrient needs owing to loss of absorptive surface area.[11–13] Through adaptation, in response to a variety of stimuli, the small intestine is able to increase its absorptive surface area and functional capacity to meet the body's metabolic and growth needs. Increases in intestinal mass also occur in other conditions in which caloric needs are increased. Two such examples include lactation and diabetes mellitus. In lactating rats, an increase in intestinal mass per unit length of bowel can be demonstrated.[14] Morphologic changes in the small intestine also have been described in diabetic rats. It has been hypothesized that these changes occur primarily in response to increased nutrient intake, emphasizing the sensitivity of intestinal adaptation to variations in enteral nutrition.[15] Adaptation also occurs to allow for decreased nutrient needs or availability. An example is starvation, which, in the rat, results in shorter villi and reduced intestinal transport.[16,17] In many ways, adaptation can be considered a compensatory overexpression of the processes that maintain normal mucosal integrity and function in response to normal enteric feeding.

The proliferative status of the intestinal epithelium is an important determinant of adaptation. The cell production rate in the crypt is governed by several factors. One is the cell cycle time (the duration of the cell cycle or interval between two successive divisions of a proliferative crypt cell). In the human jejunum, this interval is about 48 hours and, in the rat, only about 11 hours.[18,19] When the cell cycle time decreases, the cell production rate increases. Starvation, which reduces the cell proliferation rate, increases the duration of the cell cycle.[20] Cell production rate is also influenced by the growth fraction, which is defined as that portion of the cell population devoted to proliferation. In the intestine, this is usually the bottom two-thirds of the crypt.[21,22] The larger the proportion of proliferative enterocytes, the greater the cell production rate. Disorders such as starvation decrease the crypt growth fraction, whereas inflammatory conditions, which necessitate increased cell production, increase crypt growth fraction.[23,24] The crypt cell population size also influences cell production. Proliferative epithelia are commonly associated with increased crypt size and therefore increased crypt cell population. A reduction in the crypt cell population size is common in hypoproliferative states such as starvation.[20,25] Finally, there are many more crypts than villi in the normal small intestine. In the human, there are roughly six crypts for every villus, and the ratio increases to 30:1 in the rat.[26,27] Changes in the ratio of the number of crypts to the number of villi may also influence the total production of epithelial cells.

CHANGES THAT OCCUR WITH ADAPTATION

The primary event in intestinal adaptation is hyperplasia of the mucosal epithelium.[28–32] Hyperplasia is preceded by increased crypt cell production, which results in increased crypt depth and subsequent lengthening of the intestinal villi. Some dilatation of the small bowel also occurs, with increased folding of the mucosa and gradually increasing surface area. Because this process is one of hyperplasia and not hypertrophy, it is associated with growth in cell number rather than cell size. This observation can be confirmed by concurrently measuring the changes in deoxyribonucleic acid (DNA), protein, and mucosal weight. Because all increases are in direct proportion to one another, an increase in cell number is suggested. Length of intestinal villi necessitates an increased rate of migration of cells from the crypt up the shaft of the villus and an increase in the rate of cell renewal. Cell number has been shown to be the primary determinant of villus and microvillus surface area.[33] Recent evidence suggests that significant increases in enterocyte proliferation, as well as apoptosis, occur following small bowel resection. Although increasing apoptosis might seem incongruous in epithelium destined to increase its surface area, the investigators speculated that as enterocyte proliferation is increased, the rate of enterocyte apoptosis must also increase to maintain homeostasis.[34] In most animal studies, an increase has been demonstrated in the absorption of almost all nutrients following completion of the adaptation process.[35–38] Disaccharide digestion, monosaccharide absorption, and absorption of trace metals, vitamins, fluid, and electrolytes all increase. In rats, within 8 weeks, enhanced glucose-dependent electrogenic sodium absorption can be demonstrated using the Ussing chamber technique.[39]

Ultrastructural analysis of the ileum after 60% proximal small bowel resection reveals that the general structure of a single enterocyte is not impaired after resection. All subcellular organelles appear to be morphologically intact. Resected animals demonstrate more dilated intracellular spaces in the tips of the villi. Microvillus surface area also appears to decrease as a function of time after proximal resection. There appears to be no significant difference in the relative areas of mitochondria, rough endoplasmic reticulum, and nuclei as a function of time following resection.[40]

The increased absorptive surface area does not immediately result in corresponding functional improvement. Measurement of digestive enzymes such as lactase, sucrase, and maltase in hyperplastic epithelium suggests some functional immaturity of the epithelium. Consequently, replicative enzymes such as thymidine kinase are often increased. This functional immaturity appears to gradually change with time as absorptive function improves.[35–38] Adaptive improvement in intestinal function appears to be a diverse process. Improved absorption of some nutrients occurs much more rapidly than that of others.[41] Some controversy exists regarding improvement in intestinal function because of the means of expressing data in many of the experimental animal studies.[11,12] In studies using tissue preparations such as intestinal sacs or rings, isolated enterocytes, or membrane vesicles, it is customary to express the data based on some parameter of mucosal mass. Typically, absorption per unit of DNA, protein, or mucosal weight is used. Because the hyperplastic epithelial cells are often

functionally immature, at least initially, these parameters suggest that absorption following adaptation is impaired. In reality, this apparent reduction in function is of less magnitude than the positive increase in mucosal mass. Therefore, when the data are appropriately expressed per centimeter of small intestine or related to small intestinal absorptive surface area, intestinal function appears improved.

Careful analysis of transport kinetics reveals some functional changes in hyperplastic mucosa. No changes in Michaelis constant occur, suggesting no alterations in the thickness of the unstirred layer. However, maximum velocity for substrates may be reduced by 50% when expressed per unit of mucosal surface. Nonetheless, reduced enterocyte function is still more than canceled out by the larger absorptive surface area.[42,43] It is likely that hyperplastic epithelial membranes contain fewer transport proteins than are found in comparable normal ileum. Digestive enzyme function also varies significantly from study to study. In one study, specific activity of sucrase appeared to increase, but lactase decreased following resection. Messenger ribonucleic acid (mRNA) analysis suggested that sucrase changes were pretranslationally regulated, but the decrease in lactase activity was a post-translational event.[44] Unfortunately, most studies evaluating functional changes have been performed roughly 2 to 3 weeks postoperatively in an experimental model. Whether or not further maturation of absorptive function occurs with time is largely unknown, but clinical experience would suggest that it does.

Although functional adaptation per unit length of bowel accompanies morphologic changes, functional adaptation may also occur independently of villus hyperplasia.[45] In some studies, glucose uptake has been observed to increase, even in the absence of increases in intestinal mass.[46] Differences in adaptation rates of glucose and certain amino acids have also been observed. Changes in administration of nutrient concentrations can likewise cause adaptive changes in the bowel without changing morphology. For example, increasing dietary carbohydrate content may result in a marked increase in glucose transport without changing villus architecture or mucosal mass. In the proximal small intestine, mucosal mass is greater, and villus length is increased over the distal small intestine. There is a proximal to distal gradient in transport of several nutrients, especially glucose. The gradient is more pronounced with glucose absorption than with intestinal mass.[46] This suggests that there is a functional adaptive response to the high concentration of glucose in the proximal bowel, which occurs independently of morphologic adaptation. The effect of dietary substrate on nutrient transport appears to be quite substrate specific. For example, a diet high in carbohydrate and low in protein will stimulate enhanced glucose transport, whereas amino acid transport may be reduced. Likewise, a diet high in fructose may enhance fructose absorption but not glucose absorption, whereas diets high in glucose will stimulate glucose transport independently of fructose transport. These observations suggest that nutrients may act directly on intestinal cells to induce the synthesis or suppress the degradation of transport proteins.

Functional adaptation, when it occurs independently of morphologic adaptation, may progress rapidly.[15,47] Increased glucose transport may occur within 1 to 3 days of a change in dietary carbohydrate, whereas morphologic adaptation in the resected model occurs over 1 to 3 weeks. Synthesis of carrier proteins and brush border digestive enzymes is seen rapidly in response to large quantities of intraluminal nutrients.

Most of the data concerning intestinal adaptation following bowel resection have been derived from animal studies, mainly in dogs and rats. In the rat, the mucosal adaptation process occurs very rapidly, with an increase in cell replication in the crypts being visualized as early as 24 to 48 hours.[30] By 2 to 3 weeks, the villus hyperplasia process, at least from a morphologic standpoint, appears to be nearly completed. Few data of a corresponding nature exist in humans, primarily owing to the difficulty in performing such studies, but clinical experience suggests that the adaptation process proceeds more slowly. The adult patient with short-bowel syndrome will likely reach his potential much more rapidly than a child will. Previous studies concerning intestinal adaptation in 3-week-old versus 8-week-old rats suggest that older animals have greater potential for intestinal adaptation.[48] Older animals are able to increase their intestinal mass by a greater proportion than are smaller animals. It was assumed that the small animals were already under substantial stimulation just to meet the needs for growth alone and therefore had little potential to adapt beyond their natural capacity. In very old animals, the response appears to develop more slowly, although the capacity to adapt remains intact.[49] Another factor likely responsible for what appears to be delayed adaptation in children versus adults is the linear growth of the bowel. Children with very short bowels have a great capacity to increase bowel length when resection is performed as a neonate.[50] Extensive linear growth is observed in the normal small intestine during the first year of life and continues beyond that point to some degree. However, it is not clear whether there is much opportunity to enhance linear growth beyond that which normally occurs. Clinical experience has taught us that pediatric patients following neonatal small bowel resection may not reach their full adaptive potential until beyond the fifth year of life.

Whereas most data have been derived from animal studies, some data regarding functional adaptation are available on humans. In human children, following an extensive resection, a marked increase in glucose absorption was observed using the intestinal perfusion technique. Sucrose hydrolysis appeared to be increased in the same proportion as glucose absorption. In addition, studies of human children have demonstrated intestinal hyperplasia (ie, increased numbers of enterocytes per unit length of villus and a suggestion of increased villus length), although this was not statistically significant.[51] Elevation of brush border enzyme-specific activities, however, was not observed in the human children, although it is likely that overall absorption was enhanced because of the increased mucosal surface area. The hydrogen peptide transporter PEPT-1 has been shown to be up-regulated in the colonic mucosa of

patients with short-bowel syndrome.[52] This appears to occur independently of morphologic adaptation.

ROLE OF ENTERAL NUTRITION IN ADAPTATION

The adaptation process is highly dependent on enteral nutrition. In certain animal models, atrophy can occur in a small intestine deprived of nutrient contact by either bypassing the small bowel surgically or by using parenteral nutrition.[53] Following bowel resection in dogs, intravenous feeding results in slight mucosal atrophy, whereas enteral nutrition stimulates mucosal hyperplasia.[53] The mechanism by which enteral nutrients stimulate adaptation is complex. Nutrient effects have been broken down into three major categories: (1) direct stimulation of hyperplasia through contact of the epithelial cells with intraluminal nutrients, (2) stimulation of secretion of trophic gastrointestinal hormones, and (3) stimulation of the production of upper gastrointestinal secretions, which themselves are trophic to the small intestine.

Demonstration of the direct effect of nutrient contact with the intestinal epithelium is fairly straightforward. Normally, jejunal villi are longer than ileal villi, probably because they are exposed to higher concentrations of nutrients. When a segment of ileum is transposed into the proximal jejunum, ileal mucosal mass increases rather markedly, to the point where the length of the villi in the transposed ileum may actually exceed the length of adjacent villi in the jejunum.[54] The high concentration of nutrients in the jejunum appears to stimulate maintenance of jejunal villus length. Ileal villi appear to be equally, if not more, sensitive than jejunal villi to nutrient concentration. It is important to note, however, that although the length of small intestinal villi may be altered by luminal extrinsic factors, such factors are not required for the establishment of a villus height gradient. Grafts of fetal duodenum develop longer villi than grafts of fetal ileum without the influence of luminal factors.[55]

Enteral nutrition is important not only in stimulating intestinal adaptation but also in stimulating regeneration of the mucosa following injury. In a group of patients with protracted diarrhea of infancy, the combination of parenteral and enteral nutrition was superior to parenteral nutrition alone in stimulating intestinal recovery of disaccharidases.[56] Further studies demonstrated a more rapid resolution of malabsorption and diarrhea following enteral nutrition alone versus parenteral nutrition in the same disorder.[57] Enteral nutrition is also important in maintaining the mucosal mass. Maintenance of mucosal mass and glucose absorption is much improved following enteral versus parenteral nutrition. Direct contact with nutrients appears to be important in maintenance of normal glucose transport.

Several factors may contribute to nutrient-sensitive epithelial proliferation. Whereas it has been hypothesized that increased intraluminal nutrient content may provide increased fuel for proximal small intestinal enterocytes, it is more likely that trophic factors are secreted locally and act through a paracrine mechanism to stimulate increased epithelial cell production. The best evidence in support of this hypothesis comes from studies that show that nonmetabolized substances that require active transport are just as capable of stimulating adaptation as glucose.[58] Therefore, functional workload appears to be the major stimulus for adaptation. Certain enteral nutrients may be more effective stimulants than others, either because they require greater work for digestion and absorption or because they preferentially stimulate the release of trophic factors. For example, hydrolyzable disaccharides are capable of greater mucosal stimulation than constituent monosaccharides on a weight-to-weight basis.[59] The hydrolysis of the disaccharide, coupled with subsequent absorption of the monosaccharide components, appears to exert a greater functional workload on the intestinal mucosa. The effect of sucrose on mucosal proliferation can be abolished by inhibiting the sucrase enzyme with acarbose. Likewise, lactulose, which is a nonabsorbable, nonmetabolized carbohydrate, requires no workload from the intestine and consequently results in no mucosal hyperplasia.[59]

The second mechanism by which enteral nutrition stimulates intestinal adaptation is through the stimulation of secretion of trophic gastrointestinal hormones. This can be demonstrated using Thiry-Vella fistula models. Thiry-Vella fistulae have an intact blood supply but through the creation of proximal and distal ostomies are excluded from the flow of enteric contents (Figure 40.1-1). After the placement of a Thiry-Vella fistula, enteral feeding stimu-

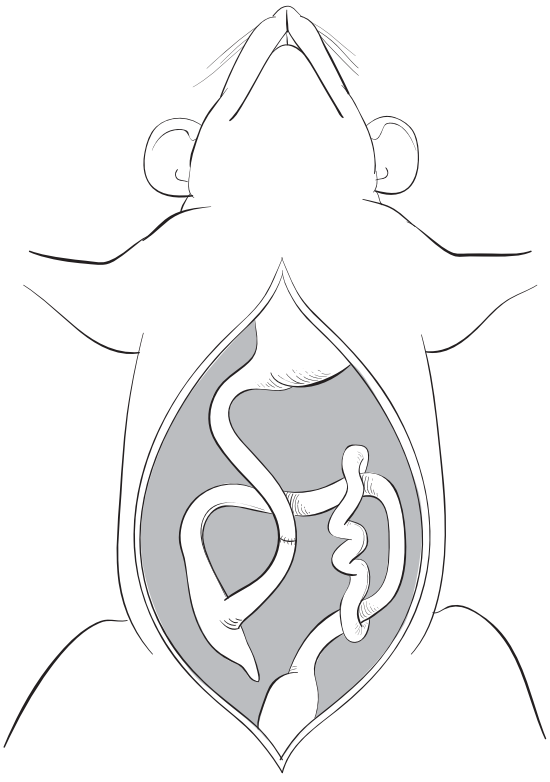

FIGURE 40.1-1 A Thiry-Vella fistula. A segment of distal jejunum and proximal ileum has been removed, its blood supply left intact, and ostomies created at both proximal and distal ends of the fistula.

lates intestinal adaptation not only in the small intestine but also in the fistula. Intravenous feeding conversely results in atrophy in both Thiry-Vella fistulae and intact small bowel.[60] Comparable findings have been observed in self-emptying blind loops, where mucosal mass in animals, who had been given an 85% jejunoileal bypass, markedly exceeded animals given a 25% bypass. This observation suggests that the defunctionalized bowel was responding to a greater adaptive stimulus produced in the animals with less functioning small intestine.[61] Trophic gastrointestinal hormones circulating via the bloodstream into defunctionalized bowel stimulate adaptation, even in the absence of direct contact with the intraluminal nutrients.

Additional evidence of the importance of the role of hormones in adaptation is derived from studies using parabiotic animals (Figure 40.1-2). In these experiments, one animal in a pair undergoes partial small intestinal resection, and blood is cross-circulated between the two animals. Increased mucosal cell proliferation is subsequently observed, not only in the resected animal but also in its parabiotic partner.[62]

The third mechanism by which intestinal adaptation can be stimulated by enteral nutrition is through the stimulation of gastrointestinal secretions. This can be demonstrated by transplant of the ampulla of Vater to the distal small intestine. Mucosal hyperplasia distal to the transplanted ampulla occurs in response to enteric feedings.[63,64] Pancreatic and biliary secretions enter the distal bowel through the ampulla in much higher concentrations than are normally present in the ileum and consequently stimulate villus hyperplasia distally. Diversion of biliary and pancreatic secretions into self-emptying ileal loops also induces villus hyperplasia.[63]

HORMONAL REGULATION

Hormonal regulation of intestinal adaptation is presently an area of intense investigation. Numerous hormonal mediators have been postulated to be important in this process (Table 40.1-1). Enteroglucagon, so named because of its structural similarity to glucagon, has been extensively studied. Patients with enteroglucagon-secreting tumors develop massive mucosal hyperplasia, which resolves once the tumor is removed.[65] Enteroglucagon is produced in highest concentrations in the distal small intestine, which is the segment that has the greatest potential for adaptation. Enteroglucagon levels and enteroglucagon mRNA levels tend to be increased following intestinal resection or jejunoileal bypass, situations in which mucosal hyperplasia is active.[66-68] Unfortunately, attempts to more directly link enteroglucagon with intestinal adaptation have been disappointing. Immunoneutralization of endogenous enteroglucagon by monoclonal antibodies failed to obliterate the adaptive response.[69] Direct administration of glucagon and enteroglucagon to animals does not result in mucosal hyperplasia.[70] Furthermore, the hormone appears to have antiproliferative properties when studied in an in vitro cell culture system.[69] Recently, precursors to enteroglucagon have received some attention and may be the means through which enteroglucagon stimulates intestinal hyperplasia.[71] Proglucagon-derived peptides may be responsible for the effects previously attributed to enteroglucagon. Ileal

proglucagon mRNA levels rise rapidly following resection.[72] Glucagon-like peptide 2 (GLP-2) now appears to be the most likely hormonal candidate for adaptation.[73,74] Recent clinical data have demonstrated that GLP-2 improves intestinal absorption and nutritional status in short-bowel patients with impaired postprandial GLP-2 secretion. This specifically included patients in whom the terminal ileum and colon had been resected. Patients with an intact terminal ileum and colon appear to have adequate GLP-2 secretion, and further adaptation was not achieved in these patients when GLP-2 was administered.[75]

Gastrin levels are highly elevated following intestinal resection. Gastrin is also known to be trophic to the stomach and the proximal small intestine.[76,77] However, hypergastrinemia appears to result in hyperplasia only in the very proximal small intestine and is not likely a major hormonal factor in stimulating intestinal adaptation more distally. Neurotensin is a hormone found mainly in the central nervous system but also in the distal small intestine. Its major role appears to be related to regulation of gastrointestinal motility but has been found to stimulate hyperplasia in the small intestine. It also has an apparent important regulatory function in the growth of colonic mucosa.[78] Secretin and cholecystokinin, when infused into parenterally fed dogs and rats, may prevent mucosal hypoplasia.[79,80] It is possible that the effects of secretin, cholecystokinin, and neurotensin can be explained by the stimulatory effect that these hormones have on pancreatic or biliary secretions.[81]

Epidermal growth factor (EGF), present in breast milk, is known to stimulate proliferation in gut epithelium, primarily in the stomach.[82] It appears to stimulate ornithine decarboxylase (ODC) activity in the small intestine, resulting in polyamine synthesis and subsequent mucosal proliferation.[83] Numerous EGF receptors are present in the small bowel, and the hormone is known to stimulate DNA synthesis.[84] In one study, no differences were detected in ileal EGF receptor mRNA or protein expression following small bowel resection, which led the investigators to conclude that ileal EGF receptor expression was not mandatory for intestinal adaptation.[85] The hormone is produced in high concentrations in both the salivary and Brunner glands and therefore could stimulate proliferation predominantly in the proximal small bowel, where mucosal surface area is normally the greatest. It may therefore play a role in the maintenance of normal gut mass in the physiologic state. Pharmacologic inhibition of the EGF receptor attenuates proliferation and other normal adaptive responses in the small intestine. This observation provides additional evidence for the requirement of a functional EGF receptor as a mediator of the postresection adaptation response.[86]

Recently, interest has developed in insulin-like growth factor I (IGF-I), so named because of its structural similarity to insulin. Otherwise known as somatomedin C, this growth factor appears to be responsible for many of the effects of growth hormone. Initial studies were conducted using a growth hormone analog, plerocercoid growth factor, produced by a tapeworm.[87] This was found to be an effective stimulant of intestinal adaptation in a rat model. Subsequent studies using growth hormone itself produced equivocal results. Studies showing a positive response were hampered by lack of control of nutrient intake.[88,89] Further studies in rats using IGF-I and a truncated analog des-IGF-I following small bowel resection demonstrated augmentation of the adaptation process.[90] Studies using a transgenic mouse model have further demonstrated the importance of IGF-I and growth hormone in regulating intestinal mass.[91] At the present time, it appears that IGF-I plays a role in the adaptation process. In a rat model of short-bowel syndrome, sandostatin has been shown to decrease cell proliferation and inhibit structural adaptation following massive resection.[92]

It is likely that additional hormonal substances may also be involved in intestinal adaptation. Peptide YY levels may be elevated by administration of menhaden oil, which also stimulates adaptation. Serum concentrations of this hormone are markedly elevated in patients with short-bowel syndrome.[93] Because this hormone reduces gastrointestinal motility and increases nutrient contact with the intestinal epithelium, peptide YY might potentially play a role in intestinal adaptation through this mechanism. Leptin, a hormone produced by adipose sites that plays an important role in the regulation of body fat and satiety, has recently been shown to increase small intestinal carbohydrate absorption beyond the normal adaptive response following small bowel resection.[94] As yet undefined, growth factors of 4,500 and 1,500 D have been isolated, which appear to be associated with nutrient-induced gut adaptation.[95] Antitrophic hormones probably also exist. Transforming growth factor-β1 has been shown to induce stem cell quiescence in the intestinal mucosa of the rat.[96] Sandostatin, for example, has been shown to impair gut adaptation.[92] The hormone ghrelin has been shown to be decreased in patients with short-bowel syndrome. The significance of this finding is unknown.[97]

PROSTAGLANDINS

Prostaglandins may also play some role in regulating intestinal epithelial cell proliferation.[98] Inhibition of prostaglandin synthesis has been shown to reduce the mitogenic effect of some gastrointestinal hormones, and, conversely, prostaglandins themselves have been shown to be trophic to numerous cell types.[99] 15,15-Dimethyl prostaglandin E_2 increases mucosal mass and intestinal length in rats. The effects are much more pronounced in the gastric antrum, however. Administration of another prostaglandin analog,

16,16-dimethyl prostaglandin E_2, results in stimulation of intestinal adaptation following resection.[100,101] Likewise, inhibition of prostaglandin synthesis using aspirin adversely affects intestinal adaptation of the ileum but not in the proximal small intestine.[100] Kollman-Bauerly and others have demonstrated that specific blockage of the cyclooxygenase-2 enzyme results in inhibition of adaptation, whereas selective inhibition of the lipoxygenase enzyme actually increases adaptation.[102] This phenomenon occurs specifically in the presence of diets containing large quantities of arachidonic acid and provides further evidence for the important role of prostaglandins in intestinal adaptation.[103] The stimulatory effects of the exogenous prostaglandins are observed primarily in the proximal small intestine.

POLYAMINES

The role of polyamines in intestinal adaptation has also been a subject of major interest. Polyamines are polycationic compounds that are present in all prokaryotic and eukaryotic cells.[15,104] The polyamine putrescine is formed from the decarboxylation of ornithine by ODC, and this constitutes the rate-limiting step in polyamine biosynthesis (Figure 40.1-3). Spermine and spermidine are subsequently synthesized. The activity of the enzyme ODC is low in resting and nondividing tissues. Polyamines are present in high concentration in rapidly proliferating tissues such as the small intestinal epithelium.[105] They appear to be essential for normal cell growth and differentiation. During adaptive hyperplasia, both polyamine content and ODC increase as intestinal proliferation increases. Increases also occur during other proliferative states, such as recovery from intestinal injury, lactation, and poststarvation refeeding.[106-109] A rise in ODC activity constitutes one of the earliest cellular events observed during the transition of cells from quiescence to active proliferation.[110]

Polyamines are known to stimulate mucosal hyperplasia. Blocking polyamine synthesis by blocking ODC reduces adaptation.[111] Likewise, blocking polyamine degradation using aminoguanidine increases intestinal adaptation.[112] In addition to the trophic effects, polyamines also appear capable of inducing maturation of sucrase isomaltase synthesis and sodium or glucose transport, probably mediated by both transcriptional and post-transcriptional events.[113]

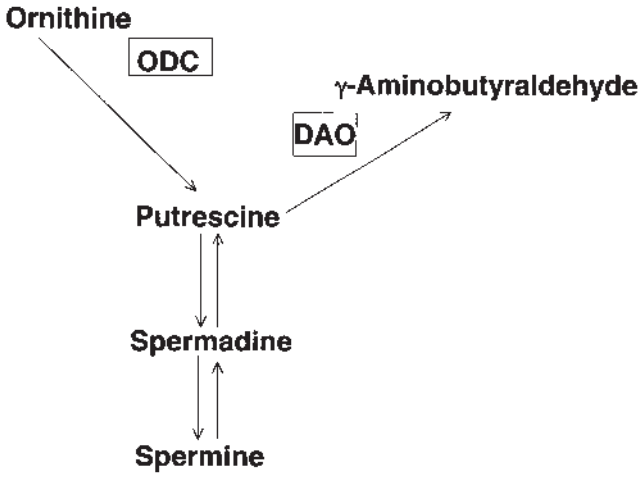

FIGURE 40.1-3 A diagram showing the synthesis and degradation of polyamines. DAO = diamine oxidase; ODC = ornithine decarboxylase.

INTRACELLULAR REGULATION

Studies have also been conducted to test the hypothesis that specific genes are transcriptionally regulated in response to loss of functioning bowel surface area to both initiate and maintain a compensatory response. Using ribonucleic acid from remnant ileum of resected rats, 40 complementary DNAs were found that were more abundant in experimental intestinal segments compared with control. Eleven clones were subsequently identified, which were thought to be proteins likely to be involved in the adaptation process. Because several potentially important genes are apparently up-regulated in the adaptation process, it appears that the genetic regulation of adaptation is complex, including genes that may help to augment nutrient trafficking, heat shock genes that maintain normal cellular function, and genes that themselves are likely to mediate the proliferative response.[114]

It is likely that protein phosphorylation by kinases may be important in controlling cell-signaling mechanisms that regulate cell proliferation and differentiation. Certain tyrosine kinases appear to be uniquely expressed in the proliferating small intestine.[115]

APPLICATIONS OF ADAPTIVE PROCESS

Manipulation of the adaptation process through diet has some potential in the treatment of short-bowel syndrome. Certain nutrients are more capable of stimulating adaptation than others (Table 40.1-2). Most studies to evaluate the function of nutrients on adaptation have been done in experimental models, primarily in rats. Complex diets tend to induce more adaptation than elemental diets, probably because they demand a greater functional workload for assimilation.[116] However, hydrolyzed casein appears to be more trophic in stimulating adaptation than whole protein.[117] Two studies have demonstrated that long-chain triglycerides are more trophic than medium-chain triglycerides.[118,119] High-fat diets also appear to more rapidly reverse starvation-induced mucosal atrophy than diets containing predominantly carbohydrate or protein.[120] Diets containing higher percentages of long-chain triglycerides but deficient in essential fatty acids are clearly less trophic than diets containing adequate quantities of essential fatty acids. This is at least partially attributable to the induction of essential fatty acid deficiency.[121] Menhaden oil, a highly unsaturated fish oil containing ω-3 fatty acids, has been shown to be more trophic than safflower oil, which is high in essential fatty acids, or beef tallow, and a highly saturated fat source.[122] The beneficial effects of menhaden oil could not be attributed to enteroglucagon secretion but were associated with a small but significant increase in peptide YY levels.[123] The effects of menhaden oil could also be due to

its high eicosapentaenoic acid content because arachidonic acid is also a major stimulant of adaptation and is likely to be mediated through prostaglandins.[103] Other lipids that may be important in adaptation include short-chain fatty acids. Short-chain fatty acids, when added to parenteral nutrition solutions, reduce atrophy associated with lack of enteral feeding and may ultimately improve adaptation following resection.[124] The addition of short-chain triglycerides to a chemically defined diet enhances both jejunal and colonic adaptation compared with a control diet containing medium-chain triglycerides.[125]

There has been increasing interest in the use of glutamine in the treatment of a variety of gastrointestinal disorders, primarily because of its apparent role as an important nutrient for the small intestinal mucosa. Administration of glutamine has been shown to reduce bacterial translocation in the small intestine and to prevent mucosal atrophy in certain animal models. Consequently, many have assumed that glutamine should be an important stimulator of intestinal adaptation. Intravenous glutamine appears to have some trophic effect on the small intestine.[126] Animal studies have been unable to demonstrate a trophic effect of oral glutamine. Even when used in pharmacologic quantities, glutamine produced less hyperplasia than either glycine or glucose.[127] One controlled study demonstrated that 8 weeks of treatment with oral glutamine and a high-carbohydrate, low-fat diet did not significantly improve intestinal morphology, gastrointestinal transit, D-xylose absorption, or stool losses in patients with short-bowel syndrome.[128] An extensive review of the literature regarding the effect of growth hormone and glutamine in short-bowel syndrome confirms the likely lack of effective therapy in inducing gut adaptation.[129]

Fiber may also enhance adaptation. Its effects are likely to be most important in the colon and are probably mediated through short-chain fatty acid production. Supplementation of an elemental diet with pectin, which is metabolized to short-chain fatty acids in the colon, improves adaptation in the jejunum, ileum, and colon following resection.[130–132] Furthermore, mucosal atrophy associated with parenteral nutrition can be reversed by parenteral administration of short-chain fatty acids.[124]

CLINICAL MANAGEMENT

The management of short-bowel syndrome is a multistage process (Figure 40.1-4).[133–135] It begins with a period of total parenteral nutrition, which is rather short in duration and is characterized primarily by stabilization of fluid and electrolytes. Immediately following bowel resection, all nutrients must be given parenterally because of a transient ileus. Initially, patients tend to have large-volume fluid and electrolyte secretion, and gastric fluid and ostomy losses may be relatively high. In this setting, it is often easiest to begin the patient on a standard parenteral nutrition solution containing all appropriate macro- and micronutrients, as well as appropriate fluid and electrolyte concentrations for metabolic needs. The excessive fluid losses from gastric tubes, gastrostomies, and diarrheal or ostomy fluid can be replaced based on the electrolyte content of these secretions. It is preferable to measure the volume of these secretions every 2 hours and replace them using a separate fluid and electrolyte solution based on actual measurement of electrolytes in the ostomy losses. Losses tend to be high in sodium content, and solutions with at least 80 to 100 mEq/L of sodium are commonly needed to maintain fluid and electrolyte homeostasis. Once ostomy losses drop, fluid replacement is reduced accordingly. In this setting, use of dual pumps, one for the parenteral nutrition solutions and the other for the replacement solutions, is needed. Despite the apparent increase in cost of the double-infusion system, reduction in wastage of parenteral solutions and frequent changes in laboratory monitoring will more than compensate for this additional expense. When fluid and electrolyte losses have decreased, continuous enteral infusion is started. Most commonly, this is done using an elemental diet.[136,137] The initial rate is quite slow, and the concentration is rapidly increased up to 0.67 kcal/mL in infants or 1 kcal/mL in older patients and adults (ie, full-strength enteral feeding solutions). Once this is done, the volume of enteral feedings can be gradually increased as the volume of parenteral feedings is decreased without overloading the patient with fluid.

The continuous enteral infusion is gradually advanced based on several parameters. If stool losses increase by more than 50% and are greater than about 40 to 50 mL/kg/d, or stool or ostomy output is strongly positive for reducing substances, advances in enteral feeding should be withheld until these parameters improve. In patients with an intact colon, a decrease in the stool pH below 5.5 is also indicative of carbohydrate malabsorption and suggests that further advancement of enteral feedings would result in a significant increase in osmotic diarrhea.

The use of continuous enteral infusion is often controversial. The major advantages to the use of continuous enteral infusion include tolerance of enteral feedings, better control of enteral caloric administration, and a reduction in emesis.[1] By using continuous enteral infusion, small intestinal carrier proteins can be continuously saturated, permitting optimal use of limited gastrointestinal function. The increased administration of enteral calories has the potential added benefit of additional stimulation of intestinal adaptation, although this has not been proven in the laboratory. Administration of extra calories reduces the parenteral nutrition need and, in theory, will also reduce the risk of liver disease, which accounts for a major percentage of morbidity and mortality in short-bowel syndrome.

Despite the inconvenience of continuous enteral feeding, portable pumps and backpacks have allowed children

FIGURE 40.1-4 A diagram of the clinical management decisions in short-bowel syndrome. bx =biopsy; EGD = esophagogastroduodenoscopy; EM = electron microscopy; SBS = short bowel syndrome; TPN = total parenteral nutrition.

to have reasonably normal mobility. Solid feedings can be initiated and fed around the nasogastric tube without difficulty, and small bolus feedings are often tolerated. Institution of solid feedings at the usual time and continued administration of small bolus feedings at least two to three times a day are important because they teach the infant how to suck and swallow and will lessen the likelihood of feeding difficulties once the tube feedings are discontinued. In theory, this will also reduce the risk of speech delay as a result of disuse of muscles of mastication and swallowing.

Elemental or chemically defined diets have been used extensively in short-bowel syndrome.[136–138] In pediatrics, truly elemental diets (ie, diets in which amino acids rather than peptides are administered) are not commonly used

and are probably not optimal for treatment of patients with short-bowel syndrome. Predigested or partially elemental formulas appropriate for use in pediatrics are available from several manufacturers. These usually consist of a protein hydrolysate, most commonly casein, a carbohydrate source that may contain one or more rapidly absorbable carbohydrates, and fats, which are usually a mixture of medium- and long-chain triglycerides. Adult elemental formulas are often inappropriate for use in pediatrics because they may be deficient in vitamins, minerals, and fatty acids and are often very high in carbohydrate content, resulting in increased osmotic diarrhea. These formulas can be modified somewhat, if an amino acid formula is desired or needed in infants, by the addition of extra vitamins, minerals, and fat.[137,138] In addition, increased fat content in the pediatric formulations may be beneficial because of the stimulatory effect of fat on adaptation in the small intestine. Long-chain fats are more trophic to the small intestine than medium-chain fats (Figure 40.1-5). Furthermore, highly unsaturated fats derived from fish oil or formulas high in arachidonic acid may prove to be even more effective in stimulating intestinal adaptation (Figure 40.1-6).[139] In reality, the form of the protein, whether amino acid, enzymatic hydrolysate, or intact protein, makes little difference from an absorptive standpoint in most patients with short-bowel syndrome. Perhaps the primary value for use of these formulas in small infants is to reduce the risk of the development of allergic disease, which is more common in children with enhanced mucosal permeability and is often the case in children with short-bowel syndrome. These patients tend to have small bowel bacterial overgrowth and frequently have had inflammatory processes in their small intestine. After the first year of life, there is probably little advantage in the use of a hydrolysate formula. Careful attention to the fat content of the formula is probably more important. Recent experience suggests that high-fat enteral feeding formulas may offer a significant advantage in patients with short-bowel syndrome provided that the fat is given primarily as long chain.[140] This is probably because fats exert a greater

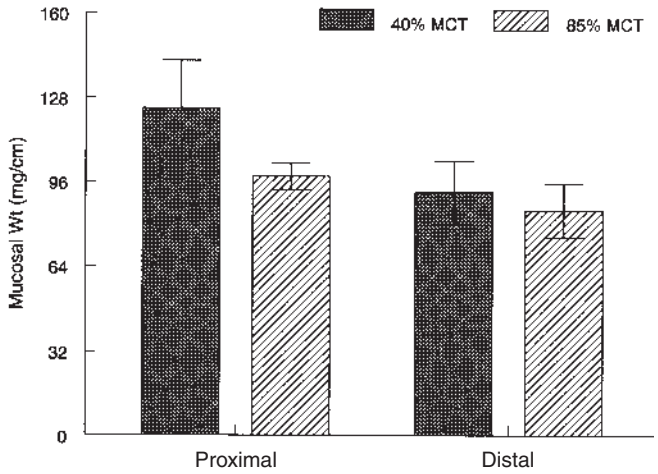

FIGURE 40.1-5 Mucosal weight in rats fed diets containing either 40% or 85% of their total lipid concentration as medium-chain triglycerides (MCT) for 3 weeks following 85% jejunoileal resection.

FIGURE 40.1-6 Mucosal protein concentration in rats fed menhaden, safflower oil, or beef tallow for 3 weeks following 85% jejunoileal resection.

trophic effect in the small intestine, produce a lower osmotic load, and are not an ideal substrate for the proliferation of excess bacterial flora in the gut lumen.

As parenteral nutrition is decreased and enteral nutrition is increased, the patient is gradually weaned to intermittent parenteral nutrition to be given over a portion of each day. This is important because the patient will likely be dismissed on home parenteral nutrition, and intermittent parenteral nutrition improves patient freedom.[136,141–143] In small infants, parenteral nutrition is often continued for a majority of the 24-hour day, but this interval can gradually be weaned as the patient's tolerance of enteral calorie increases and as the infant ages. In short-bowel syndrome, this is often a very gradual change, taking several months to years. If tolerated, the rate of enteral calories is increased and the duration of parenteral nutrition is decreased until the patient can actually be taken off parenteral nutrition on one or more nights per week. It is important to make isocaloric changes because the caloric density of the parenteral nutrition solution and the enteral nutrition solution may differ. Caloric intake is gradually increased based on the child's growth needs to ensure that the child parallels the 50th percentile, both for height and weight. Excessive caloric administration is often a problem at this stage of management because the child is incapable of regulating his own nutrient intake. It is the physician's responsibility to ensure that the patient's weight gain is appropriate for his length and is not excessive.

Fluid losses at this stage are often great. Ostomy output may have sodium concentrations of 80 to 100 mEq/L. Diluting elemental diets with oral electrolyte solution and increasing the rate of administration accordingly are often helpful in replacing these losses during the enteral feeding stage.[144]

Early in the course of therapy, the child should be prepared for home parenteral nutrition. This reduces the cost of long-term management in patients with short-bowel syndrome and decreases family stresses and nosocomial

infections. It has now become the standard of care in patients with short-bowel syndrome, and prolonged hospitalizations are rarely necessary.

Solid feedings should be introduced early in patients with short-bowel syndrome, especially infants. Chronic tube feeding, if given throughout the first year of life, may result in protracted feeding refusal later. Small children, especially infants, tolerate the osmotic effects of carbohydrates, both simple and complex, rather poorly and, consequently, do much better when fed diets or foods higher in fat content. Starting meat as the initial solid because of its high-fat and -protein and low-carbohydrate content is often beneficial. Fats stimulate gut adaptation, are a poor substrate for bacterial overgrowth in the small bowel, and produce little adverse osmotic effect. Older children and adults do better with more complex carbohydrate and more fiber in their diet. In either instance, an appropriately balanced diet with small frequent feedings is often advantageous. Increasing dietary fat and lowering dietary carbohydrate content may also reduce the substrate for bacterial overgrowth and, to some degree, reduce the need for pharmacologic intervention.

CHRONIC COMPLICATIONS

The real challenge in short-bowel syndrome comes from managing the many chronic complications that arise. Many of these are complications of parenteral nutrition, including catheter-related problems, sepsis, and total parenteral nutrition liver disease. Others are unrelated to the parenteral nutrition, such as small bowel bacterial overgrowth, or they occur when the parenteral nutrition has stopped, such as micronutrient deficiency.

Bacterial Overgrowth

Bacterial overgrowth is perhaps the least recognized complication of short-bowel syndrome but also one of the most treatable. Bacterial overgrowth is defined as increased bacterial content in the small intestine.[145] Normal small bowel bacterial counts vary from 10^3 proximally to greater concentration in the ileum. A high concentration of gastric acid normally limits the number of bacteria that successfully enter the small intestine. Bacteria are subsequently eliminated from the small intestine through the combination of normal antegrade peristalsis and mucosal immune factors. In short-bowel syndrome, many of these factors, especially anatomy and motility, are disrupted. It is not uncommon for bacterial content of the proximal small intestine to exceed 10^5. When motility is slowed, the bowel is dilated, and the ileocecal valve is absent, bacterial overgrowth is almost universally present. Reduction in gut-associated lymphoid tissue following resection might also impair the immune response to these bacteria.[3] A wide variety of organisms are present, mainly facultative bacteria and anaerobes. These bacteria deconjugate bile salts, resulting in rapid reabsorption of bile acids, depleting the bile salt pool, which subsequently impairs micellar solubilization and results in steatorrhea and malabsorption of fat-soluble vitamins. Bacterial overgrowth also causes mucosal inflammation, which further exacerbates nutrient malabsorption (Figure 40.1-7). Additionally, bacteria may compete with the host for vitamin B_{12} and perhaps other nutrients. Bacterial overgrowth should be considered when a patient experiences bloating, cramps, diarrhea, or gastrointestinal blood loss in the face of seemingly adequate gut length. It is also a common cause of clinical deterioration in a previously stable patient with short-bowel syndrome.

Diagnosis of bacterial overgrowth is classically based on demonstration of increased bacterial content by small intestinal aspiration and culture of the fluid, although this is usually not practical and is unnecessary. Screening for bacterial overgrowth can often be accomplished through the use of breath hydrogen determination. Markedly elevated fasting breath hydrogen levels or a rapid rise in breath hydrogen following oral administration of glucose (2 g/kg up to a maximum of 50 g) is suggestive of bacterial overgrowth provided that the transit time through the small intestine is not so rapid as to produce immediate entry of malabsorbed glucose into the colon. Glucose is the ideal substrate for this test because it is absorbed rapidly in the small bowel and rarely makes it to the colon, where it could produce a false-positive test. Urine indican is also an indicator of bacterial overgrowth and may be used as another simple screening test for small bowel bacterial overgrowth. Small intestinal biopsies demonstrating inflammatory changes often suggest bacterial overgrowth, especially when the small intestine is dilated, motility is poor, or a partial obstruction exists.

Two other complications of bacterial overgrowth include D-lactic acidosis and small bowel colitis. D-Lactic acidosis results because bacteria produce both D- and L-lactate, but only L-lactate is well metabolized by most humans.[146-149] Consequently, the malabsorbed carbohydrates are broken down to lactic acid by the bacteria. D-Lactate then accumulates in the bloodstream, resulting in neurologic symptoms varying from disorientation to frank coma. Bacterial overgrowth may also result in the development of colitis or ileitis, with large ulcerations that

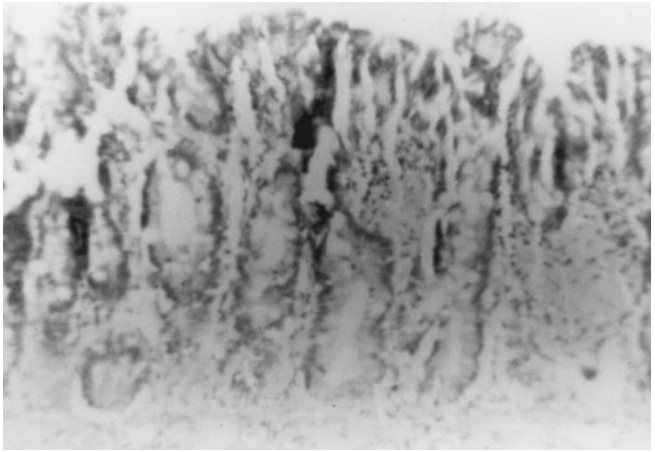

FIGURE 40.1-7 Photograph of a small intestinal biopsy from a patient with short-bowel syndrome and documented severe bacterial overgrowth showing inflammation and villus destruction (hematoxylin and eosin; ×400 original magnification).

appear to be similar to those in Crohn disease. Granulomas are not identified.[148] The presence of arthritis and other rheumatologic symptoms in some of these patients suggests the possibility that the disorder may be immune complex related, possibly owing to absorbed bacterial antigens.[149,150] This form of colitis occasionally responds to antimicrobial therapy, although sulfasalazine and other immunosuppressive medications are often efficacious. A short course of corticosteroids often produces marked improvement in patients with small bowel bacterial overgrowth–induced enterocolitis.

Bacterial overgrowth can usually be treated with broad-spectrum antibiotics given intermittently, usually the first 5 days of each month (Table 40.1-3). Oral metronidazole, 10 to 20 mg/kg/d, either alone or in combination with trimethoprim-sulfamethoxazole, is an effective combination. Oral gentamicin may also be used and is minimally absorbed. Several other combinations are often helpful. Occasionally, patients are refractory to therapy, and the antibiotics must be given continuously. In this event, the antibiotics should be rotated periodically to prevent overgrowth with resistant organisms. Probiotic therapy has been shown to reduce the risk of bacterial translocation in experimental short-bowel syndrome.[151] However, the experience with probiotic therapy in small bowel bacterial overgrowth is limited, and the addition of exogenous flora to an already overgrown small bowel ecology is likely to produce mixed results.

In some children, the absence of an ileocecal valve results in severe overgrowth in the distal small intestine. This is especially true as children age and learn to defecate less frequently. Encouraging frequent voluntary defecation may result in clinical improvement in many patients. Daily saline enemas or occasionally enteral lavage with polyethylene glycol solutions is required to reduce bacterial content in some patients. The use of antimotility agents such as loperamide in patients with short-bowel syndrome may exacerbate bacterial overgrowth and may be contraindicated in patients whose gastrointestinal motility is already delayed.

Watery Diarrhea

Excessive fluid secretion occurs in many patients with short-bowel syndrome. Often this is simply a result of excessive osmotic load in the small intestine when large quantities of carbohydrates are fed. This occurs especially after bolus feeding. However, elevated serum gastrin levels are often present in patients with short-bowel syndrome and may be partially responsible for enhanced fluid secretion. Rarely, this responds to the administration of histamine$_2$ receptor antagonists. Somatostatin analogs have been used in a limited number of such patients, with varying results.[150,152,153] Subjects improve initially, but the favorable response is often transient, and exacerbation of fat malabsorption may negate the benefits of the drug.[154] Cholestyramine is occasionally administered to patients with watery diarrhea. This resin binds bile acids, especially following ileal resection, where increased concentrations of bile acids in the colon may cause secretion and watery diarrhea. However, in the case of massive ileal resection, patients may have bile acid insufficiency, and cholestyramine may, in fact, exacerbate steatorrhea by further reducing effective bile acid concentration (Table 40.1-4). In patients with radiographically demonstrated rapid small bowel transit, the addition of loperamide may be beneficial. However, in the presence of slow transit and small bowel bacterial overgrowth, it is likely to be contraindicated.

Nutritional Deficiency States

Once patients are off parenteral nutrition, the physician no longer has control over the patient's nutritional status. The compromised small intestinal function becomes a major problem in ensuring adequate nutrient stores. Usually, macronutrients such as proteins, carbohydrates, and fats can be absorbed in adequate quantities, but micronutrients such as minerals, trace elements, and vitamins are frequently deficient. Malabsorption of fat-soluble vitamins, especially A, D, and E, is common. A variety of trace metal deficiencies have also been demonstrated in short-bowel syndrome, with iron and zinc being most common. A low serum zinc level, especially in association with a low serum alkaline phosphatase level, suggests zinc deficiency. Zinc deficiency may result in poor growth and impaired intestinal adaptation, and administration of exogenous zinc is important in such patients.[155] Selenium absorption may also be impaired.[156] Deficiencies of minerals also may exist, especially calcium and magnesium. Extra vitamin D and calcium may correct calcium deficiency, but magnesium deficiency is more difficult to manage because enterally administered magnesium often results in osmotic diarrhea. Some magnesium salts are better tolerated than others.[157] Other micronutrients, such as carnitine, choline, and taurine, may also be important.

The ileum is solely responsible for bile acid and vitamin B_{12} malabsorption. In the case of ileal resection, the proximal small intestine will not develop the ability to absorb vitamin B_{12}; consequently, such patients should be periodically monitored for vitamin B_{12} deficiency. Occasionally, parenteral administration of vitamin B_{12} may be

TABLE 40.1-4 EFFECTS OF BILE SALT MALABSORPTION

Mild = secretory diarrhea
Severe = fat malabsorption
Loss of calories
Loss of fat-soluble vitamins

required. Vitamin B_{12} deficiency may take years to develop, and periodic attention to this possibility is advisable.

Parenteral Nutrition–Induced Liver Disease

Parenteral nutrition–induced liver disease is currently the major cause of death in children with short-bowel syndrome. This disorder is especially common in children receiving long-term parenteral nutrition because the incidence increases in inverse proportion to age.[2,3,5,8] The mechanism by which parenteral nutrition causes liver injury is unknown. Toxicity of amino acids, competition of amino acids with bile acids for transport across the canalicular membrane, production of toxins in the unused bowel, excess nutrient administration, toxic substances in the parenteral nutrition solution, and nonstimulation of gastrointestinal hormones that normally control biliary secretions have all been postulated. Aggressive administration of enteral feedings, hopefully to ensure at least 20 or 30% of total daily caloric intake through the enteral route, prevention of bacterial overgrowth in the small intestine, and reduction of catheter-related sepsis all appear to be important in protecting patients from parenteral nutrition–induced liver disease (Table 40.1-5). In addition, the new parenteral solutions, especially designed for small infants, may provide some protection. In some instances, reduction or cessation of intravenous lipid administration may result in improved hepatic function or reduction in serum bilirubin concentration.[158]

Biliary disease may also occur in children who are dependent on parenteral nutrition.[159] As many as 20% of infants receiving parenteral nutrition may develop cholelithiasis. Malabsorption of bile acids, altered bilirubin metabolism, and gallbladder stasis are likely to be important factors in cholelithiasis. In some centers, early cholecystectomy is advocated in patients on long-term parenteral nutrition.[159]

Bone Mineralization

Adequate intestinal absorption of calcium, magnesium, and phosphorus is necessary for normal bone mineralization. Vitamin D, through its active metabolite 1-hydroxyvitamin D_2, is critical in the successful absorption of these elements. Normally, only about 30% of calcium is absorbed each day from the diet. About 65% of dietary phosphorus is absorbed. Inadequate dietary calcium and phosphorus intake and poor absorption of these elements appear to contribute to a high incidence of impaired bone mineralization in patients with short-bowel syndrome. Careful attention to detail in management is often able to overcome these problems.[160,161]

Catheter-Related Complications

Complications relating to chronic indwelling central venous catheters are common.[162] In one series, patients required replacement of the central venous catheter approximately every 200 days, with septic episodes typically occurring more frequently than once per year. Complications were highest in infants under 1 year of age. Catheter thrombosis is also common. Central venous catheter infections may result either from poor catheter care technique or from bacterial overgrowth, with subsequent seeding of the bloodstream with bacteria from the small intestine. The former appears more common, even in patients in whom enteric organisms are found to cause catheter infection, and a careful analysis of catheter care techniques should always be the first step in patients with frequent central venous catheter infections.

SURGICAL OPTIONS

Patients with short-bowel syndrome, especially those with bacterial overgrowth, commonly have anastomotic strictures. Further resection of already shortened small intestine may be avoided by using tapering enteroplasty, strictureplasty, and even serosal patching.[163] Relieving a tight anastomosis or stricture often improves flow of luminal contents through the small intestine and reduces bacterial overgrowth. This may occasionally produce dramatic clinical improvement provided that the patient has normal small bowel motility and previously demonstrated bacterial overgrowth.

A number of procedures have been designed to slow small intestinal transit.[164-169] These include reversed segments of bowel or colon interpositioned to slow the delivery of nutrients through the small intestine and creation of valves that produce a partial obstruction to disrupt the normal flow of contents. All of these procedures may increase bacterial overgrowth and in patients with preexisting bacterial overgrowth will likely do more harm than good.

Increasing the length of bowel through using the intestinal lengthening or Bianchi procedure has recently been popularized.[170-175] This procedure involves transecting the bowel longitudinally, preserving the blood supply to both sides of the small intestine, thereby creating a segment of bowel twice the length and half the diameter of the original segment. This procedure should be performed only when the small intestine is dilated because it allows reduction of the diameter of the dilated bowel without the loss of surface area. It is primarily a means of reducing bacterial overgrowth, although progressive intestinal dilatation will eventually result in increased absorptive surface area. In a series of 13 pediatric patients, marked improvement in absorptive capacity was achieved as measured by decreased parenteral fluid and nutrient requirements.[172] Long-term follow-up has been more disappointing. Although the procedure is successful only in the jejunum and ileum, attachment of the antimesenteric side of the small intestine to the liver or abdominal wall has been proposed, allowing vasculature to grow into the bowel from that surface and the subsequent lateral division of the small intestine; this has been partially successful in at least one patient.[176]

TRANSPLANT

Recent reports have suggested that children have been able to survive rather massive small intestinal resections during the neonatal period. Advances in parenteral nutrition and long-term management have made it possible for some children with under 15 cm of small intestine, even in the absence of ileocecal valve, to eventually become independent of parenteral nutrition. The presence of a well-functioning ileocecal valve appears to improve the prognosis in short-bowel syndrome. As a general rule, patients with greater than 25 cm of small intestine at the time of neonatal resection and who have an ileocecal valve or those with greater than 40 cm of small bowel at the time of neonatal resection who do not have an ileocecal valve have a reasonable prognosis of becoming independent of parenteral nutrition.[2,3,5,8,177] These numbers apply only to patients resected during the neonatal period because substantial growth in the small intestine occurs during the first few months of life. Application of these numbers to older children results in excessive optimism. Nonetheless, children can often adapt despite massive resection, and predicting success or failure is difficult.[172,178] Despite aggressive treatment of bacterial overgrowth, aggressive enteral feeding to stimulate the greatest amount of adaptation, and the appropriate use of intestinal lengthening procedures and other forms of surgical therapy, many patients will still never become independent of parenteral nutrition. If a patient resected as a neonate is still dependent on parenteral nutrition beyond 4 to 5 years of age, it is unlikely that the child will survive without lifelong parenteral nutrition. This form of therapy is expensive, averaging about $100,000 per year and frequently costing much more.

At the present time, small intestinal transplant is being advocated by some for children with short-bowel syndrome (see Chapter 40.2, "Small Bowel Transplant"). To date, several hundred transplants have been performed, including predominantly either combined liver and bowel or isolated intestinal transplants.[179-184] Most data now suggest that survival beyond 3 years is little better than 50% in patients undergoing combined liver and bowel transplant. Patients with isolated small bowel grafts may exhibit longer survival. Intestinal graft loss primarily owing to rejection but also to lymphoproliferative disease reduces long-term good results to nearly the same level.[185] Infection appears to be a greater problem in patients with small intestinal transplant than with liver transplant, probably owing to a breakdown in the intestinal mucosal barrier during episodes of allograft dysfunction and rejection. Subsequent translocation of bacteria and fungi into the bloodstream is likely to remain a significant problem. Diagnosis of rejection is difficult, and histologic assessment of rejection is still somewhat elusive as pathologists continue to struggle with criteria for diagnosis. Clinical parameters, such as increased ostomy output or diarrhea that cannot be attributed to feeding changes or infection, should alert the clinician to the possibility of rejection. Enteroscopy with multiple biopsies is important in making this diagnosis and should be done visually and site directed because rejection appears to be a patchy lesion, at least initially.

The key to successful small bowel transplant appears to be aggressive immunosuppression. Tacrolimus, which permits greater immunosuppression relative to its side effects, may be successful in preventing rejection that was previously not treatable with cyclosporine. The increased need for immunosuppression, however, raises concern about development of post-transplant lymphoproliferative syndrome. This Epstein-Barr virus–driven malignancy is a major problem following intestinal transplant. It may respond to reduction or cessation of immunosuppression, but graft loss is at risk when this is done. There is some question as to whether intestinal graft rejection may be somewhat less with liver and bowel transplants than isolated intestinal transplants because of the protective effect conferred by the liver on rejection in the small intestine, but through the use of tacrolimus and other new immunosuppressants, both procedures appear to be feasible.

The ultimate usefulness of intestinal transplant awaits greater experience, but concern about post-transplant lymphoproliferative syndrome, late-onset complications such as rejection and other malignancies, and infectious complications associated with intestinal transplant suggests that greater experience should be sought before recommending this procedure in patients who are otherwise stable on parenteral nutrition.[183,186] In patients with irreversible total parenteral nutrition liver disease, the combined liver and bowel transplant appears to be a potential option, and because of donor shortage, patients should be referred for transplant once liver disease is considered irreversible. Patients with impaired central venous access or patients with early progressive liver disease may be potential candidates for isolated intestinal transplant. Patients with direct hyperbilirubinemia of 12 to 15 mg/dL and fibrosis, but no cirrhosis on liver biopsy, have reverted to normal liver function following isolated intestinal transplant. In a limited number of carefully selected patients, isolated liver transplant may be useful in infants with end-stage liver disease associated with short-bowel syndrome provided that adequate bowel length is available to stimulate subsequent bowel adaptation.[187] Further experience will need to be obtained before appropriate indications for intestinal and combined liver and intestine transplant can be developed.[177]

2. Small Bowel Transplant

Susan V. Beath, MB, BS, BSc, MRCP(UK), DTM, FRCPCH

In many ways, small bowel transplant is the logical extension of treatments such as intravenous feeding (also known as parenteral nutrition [PN]), which have become accepted in the management of chronic irreversible intestinal failure. However, small bowel transplant has taken a long time to become established. The first intestinal transplants were carried out as technical experiments in dogs in the 1950s.[1] This was followed up in some quite desperate cases in the 1960s in humans, but all failed because of the intensity of rejection, which led to sepsis and multiorgan failure within a few days. In the 1970s, intravenous feeding was refined, and it became possible to maintain children and adults for years with daily infusions of carefully balanced solutions of amino acids, dextrose, and lipids.[2–4] These developments in intravenous feeding improved the nutritional state of potential transplant recipients and have probably contributed to the gradually improving results of small bowel transplant.[5,6] The other key development has been improvements in immunosuppression, specifically, the widespread availability from 1991 of tacrolimus, a drug derived from a saprophytic fungus that targets cytotoxic T lymphocytes and inhibits clonal expansion of those immune cells responsible for the recognition of new antigens.

There are some specific clinical issues to consider when contemplating small bowel transplant that distinguish it from other solid organ transplants: (1) the volume of tissue transplanted is large and contains a vast number of lymphocytes in the lamina propria and Peyer patches, and (2) the small bowel allograft is contaminated with billions of bacteria. This means that graft-versus-host disease is a possibility in patients with underlying immunodeficiencies[7] and that a large exposure to immunosuppression is routinely needed to prevent rejection. The presence of bacteria means that when moderately severe rejection develops, causing the intestine to become more permeable, then translocation of bacteria to the systemic circulation may occur via mucosal ulceration at a time when additional immunosuppression is needed to deal with rejection.[8] This clinical paradox goes some way to explaining the high complication rate and modest survival of 50 to 65% that obtain after small bowel transplant.[9–11]

INDICATIONS

Although many adult patients request small bowel transplant in preference to the inconvenience of long-term PN, the current survival rates of small bowel transplant mean that the transplant is reserved for patients who have developed life-threatening complications related to the administration of PN. It is well known that cholestasis and progressive liver disease are poor prognostic factors in patients requiring long-term PN (Figure 40.2-1),[12–14] but in addition to liver disease, unstable venous access and recurrent life-threatening episodes of infection (caused by bacterial overgrowth or contamination of the feeding catheter) constitute appropriate indications for transplant, as detailed in the consensus statement produced by Kaufman and colleagues[15] and Table 40.2-1.

These indications apply to adults and children, but the prognosis in children with short gut may be unpredictable with regard to the possibility of long-term adaptation of residual gut function. It is very important that transplant teams have pediatric gastroenterologists advising on the feasibility of improving intestinal function to make a judgment about the type and necessity of transplant (Table 40.2-2).[16,17] Furthermore, patients with disease other than short gut as the underlying cause of intestinal failure may be stabilized without resorting to small bowel transplant.[18,19] It is noteworthy that patients managed by a nutritional care team have usually required fewer replacements to their central lines and experienced less liver disease at an early age than do patients looked after by a nonspecialist team.[20,21] Given the relatively high morbidity and mortal-

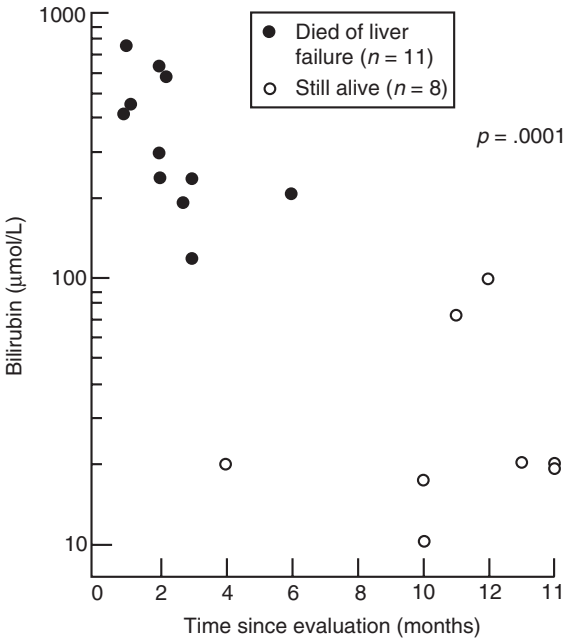

FIGURE 40.2-1 Graph showing plasma bilirubin at time of assessment and subsequent duration of survival. Adapted with permission from Beath SV et al.[20]

TABLE 40.2-1 INDICATIONS FOR INTESTINAL TRANSPLANT

LIFE-THREATENING COMPLICATIONS ARISING FROM PARENTERAL NUTRITION THERAPY	TYPE OF TRANSPLANT
Impending loss of venous access, ie, when 2 of the 4 available sites have been lost in infants or 3 of 6 in older children Recurrent sepsis (especially if metastatic, eg, brain abscess or infective endocarditis, if unusually severe, resulting in multiorgan failure)	Isolated bowel transplant
Erratic fluid balance requiring hospitalization Congenital intractable epithelial disorder, eg, microvillous inclusion disease and tufting enteropathy Some cases of short-bowel syndrome	Isolated bowel transplant or combined liver and bowel transplant depending on severity of hepatic complications of parenteral nutrition
Irreversible liver disease: hyperbilirubinemia persisting beyond 3–4 mo of age and features of portal hypertension, splenomegaly, prominent superficial abdominal veins	Combined liver and intestinal transplant

Adapted from Kaufman SS et al.[15]

ity, it is also important to identify patients who would not benefit from intestinal transplant, for example, those with severe congenital or acquired immunodeficiency or nonresectable malignancies (Table 40.2-3).

SURGICAL CONSIDERATIONS

Considerable surgical ingenuity and innovation have been required to make intestinal transplant a practical reality, although the type of transplant that is recommended, either small bowel transplant combined with liver and/or other organs or isolated small bowel transplant, is based on medical criteria. The original surgical concept of the abdominal viscera as a "bunch of grapes" and the mesentery as the "stem" is described in early operations by Starzl and Deltze[22–24] and has been modified in the late 1990s to lessen the risk of postoperative biliary leaks and strictures.[25]

The majority of intestinal transplants are done in children, 12% of whom are less than 12 months old (Table 40.2-4).[26] The infants who require combined liver and bowel transplants have often had previous abdominal surgery, which renders the abdominal cavity even smaller and more difficult to work in. This means that there is frequently a size mismatch between donors who tend to be adolescents or adults and the desperately ill babies who need the transplant. Consequently, the waiting list mortality of 50 to 60% for combined liver and small bowel transplant has been one of the highest for any solid organ transplant.[27,28] Such a high mortality has stimulated further innovations in surgical technique, including the development of the reduction en bloc technique.[29] Up to a 5:1 size mismatch between the donor and the recipient

TABLE 40.2-2 CLINICAL STAGE AND TYPE OF TRANSPLANT

CLINICAL STAGE	TRANSPLANT TYPE	NOTES AND NONINTESTINAL TRANSPLANT OPTIONS
No jaundice, no portal hypertension, normal abdominal sonogram, no venous access problems, fluid balance satisfactory	None indicated	No need for transplant; review enteral feeds and intestinal anatomy/stomas (if short gut); ensure nutritional care team involvement, shared care follow-up with pediatric gastroenterologist
No cholestasis, minimal portal hypertension (borderline enlarged spleen), modest fibrosis only in liver biopsy, only two satisfactory central veins still patent Recurrent episodes of systemic sepsis (requiring intensive care) Irreversible intestinal failure with poor prognosis, eg, microvillous inclusion disease	Isolated small bowel transplant	A good opportunity to re-evaluate tolerance of enteral feeding (if short gut) and assess hygiene related to feeding catheter Review prescriptions of motility agents and ursodeoxycholic acid Liver disease may be progressive, so delay may result in combined liver bowel transplant being needed
Patient with short gut with potential to adapt Jaundice (bilirubin greater than 100 µmol/L or 6 g/L) Severe fibrosis and marked portal hypertension, disturbance to coagulation and intermittent ascites/encephalopathy	Isolated liver transplant	Patient is so ill that liver transplant within weeks is needed; the resolution of portal hypertension may be accompanied by improvement in adaptation of residual short gut
Patient with pseudo-obtruction or mucosal disorder in which jaundice, hepatic fibrosis, impaired coagulation, ± ascites and coagulopathy have developed	Combined liver and bowel transplant	Combined liver-bowel transplant recommended, but if patient is less than 10 kg, donor organs may not be available quickly enough, so sequential liver and small bowel transplants may be carried out
Jaundice (bilirubin greater than 100 µmol/L or 6 g/L), fibrosis bordering on cirrhosis, evidence of progressive liver disease, ultrashort gut with no sign of adaptation, dysmotile gut, irreversible intestinal failure		Prevent further deterioration, review enteral feeds, review prescription for motility agents, ursodeoxycholic acid; consider selective decontamination of intestinal tract

TABLE 40.2-3 CONTRAINDICATIONS TO INTESTINAL TRANSPLANT

Patients with the following conditions should not normally undergo intestinal transplant because they are unlikely to derive an obvious benefit:
Profound neurologic disabilities
Life-threatening and other noncorrectable illnesses not directly related to the digestive system
Severe or acquired immunodeficiency
Nonresectable malignancies
Multisystem autoimmune diseases
Those with insufficient vascular patency to guarantee easy central venous access for up to 6 mo following transplant

Adapted from Kaufman SS et al.[15]

may be accommodated by removing the right lobe of the donor liver en bloc with removal of the middle section of small bowel allograft (the distal ileum is preserved for use in the recipient and is exteriorized to allow for close inspection of the small bowel allograft).[29] The vascular anastomoses are made by joining the hepatic veins to the inferior vena cava, where it joins the right atrium, and the celiac axis to the infrarenal aorta.

In contrast, the operative procedure in isolated small bowel transplant is relatively straightforward, with care being needed to anastomose the donor portal vein to the recipient portal vein to avoid kinking and torsion. If hepatic fibrosis is present, then anastomosing the portal vein to the inferior vena cava is preferred to avoid the possibility of portal hypertension affecting the small bowel allograft. The celiac axis is anastomosed to the infrarenal aorta. The proximal end of the graft may be anastomosed to jejunum in short gut patients or to the stomach in patients with a history of dysmotility. The distal end of the small bowel graft may be brought out as an end stoma if the patient has a nonfunctioning large bowel (eg, Hirschsprung disease) or connected to residual large bowel via a loop ileostomy. Whatever reconstruction is done, it is essential to allow exteriorization of the small bowel allograft to allow for regular biopsy for early detection of rejection (Figures 40.2-2 and 40.2-3).[10]

RESULTS

Since 1992, the world experience of intestinal transplant has been collected by the Intestinal Transplant Registry, which publishes updated results every 2 years on its Web site and in journals.[9,26] In the past decade, the number of transplants has grown from 5 to approximately 100 per year. Information on the age, underlying cause of intestinal failure, type of transplant (isolated bowel, combined liver and bowel transplant, multivisceral transplant), type of immunosuppression used, autonomy from PN, major complications resulting in graft removal, and survival are collected and published regularly (see Tables 40.2-4 and 40.2-5).

According to the 2001 report from the Intestinal Transplant Registry, three-fifths of all intestinal transplant candidates received combined grafts of liver and bowel (of which 13.6% were multivisceral grafts).[26] The overall graft survival is 50% at 3 years post-transplant, although survival is significantly better in centers that have experience of carrying out at least 10 transplants (Figures 40.2-4 and 40.2-5). A number of factors that influence survival have been identified by the transplant registry and in large series in single centers (Table 40.2-6).

The survival curves from the Intestinal Transplant Registry[26] show that the early mortality occurs in the first 6 weeks and is around 20%. This is related to the poor preoperative condition of the patients who develop multiorgan failure while still in the intensive care unit. The multiorgan failure is often triggered by a systemic inflammatory response to bacteremias and viral pathogens such as respiratory syncytial virus. By 6 weeks postoperatively, most patients have stabilized, and 70 to 80% of the original cohort of transplant recipients are discharged at this point free of PN but on high levels of immunosuppression. Over the next 6 to 18 months, there is a gradual reduction in survival caused by infection (56.8% of all deaths are predominantly caused by infection). The current worldwide overall survival rate of adults and children in 55 centers is 335 patients of 651 transplanted patients.[26]

TABLE 40.2-4 DEMOGRAPHIC DETAILS OF TRANSPLANT RECIPIENTS WORLDWIDE TAKEN FROM INTESTINAL TRANSPLANT REGISTRY RECORDS UP TO MID-2001

PARAMETER	DETAIL	% (*n*)
Age of recipients (yr)	0–1	12
	1–13	46

COMPLICATIONS

TECHNICAL

These correlate with the complexity of the surgery and tend to occur in the first 10 days postoperatively. They include perforation of native intestine and/or small bowel allograft, prolonged ileus, biliary obstruction or leaks, traumatic pancreatitis, and hemorrhage (see Chapter 40.3, "Aspects of Surgery"). The signs of intra-abdominal pathology may be subtle, being masked by the effects of high-dose steroids, so there is a low threshold for second-look laparotomy.

Chylous ascites as a result of interruption to lacteals may also develop if feeds high in long-chain fats are administered in the first few weeks postoperatively.

INFECTIONS

Common Bacterial and Viral Infections. There is an increased risk of all infections, including common respiratory pathogens such as *Streptococcus pneumoniae*, respiratory syncytial virus, and parainfluenza virus.[30] These require aggressive treatment, including antibiotics, ribavirin, and respiratory support such as ventilation, depending on the diagnosis and severity of infection. *Pseudomonas* has also been observed and may be difficult to detect without bronchoalveolar lavage. Adenovirus is also associated with severe infection affecting respiratory and gastrointestinal tracts; diagnosis may be difficult because the symptoms and pathology of the intestine may mimic rejection (diarrhea and apoptosis).[31,32]

Opportunistic Infections. Less common but of particular note in transplant recipients are opportunistic infections with *Pneumocystis carinii* and vancomycin-resistant enterococcus (VRE). *Pnemocystis* may be prevented by continuing treatment with cotrimoxazole until immunosuppression is reduced (in practice, usually at least for 1 year postoperatively). VRE is a low-virulence pathogen analogous to methicillin-resistant *Staphylococcus aureus* and is often present in the bowel of healthy individuals. However, when VRE colonizes the biliary tree or infects the abdominal cavity in immunosuppressed patients, the infection may be life threatening, and early treatment with the new class of antibiotic, quinupristin-dalfopristin, is recommended.[33]

Herpesviruses. One of the major groups of infectious agents relevant to pediatric intestinal transplant recipients is the herpesviruses, in particular cytomegalovirus (CMV) and Epstein-Barr virus (EBV). CMV is the cause of major sys-

temic illness, including fever, rash (Figure 40.2-6), gastrointestinal bleeding, and small bowel perforation, and transplant teams generally avoid using CMV-positive donors. Prophylaxis (ganciclovir and hyperimmunoglobulin) against CMV infection is usually given even in apparently low-risk patients for CMV because the consequences of infection are so severe. EBV appears to be more severe if it is acquired as a novel infection within months of transplant, which means that children are at greatest risk of developing the lymphomas and hematologic malignancies that are associated with this virus.[34] The use of tacrolimus, which selectively inhibits cytotoxic T lymphocytes as the principal immunosuppressant, may aggravate the progression from glandular fever to post-transplant lymphoproliferative disease (PTLD).

PTLD. Depending on the presence of risk factors (young age, no previous immunity to EBV, dependence on tacrolimus-based immunosuppression, EBV-positive donors), the incidence of PTLD ranges from 10 to 50% in small bowel transplant recipients.[34,35] In some cases, the virus is probably transplanted with the donor organs and infects the naive recipient, especially when older donors have been used. Infection with EBV is extremely common in the population, and it would be difficult to exclude donors who are EBV positive without increasing the waiting list mortality of transplant candidates. Thus, the main tactics used in reducing PTLD are early detection, stepwise reduction of immunosuppression, especially tacrolimus, and adjuvant treatment if the tumor fails to regress. For example, selective B-cell lysis (rituximab) or EBV-specific cytotoxic T cells harvested from healthy blood donors and partially human leukocyte antigen (HLA) matched to the small bowel transplant recipient have been used with success.[36,37] Some transplant centers have used chemotherapy (cyclophosphamide, prednisolone, doxorubicin, and vincristine). Even with this variety of treatments, the mortality after the onset of PTLD is high at around 50% of patients with established PTLD, especially in children.

REJECTION

Acute Cellular Rejection. Acute cellular rejection of the small bowel allograft is common and is the major cause of graft loss but not death because it is often possible to remove the small bowel graft and recommence PN (see Table 40.2-5). Clinical signs of rejection of the small bowel allograft (malaise, fever, increased stomal output, or diarrhea) occur most frequently at 7 to 14 days postoperatively, although the histologic process will have started 1 to 2 days earlier. Specific laboratory markers for rejection, such as tissue enzymes, are lacking in small bowel transplant, and reliance is made on serial histologic assessments of mucosal biopsies taken in context with clinical features. The histologic signs of rejection in the small bowel mucosal biopsy have been graded into four levels of severity depending on the degree of apoptosis, destruction of crypts, and inflammation of the lamina propria (Table 40.2-7).[38–40] Rejection may progress rapidly from mild systemic upset and a moderate increase in stomal output by about 50% to a severe secretory diarrhea associated with sloughing of the mucosa and gram-negative bacteremia, all within 1 week. Prompt recognition and treatment with a bolus of high-dose intravenous steroid (eg, methylprednisolone 20–50 mg/kg) and broad-spectrum antibiotics, followed by a general increase in tacrolimus and other agents, such as mycophenolate or sirolimus, are usually effective in restoring normal graft function.[41]

Centrilobular Rejection in Liver. In children who have received a combined liver and bowel transplant, acute cellular rejection of the liver allograft independently of the small bowel allograft is unusual. However, with increasing experience, some transplant groups have observed centrilobular changes rather than the more usual portal tract inflammation occurring months or years after the transplant. There is often a history of only minor changes in liver enzymes. The centrilobular changes usually respond to increases in immunosuppression and are thought to represent a chronic rejection process in the liver modified by cytokines emanating from the intestinal allograft.[42]

Chronic Rejection of Small Bowel Allograft. Chronic rejection of the small bowel is poorly understood, but it appears to be a vascular phenomenon starting in the mesenteric vessels that become inflamed and impede blood flow. There is little to observe in the mucosa of the allograft, although the patient will tend toward diarrhea alternating with episodes of obstruction. This pattern of symptoms has been labeled "distal ileal obstruction syndrome"[43] and may require resection of the affected bowel if recognized, but some patients go on to complete graft failure. There are no convenient noninvasive means of diagnosing chronic rejection, but selective angiography of the celiac axis and biopsy of mesenteric vessels at the time of laparotomy have been used.

Drug Toxicity

Compared with liver transplant, approximately twice as much immunosuppression is needed to achieve tolerance of the small bowel allograft. Inevitably, adverse effects occur, the most frequent being hypertension, bone marrow toxicity, and nephrotoxicity (Table 40.2-8). The majority of patients require antihypertensive medications such as nifedipine, and many become neutropenic in the first 6 months postoperatively. These effects are mainly related to tacrolimus, although the neutropenia may be induced by other drugs, including azathioprine, mycophenolate mofetil, sirolimus, cotrimoxazole, and ranitidine. Tacrolimus induces upregulation of endothelin receptors, producing constriction in arterioles in the systemic circulation and in the kidneys, and this probably explains the hypertension and the long-term effects on glomerular filtration rates. In an attempt to

TABLE 40.2-6 FACTORS ASSOCIATED WITH REDUCED REJECTION RATES AND/OR IMPROVED SURVIVAL AFTER SMALL BOWEL TRANSPLANT

	FACTOR	*p* VALUE	REFERENCE
Associated with reduced rejection (no effect on 12-mo survival)

reduce the effects of tacrolimus-induced nephrotoxicity, it has become common practice to use prostaglandin infusions for 5 to 10 days immediately after small bowel transplant.[44] Apart from the effects on renal vasculature, tacrolimus also affects the tubular handling of magnesium, resulting in the loss of magnesium in urine and low magnesium levels in blood. Low magnesium may contribute to another important side effect of tacrolimus, neurotoxicity, which is manifested by tremor and even convulsions. Patients may also complain of limb pain, the so-called reflex sympathetic dystrophy. Less common in children is the onset of insulin-dependent diabetes mellitus caused by tacrolimus, which may develop shortly after the transplant or some years later. Apart from diabetes mellitus, which seems to be an idiosyncratic response in children, all of these effects of tacrolimus are dose related and have prompted the use of alternative drugs such as sirolimus and mycophenolate mofetil, which are not neurotoxic or nephrotoxic.

Steroids are also used at higher doses and for a longer time than in other solid organ transplants and can result in impaired linear growth, especially in the first 6 months, after which growth velocity seems to improve again as steroids are reduced.

INNOVATIONS IN SMALL BOWEL TRANSPLANT

In addition to the innovations in surgical technique described above, the intensity of rejection provoked by the small bowel allograft has driven the search for alternative ways to induce tolerance.

Bone Marrow Infusions

The two observations that repeated blood transfusion in renal allograft recipients reduced rejection rates and that long-term partly tolerant recipients of liver transplants have a chimera of immune cells derived from the donor liver led to the hypothesis that more exposure to donor immune cells would further enhance tolerance. To test this idea, bone marrow from the same small bowel transplant donor was harvested at the same time and routinely infused during reimplantation. The short- and medium-term results have not produced the hoped for tolerance, although long-term results on tolerance at 5 to 10 years after transplant are not yet available.[45]

Conditioning Regimen

The experience of bone marrow transplant has been applied to the small bowel transplant field, and the relatively mild conditioning agent alemtuzumab (Campath-1H, Berlex Laboratories, Montville, NJ) has been used with some initial success. The results from one large center indicate an 80% 12-month survival rate, but no long-term results are yet available.[46] There are theoretic concerns about opportunistic infections, particularly in young recipients, but this manipulation of the immune system may prove to be important if the medium-term results match those of the first reports.[30,47]

CD25 Blockade

The humanized monoclonal antibodies basiliximab and daclizumab bind specifically with the CD25 receptor car-

TABLE 40.2-7 SMALL BOWEL ALLOGRAFT: GRADES OF ACUTE CELLULAR REJECTION

GRADE	MUCOSAL BIOPSY HISTOLOGY	CLINICAL FEATURES
1 Mild	2–5 apoptotic bodies per 10 crypts, a few inflammatory cells scattered in lamina propria	Increase in bowel frequency or ileostomy output may go up by 50%
2 Moderate	5–10 apoptotic bodies per 10 crypts, infiltration of crypts by lymphocytes, obvious increase in inflammatory cells in lamina propria	Secretory diarrhea, malaise, low-grade fever
3 Severe	Greater than 10 apoptotic bodies per 10 crypts, some loss of villi, destruction of crypts in places, ulceration may be seen, numerous inflammatory cells in lamina propria	Secretory diarrhea associated with thirst and dehydration, protein-losing enteropathy, lassitude, fever ± peripheral edema, gram-negative septicemia
4 Exfoliative	Extensive ulceration, lamina propria replaced by inflammatory cells, complete loss of crypts in places	Prostration, fever, gastrointestinal bleeding, systemic inflammatory response syndrome

Adapted from Lee RG et al,[38] Roberts CA et al,[39] and White FV et al.[40]

TABLE 40.2-8 IMPORTANT TOXIC EFFECTS OF IMMUNOSUPPRESSANT DRUGS COMMONLY USED AFTER SMALL BOWEL TRANSPLANT

DRUG	TOXIC EFFECTS
Tacrolimus (Prograf, Fujisawa Benelux, Houten, The Netherlands)	Vasoconstriction, hypertension, reduced glomerular filtration, elevated urea and creatinine, hypomagnesemia, tremor and convulsions, impaired glucose tolerance, neutropenia, reflex sympathetic dystrophy, hypertrophic cardiomyopathy
Sirolimus (Rapamune, Wyeth Laboratories, Madison, NJ, USA)	Generalized suppression of bone marrow, thrombocytopenia, elevated serum triglyceride and cholesterol, increased incidence of thrombosis,* impaired wound healing*
Mycophenolate mofetil (CellCept, Roche, Basel, Switzerland)	Diarrhea, vomiting, gastritis and gastrointestinal bleeding, neutropenia, generalized suppression of bone marrow
Azathioprine (Imuran, GlaxoWellcome, Uxbridge, UK)	Agranulocytosis, generalized suppression of bone marrow, myalgia, arthralgia, hepatotoxicity
Basiliximab/daclizumab (Simulect, Novartis/Zenapax Roche)	Fever, lymphopenia, pulmonary edema, anaphylaxis
Steroids, ie, prednisolone, methylprednisolone, hydrocortisone	Sodium and water retention, hypertension, impaired glucose tolerance, impaired bone mineralization, impaired linear growth, muscle wasting, risk of hypotensive collapse if sudden withdrawal, impaired wound healing

*It is not clear if there is a causal link between these events and the drug.

ried on T lymphocytes. The CD25 receptor normally recognizes interleukin-2, a lymphokine released by cytotoxic T cells, which amplifies the rejection process. These monoclonal antibodies have been widely used in renal and liver transplant and have a half-life of 4 to 8 weeks.[48] They are used to reduce the severity of rejection episodes at a time when the patient is most vulnerable, which is a useful outcome particularly in small bowel transplant, although it does not appear to reduce the length of stay.[49]

Sirolimus

Sirolimus has been used predominantly in renal transplant since 1990. It acts on the T-cell receptor of rapamycin in immune cells, inhibiting the cell cycle at G_1, resulting in an antiproliferative effect that is most pronounced in lymphocytes but can extend to other hematologic cell lines (megakaryocytes, granulocytes).[50] This is potentially beneficial in patients at risk of PTLD. Because sirolimus acts on a different point from the cell cycle (G_1) compared with the calcineurin inhibitors, which act at G_0 (G_0 is the resting phase), the two agents can be used in combination, although this appears to be a very potent combination.[51] Early reports from some transplant centers suggest that rejection after small bowel transplant is significantly reduced in those patients receiving sirolimus, but this may just be a cohort effect.[52]

Ex Vivo Irradiation

This is a radical idea designed to remove mature T and B cells from the allograft by irradiation after harvesting and before reimplantation and repopulating the graft by infusing stem cells and other precursors from the donor's marrow. The irradiation also reduces the bacterial contamination of the graft, but access to radiation sources at a time convenient to the operative procedure while maintaining the aseptic condition of the organ has posed practical difficulties, and it is too early to know if this kind of immunomodulation will induce tolerance and better outcomes for small bowel transplant.[10,53]

None of these treatments have become established practice, but in the next few years, it is possible that one or more may produce a genuinely positive improvement in the long-term results of small bowel transplant.

POSTOPERATIVE GRAFT FUNCTION AND DIETETIC MANAGEMENT

Oral fluids are introduced as soon as the ileus resolves, and if no major complications have occurred, enteral feeding will have been introduced from day 7. Typically, the allograft switches from a state of ileus to secretory diarrhea around day 5,[54] and the stoma becomes very productive, with as much as 500 mL/kg/d of stomal output in extreme cases. The differential diagnosis for the secretory state at this point includes recovery from the effects of preservation procedures during harvesting and reimplantation, sepsis, and rejection. Provided that rejection and sepsis are accurately diagnosed and treated if present, the secretory diarrhea lessens such that by day 14 to 21, most patients are in balance with oral intake and stomal output.

Different transplant teams have varying approaches to establishing enteral nutrition, but the common theme is avoidance of long-chain fats in the first 6 weeks. Many teams also use a hydrolyzed protein source. At Birmingham Children's Hospital, we use a modular feed as a means of choosing individual components such as glucose polymer, which incorporates calories without increasing the osmolality of the feed excessively. The feed is introduced as relatively calorie dense (0.8 kcal/mL) but low volume (eg, 5 mL/h) and is increased stepwise over 21 days so that full enteral sufficiency is achieved by day 30 postoperatively, and PN is discontinued.[55] Previously, we have used hydrolyzed whey protein[56] but now use a whole-protein source, with no increase in allergy or intolerance (Table 40.2-9).

TABLE 40.2-9 DIETETIC MANAGEMENT AFTER SMALL BOWEL TRANSPLANT

POSTOPERATIVE DAY	FEED COMPONENTS	COMMENT
0–7	Balanced glucose and salt solution, eg, Diorolyte or Rehidrat*	Sips of sterile water allowed
7–30	Start 5 mL/h modular feed containing whole protein (eg, Maxipro†), medium-chain triglyceride (eg, Liquigen†), and glucose polymer (eg, Maxijul†) made up to produce a calorie density of about 0.8 kcal/mL L-Glutamine† added (0.25% of total protein) and pectin to thicken the feed	Volume is increased as rapidly as patient will tolerate; patient is encouraged to take feed by bottle or cup as well as by nasogastric tube
30–90	A small amount of long-chain fat (Calogen†) is allowed (up to 25% of total lipid), adjustments made to carbohydrate content, glutamine discontinued, total volume between 500 and 1,200 mL/d	Low-fat diet is encouraged; discharge advice about avoidance of live yogurts, sugary "pops," and tap water, which may contain cryptosporidia
90–onward	Modular feed discontinued in favor of a normal standard feed with whole protein and long-chain fat, eg, Nutremi‡	Not all patients need feed supplements unless prone to dehydration or averse to eating food

*Searle, High Wycomb, Bucks, UK.
†Scientific Hospital Supplies, Liverpool, UK.
‡Nutricia Clinical, Wiltshire, UK.

The motility of the small bowel allograft depends on the intrinsic nervous system and is sensitive to local factors such as nutrient content and luminal distention rather than autonomic nervous control.[57] This means that there is no vagally mediated postprandial suppression of motility, and drugs such as loperamide (50–200 μg/kg/dose) are needed to slow transit. Care must also be taken with the carbohydrate content of the feed, which, if excessive, can induce an osmotic diarrhea that could be mistaken for rejection.

Improving allograft function allows modification to the dietetic support with time, such that by 6 months postoperatively, most patients are on a normal family diet supplemented by nutritionally complete calorie-rich drinks that can be taken by cup or beaker or by nasogastric feed in children with an aversion to eating. Most patients seem to transfer from PN to enteral feeding with no loss in growth velocity provided that the small bowel allograft is functioning well.[55,58]

LONG-TERM ISSUES AND SMALL BOWEL TRANSPLANT

Rehabilitation

Successful rehabilitation depends on a multidisciplinary team, which, ideally, should be composed of individuals with the following skills: play therapy, teaching school-age children while they are in hospital, physiotherapy, dietetics, stoma care, and liaison work. In the United Kingdom, specialist nurses increasingly take on a key coordinating role to ensure that local community teams, including the family doctor and schoolteachers (for older children), are aware of the child's needs after transplant and that supplies of immunosuppression (eg, stoma bags) are arranged before discharge. Depending on the extent of provision of community facilities, physiotherapy and speech therapy initiated in hospital can be continued at home. This is important because many children who are recipients of small bowel transplants have had a life of emergency hospitalizations, poor experience of eating, and restrictions to their physical and psychological development. Integration in mainstream schooling is possible, but susceptibility to infection, especially varicella-zoster, rotavirus, and adenovirus, remains high.

Monitoring

The aim of monitoring is to detect and treat complications at an early stage. The principal complications are rejection, infection, and drug toxicity, so the monitoring regimen revolves around blood tests, assessment of small bowel function by measuring growth, and recording significant symptoms such as diarrhea or increases in the volume stomal output, mucosal biopsy, measurement of blood pressure, and screening for the onset of PTLD, which may include endoscopy and detailed imaging such as computed tomography or magnetic resonance imaging (Table 40.2-10). The blood tests are performed once per month, when the patient is stable (from about 6 months postoperatively), and mucosal biopsy at the same time as the screening test for PTLD is done every 3 to 6 months depending on the patient's risk factors and symptoms.

QUALITY OF LIFE

Although the long-term survival is not yet known, it is encouraging to note that quality of life in the medium term seems to improve. It is difficult to judge the quality of life in young children,[59,60] but some attempts have been made to do so either by objective evaluations of hospital attendance, the number and use of appliances such as indwelling central lines and stoma bags,[61] or a semistructured questionnaire using instruments such as the General Health Questionnaire.[62] Children and families who are recipients of small bowel transplant do not have a normal quality of life, and it is clear that many of them have adapted to their predicament by developing obsessive or neurotic traits, but their scores are similar or superior in some cases to those of children on home PN.

TABLE 40.2-10 MONITORING TESTS GROUPED ACCORDING TO COMPLICATION

TEST	REJECTION	INFECTION	TOXICITY
Clinical	Weight loss, fever, lassitude, loss of appetite, stomal output or stool frequency doubles or triples	Fever, obtundation, stomal output or stool frequency increases but not usually as much as in rejection, enlarged painful lymph nodes	Hypertension, tremor, recurrent infections, glucose intolerance, bruising (thrombocytopenia)
Blood tests	Nil specific Urea and creatinine often increased Low levels of tacrolimus (and sirolimus) may be noted	Blood culture EBV and CMV PCR Pattern of lymphocyte subsets to detect over suppression of immune system	Tacrolimus (± sirolimus) levels Magnesium Urea and creatinine, full blood count Cholesterol triglyceride
Histology	Mucosal biopsy may show apoptosis, infiltration of crypts by lymphocytes, increase in inflammatory cells in lamina propria, ulceration; low-grade rejection may be detected despite mimimal symptoms; allows for modification of immunosuppression	Adenovirus and other enteric infections may also induce apoptosis but regenerative features common as well In situ hybridization can detect worsening EBV infection; allows for modification of immunosuppression	Gastric erosions may be seen with high levels of immunosuppression, also malignant transformation of lymphoid tissue by EBV
Other monitoring tests	Liver biopsy, endoscopically aided mucosal biopsy (with zoom facility)	Stool and urine culture, throat swab Culture of internal sites such as liver tissue, ascitic fluid, thoracic or abdominal fluid collections, cerebrospinal fluid, bronchoalveolar lavage Imaging to evaluate possible malignancy (CT or MRI)	Bone marrow aspirate, bone density studies, upper and lower intestinal endoscopy

CMV = cytomegalovirus; CT = computed tomography; EBV = Epstein-Barr virus; MRI = magnetic resonance imaging; PCR = polymerase chain reaction.

COST-EFFECTIVENESS

The relatively small numbers distributed across many transplant centers have made it difficult to produce cost-effectiveness studies of the robustness of the ones published for renal replacement therapy. However, it is noteworthy that medical insurance companies in the United States will now fund small bowel transplant. In the United Kingdom, a small study following the outcome of 50 children referred for small bowel transplant is under way, and although it is too early to report the outcome of this, it is clear that the cost of managing intestinal failure with or without transplant is much higher than previously calculated (M. Buxton, personal communication, 2003).

SUMMARY AND CONCLUSION

In the past 10 to 15 years, there have been major advances in the surgery of small bowel transplant and management of rejection and specific opportunistic infections. Small bowel transplant has become an established treatment for chronic intestinal failure in children who cannot remain on intravenous feeding long term because of progressive liver disease, pulmonary disease from recurrent feeding catheter embolization, and/or impaired venous access.[15,63] There has been a steady increase in the number of transplants performed annually worldwide to around 100, of which approximately 65 are in children, the majority of whom have a history of short gut and liver failure.[26] The current survival at 3 years postoperatively is around 50%, although the results in the larger centers are better, and this may improve further with the availability of new approaches to immunomodulation.[11,30] Quality of life and cost-effectiveness studies in countries with well-financed health care systems suggest that this treatment will continue to be of benefit to children who are experiencing complications related to the long-term administration of intravenous feeding solutions.

ACKNOWLEDGMENT

I would like to thank the following individuals for their inspiration and advice: Deirdre Kelly, David Mayer, Ian Booth, John Buckles, Darius Mirza, Jean de Ville de Goyet, Patrick McKiernan, Gill Brook, and Chris Holden.

3. Aspects of Surgery

Paul W. Wales, BSc, MD, MSc, FRCSC

Short-bowel syndrome (SBS) is the spectrum of malabsorption that occurs after resection of a major portion of the small intestine for congenital or acquired lesions.[1,2] A useful definition is based on the need for intervention. Patients requiring total parenteral nutrition (TPN) support for more than 1 to 3 months after major resection can be defined as having SBS.[3] Other definitions are based on residual bowel length. For instance, small bowel resection greater than 75% of small bowel length is considered SBS.[1] Variation in the definition between institutions produces differences in outcome between published series. The Canadian Association of Paediatric Surgeons defines SBS as the need for TPN greater than 42 days after bowel resection or a residual small bowel length of less than 25% expected for gestational age.[4] This is the definition used at The Hospital for Sick Children in Toronto. Unfortunately, patient characteristics such as gestational age, region of bowel resected, functional capacity of the remaining intestine, and the presence or absence of the ileocecal valve all contribute to the difficulty in determining the critical length of bowel required to avoid SBS.[5]

The most common causes of pediatric SBS are neonatal conditions such as necrotizing enterocolitis, extensive aganglionosis, intestinal atresia, midgut volvulus, and abdominal wall defects.[3,6] In older children and teenagers, Crohn disease and trauma are more common causes.[7] Accurate estimates of incidence and outcome in children with SBS remain difficult owing to variation in the definition of SBS between institutions, difficulty of tertiary care referral centers to accurately determine their catchment population, and problems ensuring complete follow-up of the whole cohort. A recent population-based study at our institution determined the incidence of neonatal SBS to be 24.5 per 100,000 live births, with a much higher incidence in babies born before 37 weeks gestation compared with term newborns (353.7 in 100,000 live births vs 3.5 in 100,000 live births).[8]

The major features of SBS are dehydration secondary to diarrhea, malabsorption of macro- and micronutrients, malnutrition, and failure to thrive.[3,5] After intestinal resection, the residual small bowel undergoes intestinal *adaptation*, which is the gut's attempt to optimize its absorptive capacity. The adaptation process may take several months or years to complete. During that time, the infant is either partially or totally dependent on parenteral nutrition. A multitude of complications ensue with long-term hospitalization and prolonged parenteral nutrition, including central line complications, multiple systemic infections, cholestasis, liver failure, failure to thrive, and the resultant effects on family dynamics.[2,6]

The advances in medical management of SBS over the last 30 years, most importantly TPN, have led to improved survival.[9,10] Parenteral nutrition permits survival after massive small bowel resection and provides the patient with time and opportunity to achieve intestinal adaptation. Spontaneous adaptation occurs in approximately 75% of SBS patients and allows them to be weaned from TPN.[2] Reasons for continued TPN dependency include bowel dysmotility, bacterial overgrowth, insufficient adaptation, and very short bowel length. These patients may benefit from surgical procedures that improve intestinal function to optimize adaptation and increase the absorptive surface area.[11] This chapter summarizes the surgical techniques available to the surgeon who is treating this complicated group of patients.

ROLE OF SURGERY IN SBS

The surgeon has an important role in the natural history of all patients with SBS. The surgeon is present at the beginning of every case in which their perioperative and operative decisions have a direct impact on whether a patient will develop SBS. Often they are making the best of a poor situation. The surgeon is also intimately involved during the subsequent adaptation process to perform adjunctive operative procedures, as necessary, to optimize a patient's chance for TPN independence. Ultimately, if adaptation is insufficient and the patient develops end-stage liver disease, the surgeon will perform an intestinal or liver transplant.

Initial Resection

Primary prevention of SBS should be a high priority. Thompson outlined how it may be possible to avoid extensive bowel resection if surgeons intervene early in cases of intestinal ischemia, mesenteric emboli or clots, and complete bowel obstruction.[12] Intraoperative determination of intestinal viability and the use of second-look laparotomies can potentially preserve what looked like bowel of questionable viability. A conservative attitude regarding resection in Crohn disease and the use of strictureplasties may minimize the chance of SBS in these patients.

One of the most difficult intraoperative decisions for a surgeon to make when faced with a patient who requires massive intestinal resection is whether to proceed with a resection that will result in SBS. In general, we have a fairly aggressive approach to resection, but the overall mortality rate of SBS remains high. The wishes of the family and the existence of comorbidities such as prematurity, bronchopulmonary dysplasia, or other structural anom-

alies are all important considerations that will influence one's decision.[12,13]

Once the decision is made to proceed with massive bowel resection, the goal should be to preserve all bowel length that is possible, including the ileocecal valve. The use of internal stents for patients with multiple intestinal atresias or patchy necrotizing enterocolitis requiring multiple resections is helpful.[13] It is important to document the length of residual small and large bowel remaining with the patient. Stomas are frequently required because of intra-abdominal contamination, inflammation, or hemodynamic instability. Placing the end stoma beside the mucous fistula, at the same stoma site, is a simple way of making subsequent stoma closure more straightforward. Bowel continuity can be re-established without the need for a full laparotomy and lysis of adhesions. In my experience, patients tolerate this approach better and have faster resolution of their ileus. The early treatment of SBS is focused on the acute surgical emergency. Adjunctive SBS procedures should not be performed at the time of the initial resection. Intestinal adaptation will often be adequate enough to preclude the need for surgical therapy.[12]

Reoperation

During the adaptation phase, surgical intervention is reserved for the management of significant surgical complications or to provide central venous or enteral access (eg, gastrostomy) to allow adaptation to continue.[14]

It is difficult to know the precise point at which adjunctive surgical procedures should be performed in SBS patients. Patients who plateau and fail to make progress with TPN weaning should be considered for surgery. Also, patients who develop complications such as TPN cholestasis, recurrent line sepsis, or bacterial overgrowth may be candidates. Three factors guide the decision of which operation to perform: the underlying intestinal function, the length of the residual bowel, and the caliber of the intestinal remnant.[14]

Before surgery occurs, patients require a complete assessment of their general medical condition and comorbid diseases. It is important to know if the patient has end-stage liver disease because this would be a contraindication for surgery. A referral for intestinal and liver transplant may be more appropriate. All previous operative notes should be reviewed, and a small bowel follow-through should be obtained to assess motility, bowel length, and caliber.

At the time of the adjunctive surgical procedure, a liver biopsy should be performed to determine the extent of TPN cholestasis. Prophylactic cholecystectomy should also be considered at the time of reoperation. Patients with a history of ileal resection and long-term parenteral nutrition are at risk for cholelithiasis. Twenty percent of infants on long-term parenteral nutrition develop gallstones secondary to lack of enteral feeding and gallbladder stasis.[15] Patients with SBS are three times more likely to develop gallstones because the loss of bile salts from ileal resection permits cholesterol in bile to precipitate.[16] The incidence of complications from cholelithiasis is not known in children; however, it is probably prudent that patients with cholelithiasis at the time of reoperation have a cholecystectomy because it can usually be performed quickly and safely.[17]

The primary objective of surgery for SBS is to improve intestinal function, optimize bowel motility, and increase the mucosal absorptive surface area.

TECHNIQUES TO IMPROVE INTESTINAL FUNCTION

Lysis of Adhesions, Strictureplasty, or Segmental Intestinal Resection

Children with a history of gastrointestinal pathology are at risk of developing mechanical bowel obstruction. The etiology may be stenosis secondary to the late effects of bowel ischemia or inflammation, as seen in patients with necrotizing enterocolitis or Crohn disease. In addition, previous intra-abdominal surgery or inflammation produces adhesions that may be the source of obstruction. Bowel obstruction causes proximal bowel dilatation, dysmotility, and bacterial overgrowth. Dilated bowel from primary or secondary dysmotility conditions, such as adaptation with bacterial overgrowth, can be very difficult to distinguish from mechanically obstructed bowel with proximal dilatation. Mechanical obstruction may be corrected by lysis of adhesive bands, strictureplasty if bowel length is short, or segmental resection for patients with adequate bowel length.[18]

Re-establishing Intestinal Continuity

Diverting stomas are often necessary at the time of laparotomy for children suffering acute, life-threatening conditions. The presence of peritoneal contamination, extensive inflammation, hemodynamic instability, or other systemic factors that might affect anastomotic healing (eg, malnutrition or immunosuppression) often preclude the desire to perform a primary anastomosis.

There are several advantages to reversing stomas and re-establishing gastrointestinal continuity. The primary benefit of stoma closure is that it increases the mucosal surface area available for nutrient absorption. Nutrient absorption is improved because the longer intestinal length increases transit time and permits nutrients more time for contact with the absorptive mucosa. If the colon is present, the patient benefits because the colon is the major site of water reabsorption and therefore affects the volume of stool output. It also enhances carbohydrate absorption because bacteria ferment unabsorbed carbohydrates into short-chain fatty acids, acetate, butyrate, and proprionate, which are then absorbed by colonocytes. These substances are then used as caloric substrate. This salvage mechanism may provide up to 5 to 10% of calories.[16]

Diverted intestine undergoes mucosal atrophy; therefore, re-establishing intestinal continuity facilitates the adaptive response in the distal bowel.[19] Multiple mechanisms and mediators have been proposed for the adaptation response, but no single factor adequately explains all of the changes that occur in intestinal structure and function. There is a role for luminal nutrients, gastrointestinal secretions, and humoral factors, and delivery of these substances to the previously diverted segment enhances adaptation.[20]

The main disadvantage to stoma closure is diarrhea and the resulting perineal irritation. Elevated stool volume and frequency result from inadequate absorption in the proximal bowel but also from colonic mucosal inflammation caused by the irritating effects of bile acid delivery to the large bowel, producing secretory diarrhea and steatorrhea.[11] Usually, aggressive application of barrier products to the perineum can protect the skin, but it is important to begin applying these immediately after surgery because it can be difficult, and more painful for the patient, to treat a rash that is already well established.

Patients with a colon in continuity are at risk of calcium oxalate nephrolithiasis. Oxalate is absorbed because the delivery of bile acids to the colon prevents oxalate excretion in the stool. The circulating oxalate can then precipitate with calcium and cause renal calculi.[3]

Determining the optimal time for stoma closure can be difficult. These patients often have significant comorbid conditions in addition to their gastrointestinal disorders. Predicting which patients will tolerate stoma closure without significant diarrhea and perineal complications is often not possible. Even though high stoma output often initially gets converted to large stool volumes, most patients usually benefit from the longer intestinal surface area. The goal should be to reverse stomas early once the patient is deemed able to tolerate it from a technical and physiologic perspective. Maximizing the percentage of calories received from the enteral route helps decrease the risk of parenteral nutrition–associated cholestasis.[21] Experience from the Intestinal Care Center in Pittsburgh suggests that patients who have had more than 30% of their colon resected and who have stoma output totaling greater than 40 cc/kg/d are more likely to suffer significant perineal complications.[14]

TECHNIQUES TO IMPROVE INTESTINAL MOTILITY

Intestinal Tapering and Plication

An increase in intestinal caliber is the normal physiologic response to extensive bowel resection. Bowel dilatation slows intestinal transit and increases mucosal absorptive area. At a point, however, this normal adaptive mechanism becomes pathologic. The dilated segments become dysmotile, and fecal stasis, bacterial overgrowth, and malabsorption ensue. Oral antibiotic therapy can help suppress overgrowth, but some patients develop refractory bacterial overgrowth and require surgical intervention.

Dysmotile segments of bowel must be distinguished from mechanically obstructed bowel with proximal dilatation. Mechanical obstruction can be corrected by release of adhesive bands, strictureplasty, or resection of the obstructing segment. Functionally dysmotile segments should be streamlined by tapering or plication to improve peristalsis and decrease bacterial overgrowth. Streamlining has the advantage of preserving bowel length compared with resection of dilated segments.[18]

Tapering enteroplasty involves partial resection of the antimesenteric border of the dilated segment to reduce the diameter of the intestinal loop (Figure 40.3-1). The blood supply arising from the mesenteric side is not disturbed. The disadvantage is that some absorptive surface area is lost, which is already limited in these patients. There is also a risk of postoperative leak from the suture line, but this is not significant. To ensure an adequate and uniform lumen, an appropriately sized Foley catheter or chest tube can be inserted into the bowel lumen through a small enterotomy at the beginning of the dilated segment. It can be gently held in position along the mesenteric border of the bowel with a Babcock clamp, and then the excess bowel can be excised with a stapler or free hand.

Plication also streamlines the bowel, but no bowel wall is resected. The dilated bowel wall is inverted into the lumen, and the serosal surfaces are imbricated (Figure 40.3-2). Therefore, mucosal surface area for absorption is maintained, and motility is improved.[22] Unfortunately, the inverted bowel may cause bowel obstruction because it blocks the bowel lumen. Also, the suture line may fail, resulting in repeat dilatation and dysmotility.[11] The serosa can be removed along the antimesenteric bowel wall at the site of the imbrication in an attempt to prevent suture line failure.

Antiperistaltic Small Intestinal Segments

Reversed small bowel segments to slow intestinal transit and increase absorption have been used mostly in adults. A segment of small bowel is placed in the opposite direction of normal intestinal flow or peristalsis. The reversed peristalsis in the interposed segment slows the movement of intestinal content. The difficulty is determining how long the reversed segment should be because long segments can stop intestinal flow altogether, producing intestinal obstruction.

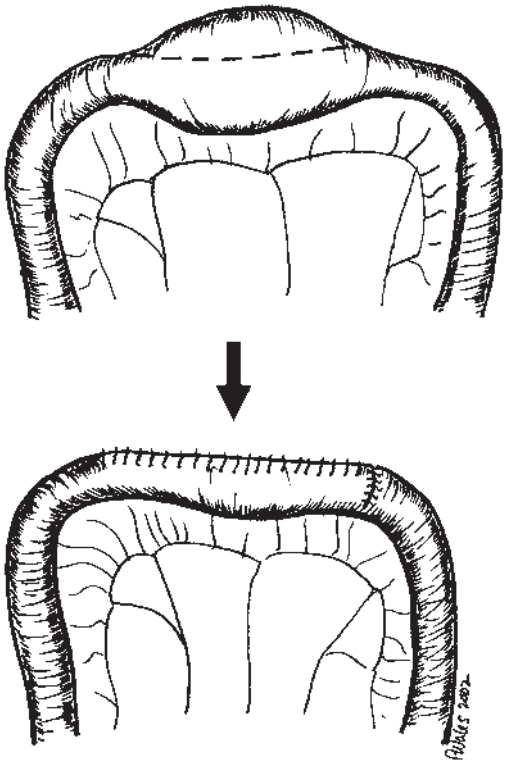

FIGURE 40.3-1 Tapering enteroplasty. The antimesenteric portion of the dilated segment of bowel is removed. A portion of the absorptive surface is lost.

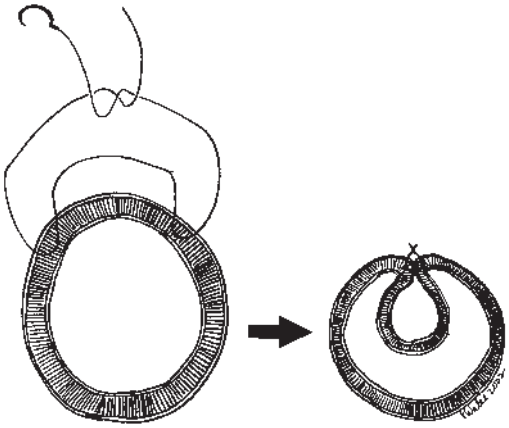

FIGURE 40.3-2 Intestinal plication. A portion of the dilated bowel wall is inverted into the bowel lumen and secured by seromuscular sutures.

Experience with reversed small bowel segments occurred in the 1970s when they were employed to slow peristalsis in patients with postvagotomy diarrhea.[23] The indication for reversed intestinal segments was expanded to include patients with SBS. In a canine model of beagle puppies with extensive small bowel resection, there was a short-term improvement in water, lipid, and nitrogen absorption.[24] Panis and colleagues described reversed small bowel segments in a case series of eight adult patients.[25] A median length of 12 cm was used for the reversed segment. Complications occurred in six of eight (75%) patients, and one patient died. Four patients (50%) weaned off parenteral nutrition, and the other four had decreased TPN requirements. In general, adult series have shown a favorable response to reversed segments in approximately 70% of patients, but the experience in children has shown a lack of sustained benefit.[23,26]

Neonates and infants are less favorable candidates for reversed small bowel segments because of their potential for intestinal growth (lengthening). Growth of a reversed segment may ultimately produce complete bowel obstruction.[26] In adults, the ideal length of the reversed segment is approximately 10 to 15 cm; in infants, it is 3 cm.[14] This procedure has limited use as a definitive procedure for patients with SBS.

Colonic Interposition

The frequency of colonic peristaltic contractions is lower than that in small bowel. Proximal placement of an isoperistaltic segment of colon between two ends of small bowel may prolong intestinal transit and permit more effective absorption of nutrients and electrolytes. Animal studies performed in the 1970s in both rats and canines were successful in showing delayed intestinal transit and improved growth.[27,28]

As with reversed small bowel segments, pediatric data show some favorable outcomes, with the ability to wean parenteral nutrition, but the results are variable.[29,30] The proposed advantage of isoperistaltic colonic interposition is fewer obstructive complications than witnessed in reversed small bowel segments, but the overall human experience is low.[23]

Creation of Intestinal Valves

The ileocecal valve has two functions. It slows transit of small bowel content into the colon and prevents reflux of colonic bacteria into the ileum. Colonic bacteria in the small bowel induce mucosal inflammation and malabsorption. Wilmore published his landmark article in 1972 in which he demonstrated the relationship between residual intestinal length, the presence or absence of the ileocecal valve and gut adaptation, and parenteral nutrition independence.[31] As a result, numerous procedures have been developed over the years to create intestinal valves that will slow intestinal transit and minimize colonic reflux in SBS patients. In most cases, the valve represents a short intussusception created by "telescoping" a proximal segment of bowel into the distal segment and suturing the seromuscular layers together (Figure 40.3-3).[32] Serosal stripping can be performed between the two walls of intestine being sutured to try to reduce the chance of valve failure.

An intestinal valve produces a partial obstruction with proximal dilatation of the small bowel. The partial obstruction increases absorption time, but, more importantly, it induces adaptation and dilatation that could permit a subsequent lengthening procedure. Georgeson and colleagues presented a series of six patients who received valve construction followed by an intestinal lengthening procedure 3 to 9 months later.[33] There were no complications associated with the valve. Three patients were weaned from parenteral nutrition. Other reported cases of intestinal valves in children have had mixed results.[11]

The major limitation is to determine the optimal valve length to slow intestinal transit without inadvertently causing a mechanical bowel obstruction. The variability between patients makes standard recommendations difficult. It has been reported that valve length in children should be less than 3 cm.[14] Creation of a valve requires approximately 8 cm of bowel; therefore, this procedure may not be feasible for many patients with SBS.[26]

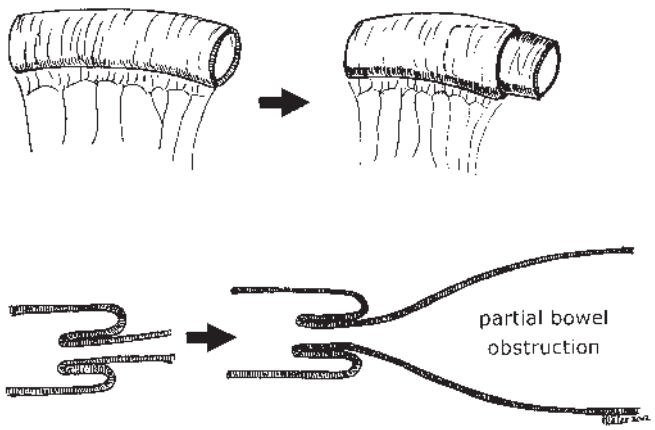

FIGURE 40.3-3 Creation of intestinal valves. A segment of bowel is telescoped into the distal bowel and secured with sutures. This will slow transit and induce a partial bowel obstruction. The proximal bowel dilates, and an intestinal lengthening procedure becomes possible.

Reversed Electrical Intestinal Pacing

Hyperperistalsis is common in SBS. The premise of reversed electrical intestinal pacing is based on the cardiology experience in which the heart is paced to treat arrhythmias. Overriding the intrinsic intestinal pacemaker could slow intestinal transit in SBS patients with hyperperistalsis to optimize water and nutrient absorption.

The normal intestinal pacemaker is located in the foregut within the duodenum. The electrical wave is propagated toward the ileum to generate peristalsis. Canine experiments have demonstrated better absorption of water and electrolytes, but manipulation of the duodenal pacemaker requires duodenal transsection.[34,35] Hence, no humans have received this approach because of the perceived high morbidity.

More recently, entrainment of intestinal slow waves in dogs has been achieved by Lin and colleagues.[36] Four pairs of intraluminal intestinal electrodes placed within the jejunum permitted intestinal pacing by entraining the intestinal slow waves. This treatment has not been evaluated in human trials, but it may be helpful in both SBS patients and in patients with primary motility disorders.

TECHNIQUES TO INCREASE ABSORPTIVE SURFACE AREA

As previously mentioned, the underlying problem in SBS is inadequate mucosal surface area for absorption. In addition, the adaptive response or partial mechanical obstruction from strictures produces proximal bowel dilatation, stasis, and bacterial overgrowth. The common thread between all intestinal lengthening procedures is the exploitation of the dilated segment of bowel to gain gut length. More importantly, however, the bowel is tapered, which improves peristalsis and prevents the sequelae of recurrent bacterial overgrowth.[26]

Longitudinal Intestinal Lengthening Procedure (Bianchi)

Bianchi first described the longitudinal intestinal lengthening procedure (LILP) in 1980 using a porcine model.[37] The procedure is based on the small bowel's dual blood supply that enters the bowel wall within the two layers of the mesentery. The bifurcated blood supply enters each hemicircumference of the bowel wall. The two leaves of the mesentery that contain the blood vessels are separated on the mesenteric surface of the bowel. The bowel is divided longitudinally, between the two layers, so that each parallel lumen has its own single source of blood supply.[26] The two newly created bowel segments are then anastomosed end to end, creating one intestinal segment that is twice as long and half the diameter of the original (Figure 40.3-4). The absorptive surface area may increase as the newly created loops slowly dilate over time. LILP is indicated for TPN-dependent patients with very short and dilated bowel.

Bianchi reported outcome in 20 patients who received a LILP.[38] At 6 years follow-up, 9 patients were alive. Seven of nine survivors were independent of parenteral nutrition. Survival was influenced by a small bowel length greater than 40 cm and no liver dysfunction at the time of the procedure. Weber reported 16 children who received a Bianchi procedure.[39] Eighty-eight percent were TPN independent; however, some of the children in that series had good residual small bowel length to begin with; therefore, it is possible that some of the patients would have adapted spontaneously and weaned off TPN without a lengthening procedure. Thirty-one percent required reoperation for complications. Thompson and colleagues published a series on long-term outcome after LILP in 16 patients with residual small bowel lengths ranging from 23 to 120 cm. Forty percent of the patients were independent of parenteral nutrition at both 1 and 5 years postsurgery.[40]

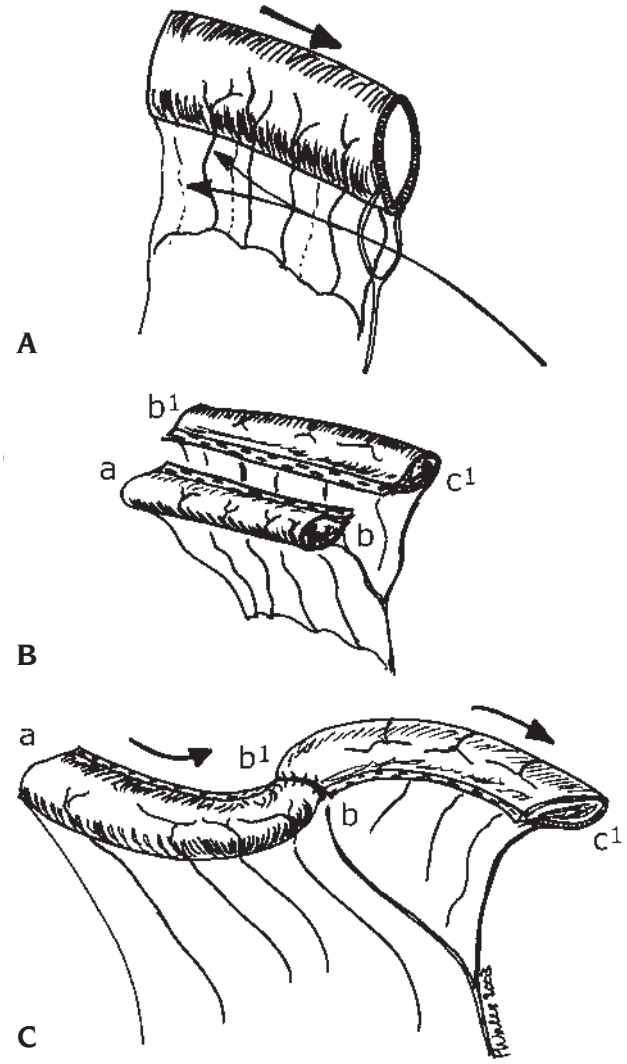

FIGURE 40.3-4 *A*, The mesenteric blood vessels within the two leaves of the mesentery are separated under the dilated bowel segment. *B*, The dilated bowel is divided longitudinally within the mesenteric leaves to create two parallel loops of bowel half the diameter of the original loop. *C*, The two bowel segments are anastomosed end to end to create a bowel segment double the length of the original. The bowel mesentery needs to be amenable to mobilization for this to be feasible. The bowel at "a" is the most proximal portion and the bowel at "c" is the most distal. The end of the reduced loop at "b1" is anastomosed to the proximal end of the other loop at "b2" to create an isoperistaltic segment of tapered and lengthened bowel.

Complications from this procedure include adhesive small bowel obstruction, anastomotic strictures or leak, and recurrent bowel dilatation. Patients who develop recurrent dilatation are candidates for the Kimura procedure or preferably the serial transverse enteroplasty (STEP).[26,41] The Bianchi procedure requires mobility in the mesentery to be able to anastomose the two tapered segments end to end. If a patient has a short, tethered, or thickened mesentery, a Bianchi procedure may not be technically feasible.[40,42]

Kimura Procedure (Isolated Bowel Segments)

The Kimura procedure is an alternative bowel-lengthening technique that may be used when the mesentery is very short, tethered, or absent.[43] It is a two-staged approach that consists of the initial coaptation of the antimesenteric surface of a dilated bowel segment to host organs (abdominal wall or liver) and then secondary longitudinal division of the bowel to create two bowel loops, one from the mesenteric half and one from the antimesenteric half.[42]

The serosal surface of the antimesenteric bowel wall is deseromyotomized to expose the submucosa. It is then sutured to the abdominal wall or liver that has had its peritoneum removed. Over a period of months, collateral blood supply develops from the host organs into the antimesenteric surface of the bowel. The bowel is then amenable to horizontal division into two parallel structures. The two bowel segments are then anastomosed end to end, creating a lengthened, tapered intestinal segment analogous to the Bianchi procedure.

No large reports of the Kimura procedure in humans have been published. This operation is not considered a first-line procedure for bowel lengthening. One major concern with this procedure is the limited access to the abdominal cavity owing to the nonanatomic placement of the bowel. Repeat laparotomy is frequent in this patient population; therefore, bowel parasitized to the abdominal wall makes these operations more difficult. Another criticism of the Kimura procedure is the lack of nutrient blood flow through the portal system, but in patients who have received this procedure, no problem has been noted.

Serial Transverse Enteroplasty

The STEP has been the most exciting addition to the surgical management of SBS in several years. The results from porcine experiments were first published in March 2003, and the first case report in a human was published in June 2003.[41,44] The STEP procedure satisfies the objectives of other bowel-lengthening procedures such as lengthening and tapering, but it has the advantages of being easy to perform and not requiring bowel anastomoses; it can theoretically more than double the intestinal length and can be applied as a primary or secondary procedure, such as after a Bianchi operation.

The procedure is performed by first dividing all of the abdominal adhesions to have full bowel mobility (Figure 40.3-5). The antimesenteric border of the dilated bowel is marked with a surgical pen to prevent twisting of the bowel during placement of the surgical stapler (Figure 40.3-6). A reusable gastrointestinal anastomotic (GIA) stapler is applied sequentially, from alternating and opposite directions through small mesenteric windows at the site of each staple line. The stapler is placed from the 90° and 270° positions (with 0° being the mesenteric border). The sequential stapler firings create a zigzag-like channel (Figure 40.3-7).[41] The diameter of the channel is determined by the surgeon and is commonly approximately 2 cm. The presence of normal caliber bowel can be used as an internal guide to channel size.

The blood supply to the intestine enters from the mesenteric side and travels along the bowel wall perpendicular to the long axis of the intestine; therefore, if the staple lines remain perpendicular to the long axis, the bowel segments should remain well vascularized.[41] As opposed to the Bianchi procedure, the mesentery is never in danger, and the bowel is never opened.

The Bianchi and Kimura procedures reduce the caliber of the bowel by 50%. With the STEP procedure, the extent of the tapering is dependent on the surgeon. The potential increase in bowel length depends on the extent of the bowel dilatation and the chosen size of the channel created. If the bowel segment is massively dilated, one could theoretically more than double the segmental length.[41]

The preliminary reports by Kim and colleagues establish the feasibility of the STEP procedure for bowel lengthening.[41,44] It could potentially be applied to other situations for which intestinal tapering is desired, but the loss of mucosal surface area should be avoided, such as in small bowel atresias with a very dilated proximal loop. The proximal end usually needs to be tapered or partially resected to deal with the size discrepancy between the proximal and distal bowel ends that are to be anastomosed. The STEP procedure deals with the size discrepancy and preserves surface area.

As with any new treatment modality, enthusiasm needs to be controlled until longer-term patient outcomes become known. We have performed two STEP procedures to date at The Hospital for Sick Children. Both children are early in their postoperative course. The first child was born at 30 weeks and suffered necrotizing enterocolitis requiring a bowel resection. She had recurrent episodes of bacte-

FIGURE 40.3-5 Patient with short-bowel syndrome and recurrent bacterial overgrowth. Note the very dilated loop of bowel that will be tapered and lengthened.

FIGURE 40.3-6 Serial transverse enteroplasty: marking of the antimesenteric border of dilated bowel with a surgical pen. This helps prevent twisting of bowel during application of stapler.

rial overgrowth from a very dilated intestinal loop and was suffering from TPN cholestasis. She underwent a STEP procedure at 12 months corrected age. She had a focally dilated loop of small bowel that was lengthened 60% from 25 to 41 cm. In the 2 months since the surgery, her stool consistency has changed from that of water to more particulate, and she has started to tolerate an increase in enteral feed volume and the introduction of a small amount of carbohydrate into her gut. To date, she has not had a recurrent episode of bacterial overgrowth.

The second patient was an ex-26-week gestational age male with recurrent necrotizing enterocolitis. He had carbohydrate intolerance and refractory bacterial overgrowth. He underwent a STEP procedure at 16 months corrected age and had his small bowel lengthened and tapered from 117 to 169 cm. He developed a gastrointestinal bleed from one of the staple lines postoperatively and subsequently an anastomotic leak from the terminal ileal staple line on the fifth postoperative day. A second laparotomy was performed to repair the bowel and create a diverting distal ileostomy. He is presently receiving 70% of his calories enterally and has not had another episode of sepsis to date.

Sequential Intestinal Lengthening Procedures

In 1994, Georgeson and colleagues reported their approach to nine infants and children with refractory SBS.[33] The authors employed a combination of several short-bowel operations described above, applied sequentially in patients with intestinal failure. For six patients who had a remnant bowel of normal caliber, an intestinal valve was created to induce partial bowel obstruction and proximal dilatation. After several months, a Bianchi procedure was performed. One patient had a Bianchi procedure initially, followed by a Kimura procedure for recurrent bowel dilatation. The outcome in the seven survivors was good after a range of 5 to 49 months of follow-up. Patients were tolerating a higher percentage of their calories enterally, and two patients were completely weaned from parenteral nutrition. This publication was a significant contribution because it emphasized the need for perseverance, flexibility, and creative solutions to this very complicated population of patients.

FUTURE CONSIDERATIONS

Tissue-engineered intestine is on the horizon as a possible treatment for SBS. Rat experiments have been performed and show promise.[45,46] A microporous biodegradable polymer is implanted with intestinal epithelial units for several weeks. The polymer is then implanted into adult rats that have received a 75% small bowel resection. The polymer is subsequently anastomosed to the native gut. The tissue-engineered intestine maintained patency for up to 36 weeks and was lined by columnar epithelium and goblet and Paneth cells; however, the unit's ability to absorb water and nutrients was poor.

CONCLUSIONS

SBS is a complex condition with significant morbidity and mortality. These patients require the expertise of a multidisciplinary team. The advent of TPN provided these acutely ill patients with a chance at survival, but it is also the cause of life-threatening complications. Fortunately, most children with SBS will adapt spontaneously over time. Children who remain TPN dependent are candidates for one of several adjunctive operations that promote adaptation by optimizing intestinal function, motility, and surface area. The choice of procedure must be individualized. Patients with a short and dilated bowel should receive an intestinal lengthening and tapering procedure such as the Bianchi or STEP. If the bowel is not dilated, then a colonic interposition is an option. Alternatively, creation of an intestinal valve to induce dilatation followed by a lengthening procedure could be beneficial. If bowel length is adequate but the bowel is dilated, then a simple tapering enteroplasty or plication would suffice.

Objective assessments of outcome from the various surgical techniques are lacking because of the relatively small number of patients at individual institutions and the lack of a consistent definition of SBS. All of these procedures, however, do provide an option that is of less magnitude than intestinal transplant.

FIGURE 40.3-7 Serial transverse enteroplasty. Zigzag pattern of bowel created after sequential and opposite firings of a surgical stapler across the dilated bowel loop. The channel size is determined by the surgeon. The normal loops of bowel can be used as an internal guide. A gastrointestinal contrast study is performed on the seventh postoperative day prior to initiation of enteral feeds.

4. Outcomes

Stuart S. Kaufman, MD
Thomas M. Fishbein, MD

Intestinal failure designates a state of intestinal tract function that is inadequate to fulfill the nutrient and fluid requirements of the body.[1] In children, intestinal failure often begins in the neonatal period. Implicit in the concept of intestinal failure is a prolonged and potentially permanent requirement for parenteral nutrition (PN). The outcome of intestinal failure is judged in two related ways. The first outcome measure is *recovery*. Recovery is generally synonymous with the ending of PN, although special enteral feeding techniques and nutrient supplements may remain necessary in individual patients. The second outcome measure is patient *survival*, particularly survival on PN.

Intestinal failure has two fundamental causes. Most commonly, intestinal failure results from anatomic short-bowel syndrome (see previous chapters). Second, intestinal failure may result from a critical loss of intestinal function in the absence of significant reduction in intestinal length. The distinction is somewhat artificial because anatomically short bowel is often dysfunctional. Intestinal failure from short-bowel syndrome is temporary in the majority of affected pediatric patients, whereas functional intestinal failure usually mandates permanent PN. In light of this difference, anatomic failure and functional intestinal failure are considered separately.

DURATION OF PN IN PATIENTS WITH ANATOMIC SHORT-BOWEL SYNDROME

The body undergoes physiologic changes to compensate for or adapt to intestinal loss. Adaptation may take the form of axial (longitudinal) intestinal growth, augmented colonic nutrient and fluid absorption, and possibly reduced metabolic expenditures. The magnitude and timeframe over which these changes occur have not been established with certainty in humans,[2] but they may eventually permit discontinuation of PN, especially in the growing child. In adults, PN may be successfully discontinued when as little as 25 to 35% of enteral calories are assimilated.[3,4] In children, tolerance of 50% assimilation of enteral calories is probably a more realistic requirement for ending PN, given the increased nutritional demands of growth and development. The corollary is that caloric intake that is 100% or more above the basal metabolic rate may be required for the patient to remain off PN.[3] Diarrhea may limit the ability to deliver this quantity of calories to a short gut. In most series, the average age at which PN that was started in infancy can be ended is around 18 months.[2,3,5,6] A need for PN beyond age 3 to 5 years in patients with neonatal short bowel predicts lifelong therapy.[6–8]

Length of Remnant Small Bowel

The most important determinant of PN duration in individual patients is postresection small-bowel length. A period of PN dependency is expected when more than 75% of the small bowel has been removed.[9–11] As small-bowel length approximates about 250 cm in the full-term newborn infant, prolonged PN is likely when no more than 60 to 70 cm of small bowel remains after resection surgery. Infants with 40 cm of small bowel have a 50% probability of coming off PN.[7] This percentage may be conservative because some reports include an early PN experience with death rates that are high by current standards. Children with at least 70 to 80 cm of small bowel remnant now have a 90 to 100% probability of ending PN.[6,12] It is generally thought that jejunal resection is less likely to require permanent PN than an equivalent magnitude of ileal resection.[13] However, anatomic detail regarding how much residual bowel is jejunum or ileum is lacking in most pediatric literature on this topic. Slower peristalsis, active bile salt and vitamin B_{12} absorption, and intrinsically greater ability of ileal enterocytes to proliferate and thereby increase nutrient uptake per unit of bowel length may be responsible for the greater adaptive capacity of the ileum.[10,11]

Colon and Ileocecal Valve

The colon is the key modifier of small intestinal length in determining PN dependence in short-bowel syndrome.[14] An intact colon, which implies salvage of the ileocecal valve (ICV) and some ileum, effectively doubles de facto digestive capacity in the pediatric short-bowel syndrome patient. In older patients, an intact colon may provide the absorptive capacity of as much as 80 cm of small bowel.[15] Thus, ending PN is commonly accomplished in pediatric patients who have 20 to 25 cm of small bowel[16–18] and may even be possible in some infants with as little as 10 to 15 cm of small bowel and an intact colon with ICV.[19]

Less clear is the impact of partial colon loss, including loss of the ICV, on the ability to end PN. Most[6,8,12,20] but not all[7,21,22] pediatric outcome studies fail to demonstrate an independent effect of the ICV on the duration of PN in those able to end therapy. Similarly, it has never been demonstrated that a limited colon resection is less deleterious to prognosis than a relatively long resection in pediatric patients,[8] although adult studies demonstrate that retention of half of the colon is functionally equivalent to about

50 cm of small bowel.[14] Most pediatric patients remaining on PN indefinitely have lost the ICV and some colon.

Pediatric patients uncommonly have a terminal enterostomy placed with the expectation that it is to be permanent. Rather, anastomosis to an intact or partially resected colon is the aim, given the potential for improved nutrient and fluid absorption following re-establishment of enterocolonic continuity.[23] Infants with remnant small bowel and/or a colon so short as to preclude anastomosis are expected to remain on PN indefinitely.[24] Patients with total colon Hirschsprung disease may undergo ileoanal anastomosis when attainment of continence postoperatively is realistic.[25] Relatively little information is available concerning the amount of remnant small bowel required to end PN when aganglionosis extends to the small bowel. In one study, resection of less than 50 cm of aganglionic ileum mandated PN for an average of 10 months (up to maximum of 35 months). Removal of greater than 50 cm of aganglionic bowel, considered equivalent to retention of up to about 100 cm of ganglionic bowel, required indefinite PN (ie, for more than 5 years) in 80% of affected patients.[26] Thus, patients with anatomic short bowel plus additional underlying functional intestinal impairments generally require longer remnant small-bowel length to obtain PN independence than do short-gut syndrome patients without functional impairments.

Age at Time of Intestinal Loss

The small bowel lengthens roughly twofold in the second half of gestation.[9] Numerous studies have demonstrated that prematurity favorably influences the ability to wean PN, presumably because the small bowel of premature infants has inherently greater growth potential than that of the full-term infant.[8,18,27] Conversely, studies of adult patients imply little or no intestinal lengthening following major resection,[15] which also probably applies to older children and adolescents because normal intestinal growth slows considerably by 3 to 4 years after birth.[6] Although PN has been successfully ended in children after 7 years of therapy,[7] the duration of PN in adults lasting more than 2 years predicts a 94% probability of lifelong PN.[28] Patients who develop short-bowel syndrome after infancy require approximately twice the length of small bowel than infants to wean from PN for any given magnitude of colon loss. Thus, by adulthood, 100 to 115 cm of small bowel ending as a jejunostomy is needed to obtain a 75 to 100% probability of ending PN. In this age group, possession of 60 to 65 cm of jejunum is usually required to permit ending of PN when anastomosed directly to partially resected colon, whereas only 30 to 35 cm of small bowel permits ending of PN when the colon and ICV are intact.[15,28]

Etiology of Short-Bowel Syndrome

Most studies fail to identify a definite effect of short-bowel etiology on the duration of PN.[8,12,22] However, there are some indications that necrotizing enterocolitis may give affected infants a PN-weaning advantage over those with congenital anomalies, possibly because of coassociated prematurity.[6,29] Disorders such as gastroschisis or proximal jejunal atresia may yield a less favorable prognosis than necrotizing enterocolitis because remnant small bowel may be relatively ischemic and atrophic, with resultant poor function and growth potential.[30] Pediatric recipients of an intestinal transplant appear to include a disproportionate number of patients with obstruction in utero.[31] An analogous example is Hirschsprung disease. Patients with this disorder who have lost the entire colon and some small bowel appear to be more likely to remain PN dependent than patients with other diagnoses who have comparable remnant small-bowel length and a terminal enterostomy.[26] Defective motility of remnant bowel in Hirschsprung disease may be responsible for this phenomenon. Similarly, infants with cystic fibrosis and short-bowel syndrome owing to meconium ileus may have a lesser probability of ending PN because of concurrent pancreatic deficiency, hepatobiliary disease, defective enterocyte transport, and increased caloric requirements.[32]

Ability to Resume Enteral Feeding after Resection

Studies consistently show that the sooner enteral feeding can be tolerated after a major neonatal resection, the greater (and earlier) the ultimate probability of ending PN.[12] Failure to tolerate enteral feeds in a nutritionally significant quantity by 12 weeks of age after neonatal resection portends an especially poor prognosis for achieving eventual independence from PN.[6] In contrast, infants with only 25 cm of small bowel who tolerate 50% of total delivered calories via the gastrointestinal tract by age 12 weeks have a 70 to 75% chance of ending PN. Presumably, early ability to establish (or re-establish) enteral nutrition is a surrogate marker for the overall quality of remnant bowel.

Managing Ongoing Complications of Short-Bowel Syndrome

Prognostic factors that are apparent at the onset of short-bowel syndrome are modified by subsequent clinical events. In short-bowel syndrome beginning in infancy, there are indications that amino acid–based formulas are tolerated better and permit faster weaning of PN than hydrolysate or intact protein formulas.[12] Similarly, use of breast milk appears to confer a weaning advantage to the PN-dependent infant. However, in adult patients with short-bowel syndrome, intact protein-based diets are equivalent to those with modified nitrogen sources.[11] The applicability of this information to children beyond the infant age range is unclear.

In younger patients, susceptibility to protein hypersensitivity may explain the superior performance of amino acid formulas. Protein hypersensitivity may be one of several factors that influence the tendency of pediatric patients to develop an active, and occasionally eosinophilic, enterocolitis.[8,33] Enteritis associated with short-bowel syndrome delays ending of PN up to 2 years compared with children without significant inflammation when gut anatomy is otherwise favorable for weaning.[8] Bacterial overgrowth may contribute significantly to mucosal inflammation in these patients.

The propensity for the short bowel to increase in diameter, in addition to length, over time contributes to ineffective peristalsis, stasis of intestinal succus, and secondary bacterial overgrowth. Reconstructive operations that taper dilated intestinal segments are intended to improve peristaltic efficiency and thereby improve feeding tolerance and hasten weaning of PN. When dilatation is severe enough, operative tapering may be combined with lengthening simultaneously to reduce the diameter of the affected segment by half while doubling its length. Numerous reports indicate that intestinal lengthening improves enteral feeding tolerance and permits ending of PN in some patients within 4 to 6 months after surgery.[34,35] Careful patient selection is important because the operation appears primarily to benefit patients beyond infancy who tolerate some enteral feeding and have mild or no cholestasis.[36,37]

PN-Associated Cholestasis

Premature infants receiving PN for intestinal failure are thought to be more likely to develop cholestasis than older children or adults,[38] although this claim has been disputed.[39,40] Mild and transient cholestasis has not been shown to prolong PN therapy in pediatric patients with short-bowel syndrome.[8,41] Cholestasis usually remits as PN is progressively reduced and then discontinued.[38,39] When sufficiently severe enough to produce portal hypertension, cholestasis slows the transition from PN to enteral feeding, assuming that patients do not succumb to complications of liver failure.[42] Deleterious effects on bowel motility and promotion of bacterial overgrowth are possible explanations.[43]

Factors that Do Not Predict Duration of PN in Pediatric Short-Bowel Syndrome

A high frequency of catheter-associated sepsis does not delay eventual ending of PN in those patients able to survive recurrent infection.[8,12] Furthermore, factors that might contribute to an unusually high frequency of catheter-related complications in home PN patients, such as the level of parental education and socioeconomic status, have also been shown not to affect the duration of PN.[8]

SURVIVAL WITH SHORT-BOWEL SYNDROME

The survival of pediatric patients who have received PN for short-bowel syndrome is about 85 to 90%, reflecting the high rate of adaptation to total enteral nutrition.[6,44] Survival of adults with short bowel appears inferior; about 20 to 40% are dead after 4 to 5 years of PN.[28,45] Patients with intestinal failure who are destined to die while receiving PN should be considered for intestinal transplant, either with or without concurrent transplant of other failing organs, most notably the liver.[46]

In adult patients with short-bowel syndrome, reduced survival reflects the causes of intestinal failure in this age group, rehabilitation from which is unlikely, including extensive intestinal infarction, inflammatory bowel disease, and radiation enteritis.[28] Furthermore, other systemic disorders, particularly vascular diseases, are important sources of mortality. Conversely, superior survival in children likely accrues to the disproportionate representation of young infants with marked intestinal growth potential who are destined *not* to require PN indefinitely. Nonintestinal comorbidities are typically absent in these patients, extremely premature infants with necrotizing enterocolitis being a key exception.[20,47]

When all infants diagnosed with short-bowel syndrome are considered, about 70 to 80% are eventually able to end PN therapy, meaning that 20 to 30% of pediatric patients with short-bowel syndrome require PN indefinitely.[6–8,12] Although death is uncommon in the entire cohort of pediatric patients who have experienced intestinal failure, about half of all pediatric patients who are destined to remain on PN indefinitely do succumb to complications directly associated with short-bowel syndrome or its treatment. The probability of death on PN is not a simple function of cumulative time on therapy.[27,39] The median age of death on PN, which resulted mainly from liver failure, in three recent studies was only 19 months,[6,8,19] which is similar to the duration of PN for all pediatric patients successfully ending this therapy.[8,12,22]

Death from Sepsis

During the first decade of PN therapy, the 1970s, sepsis was probably the most common cause of demise, sources of which included contamination of PN delivery systems.[7,48,49] Additional deaths accrued to metabolic abnormalities associated with PN and noninfective catheter complications that are uncommon at present.[50] Although a high frequency of infection has not been demonstrated statistically to delay the ending of PN, patients who die on PN also have the highest rates of infection.[44] Undoubtedly, these deaths included some patients who would have ended PN had fatal sepsis not supervened. Improved management of PN delivery, including central venous catheters and catheter-related sepsis, has contributed to the reduction in mortality unrelated to liver disease, as has the subsequent shift from hospital-based to home-based care.[51] Whether recurring sepsis is an independent risk factor for death or is just a marker of unusually severe and complex intestinal disease is not established.[48]

Death from Liver Failure

Currently, mortality from short-bowel syndrome in children results primarily from progressive PN-associated liver disease. Consequently, the majority of intestinal transplants in children are performed with a simultaneous liver transplant to forestall impending demise from liver failure and its complications.[31,46] Historically, the death rates of pediatric patients with short-bowel syndrome caused by liver failure have ranged from about 33 to 66%.[6,12,52]

The risk of fatal PN-associated liver disease in patients receiving indefinite PN is predictable based on factors that are often apparent at the time PN is initiated. Aggressive liver disease is not a function of duration of PN therapy, onset of which most often occurs comparatively early in the course of PN. In infants, hyperbilirubinemia often presents after an initial septic episode and gradually worsens over the next 9 to 24 months.[8,39,53,54] Plasma bilirubin greater

than about 10 mg/dL in this setting is particularly ominous and has been associated with death within 6 months.[55] In older patients, hyperbilirubinemia may appear after a few months to a decade or more after the start of treatment.[56–58] The probability of advanced disease is 50% after 6 years of PN in adults, and once jaundice supervenes, death comes quickly, with an average survival of only about 1 year.[57,58] In older PN-dependent patients, reported death rates directly attributable to liver failure vary from 7 to 22%.[56–58] The short interval between the onset of significant liver disease and the progression to fatal liver failure necessitates rapid consideration of intestinal transplant when liver disease becomes apparent. If performed early, cholestasis resolves following isolated intestinal transplant, obviating the need for simultaneous transplant of the liver.[59,60] The clinical risk factors for advanced liver disease follow.

Extreme Short Bowel. Patients receiving PN therapy that is predicted to be permanent based on unfavorable anatomy are at high risk of developing fatal liver disease. Pediatric patients who are able to wean from PN rarely are left with end-stage PN-associated liver disease.[61] In adults and presumably older children, predictors have included small bowel length less than 50 cm[56] and loss of all small bowel distal to the ligament of Treitz.[58] In infants with PN dependence dating to the neonatal period, most succumbing to liver failure have a small bowel length of no more than 35 cm.[8,39] Termination of small bowel as a stoma (ie, absence of enterocolonic continuity) may place pediatric patients at further risk.[12]

Sepsis and the Systemic Inflammatory Response. Infants with fatal liver failure have an increased frequency of confirmed early bacterial or fungal sepsis in association with bowel resection, on average within 30 days of birth.[39] The propensity for sepsis to be associated with liver disease is not surprising because the systemic inflammatory response is inherently prone to produce cholestasis.[57,62] Bacteria and their by-products from the short gut have been hypothesized to be an important source of liver injury.[34,63] The distinction between death from sepsis and death from liver failure is blurred by the fact that liver failure begets an increased vulnerability to sepsis, which is progressively likely to be fatal as liver disease worsens.[58,53]

Lack of Early Enteral Feeding. Tolerance of little if any enteral nutrition after major bowel resection is another risk factor for fatal PN-associated liver disease.[39] It is unclear whether a lack of enteral feeding itself represents the risk or whether delayed feeding reflects systemic sepsis and possibly intra-abdominal infection associated with the original indication for surgery.[64]

PN Quantity and Composition. Although total parenteral calorie intake greater than 70 to 80% of the calculated energy requirement is associated with an increased propensity for liver disease, an effect of PN calories independent of gut loss has not been shown.[65] In contrast, provision of greater than 1 g/kg/d of intravenous emulsified lipid is associated with fatal liver disease.[56] Although the effect may reflect direct hepatotoxicity of components in lipid emulsion,[66] extra lipid may also provide substrate to fuel the systemic inflammatory response and its deleterious effect on the liver.[67]

Death from Loss of Central Venous Access

It is axiomatic that relentless thrombotic occlusion of all sites of venous access will ultimately be fatal to those who depend on PN for survival.[68,69] Precise data regarding the incidence of death of pediatric patients with intestinal failure and this complication are lacking. The relative frequency of impending total loss of venous access may be inferred from the number of recipients of an isolated intestinal transplant (as opposed to a combined liver and intestinal or multivisceral graft), which amounts to 35 to 40% of the total.[31] This percentage is undoubtedly an overestimate of the number of patients with loss of access because early, reversible liver damage and recurrent, life-threatening, catheter-associated sepsis are also indications for isolated intestinal transplant.[46] Coincident congenital thrombophilic syndromes probably predispose the patient to catheter-associated vein occlusion.[70]

OUTCOME OF FUNCTIONAL INTESTINAL FAILURE

Functional intestinal failure is rare in comparison with anatomic short-bowel syndrome. There are two forms of functional intestinal failure: the congenital enteropathies and the pseudo-obstruction syndromes.

Congenital Enteropathy

As a group, these disorders preclude meaningful assimilation of calories and fluid because of the combination of severe malabsorption and secretory diarrhea.

Microvillus inclusion disease and tufting enteropathy are prototypes. Abnormalities of apical plasma membrane protein trafficking appear to cause microvillus inclusion disease,[71] whereas abnormal basement membrane proteins are present in tufting enteropathy in association with crowding of surface enterocytes.[72] These disorders generally present soon after birth.[73,74] Affected patients tolerate little or no enteral feeding. No treatments including anti-inflammatory agents or growth factors have proven beneficial. Early onset of progressive PN-associated liver failure is common and, combined with recurring sepsis, makes intestinal transplant the only viable option when present.[75] In the absence of liver disease or loss of venous access, PN may be continued indefinitely. There exist only rare reports of spontaneous improvement that permits ending of PN support.[76]

Congenital deficiency of mitochondrial respiratory chain enzymes resulting in defective cellular energy production represents a second cause of intestinal failure associated with intractable diarrhea.[77,78] Intestinal biopsies demonstrate villous atrophy. Age at onset is variable, frequently between infancy and adolescence. Multiorgan involvement is the rule, eventually affecting the liver, skeletal musculature, and central nervous system in vari-

ous combinations. Death at an early age is typical and is often caused by failure of other affected organ systems rather than supportive PN therapy.

Pseudo-obstruction

The second form of functional intestinal failure is that resulting from profoundly defective intestinal motility (ie, intestinal pseudo-obstruction). Pseudo-obstruction may result from various defects in visceral smooth muscle (ie, myopathic pseudo-obstruction) or from abnormalities of the enteric nervous system (ie, neuropathic pseudo-obstruction). One mitochondrial disease variant, the mitochondrial neurogastrointestinal encephalomyopathy syndrome (MNGIE), presents primarily with dysmotility rather than intractable diarrhea in association with combined neuromuscular dysfunction.[78,79] In contrast to MNGIE, in which extraintestinal neuromuscular involvement is prominent and familial with autosomal recessive inheritance, most pseudo-obstruction syndromes in childhood are sporadic and affect only the gastrointestinal and genitourinary tracts.[80]

Pseudo-obstruction syndromes in childhood take a more variable clinical course than the primary disorders of enterocyte function such as microvillus inclusion disease. Effective peristalsis may resume transiently, allowing for periodic interruption of PN.[81] Regions of the gastrointestinal tract may be differentially affected, such that palliation can be obtained with decompressing enterostomies and colostomies. The urinary tract is involved in about 85% of patients with myopathic pseudo-obstruction but only 10 to 15% of patients with neuropathic pseudo-obstruction, resulting in urinary bladder, ureteral, and pyelocalyceal dilatation; hydronephrosis; urinary stasis; and renal insufficiency.[80]

The prognosis of intestinal pseudo-obstruction in childhood is determined by the severity, the key criterion of which is the need for PN. About 15 to 40% of patients require total PN, and an additional 30% require partial PN.[82,83] Only 50% survival through childhood can be anticipated if continuous PN is needed.[80] Thus, PN-dependent pseudo-obstruction appears to carry a prognosis similar to extreme short-bowel syndrome in children. In contradistinction, studies in adults consistently demonstrate reduced survival of PN-dependent patients with motility disorders compared with those with nonmalignant short-bowel syndrome.[45,84]

Death largely results from septic complications of chronic venous catheterization or PN-associated liver disease. Patients with myopathic pseudo-obstruction appear to have more consistently refractory ileus and earlier and greater PN requirements, resulting in correspondingly higher mortality.[83]

CONCLUSION

The outcome of intestinal failure is good in children, reflecting the transient nature of PN dependence in the majority, most of whom have short-bowel syndrome. An indefinite need for PN is associated with a guarded prognosis, which reflects the severity of disease that leads to PN rather than PN itself. Most children who die as a consequence of intestinal failure, probably around 10% who have carried this diagnosis, will succumb owing to PN-associated liver failure and its complications. Interventions that facilitate the ending of PN and/or reversal of developing or impending liver failure, including intestinal transplant, promote survival.

CHAPTER 41

INFLAMMATORY BOWEL DISEASE

1. *Crohn Disease*

Anne M. Griffiths, MD, FRCPC
Jean-Pierre Hugot, MD, PhD

Crohn disease is a chronic inflammatory disorder of the gastrointestinal tract that manifests during childhood or adolescence in up to 25% of patients. In 2001, two independent groups of investigators concurrently identified nucleotide oligomerization domain (NOD2), subsequently renamed caspase recruitment domain protein 15 (CARD15), as a Crohn disease susceptibility gene.[1,2] This landmark discovery marked the first time that a gene in any complex disorder had been first localized by linkage studies[3] and then positionally cloned.[1] *NOD2/CARD15* participates in the innate immune system, which regulates the immediate response to microbial pathogens.[4] The recognition of *NOD2/CARD15* mutations in roughly one-third of patients with both sporadic and familial Crohn disease[1,2,5] clearly links genetic susceptibility and enteric bacteria, two factors long hypothesized as important in etiopathogenesis.[6,7]

Although yet to be translated into a therapeutic breakthrough, the identification of Crohn disease–associated *NOD2/CARD15* polymorphisms has refocused and inspired research efforts in many ways. The role of bacteria and the mechanisms by which *NOD2/CARD15* polymorphisms predispose individuals to chronic intestinal inflammation require precise elucidation. Other susceptibility loci continue to be intensely investigated. For the first time, it is possible to begin to explain the well-recognized clinical heterogeneity of Crohn disease on the basis of genotype.[8,9]

This chapter reviews the epidemiology, etiologic hypotheses, clinical manifestations, and current management of Crohn disease in children and adolescents. The emphasis is on the exciting recent progress in understanding factors involved in disease pathogenesis and on the significant evidence-based advances in medical treatment.

EPIDEMIOLOGY

Classic epidemiologic studies characterize disease with regard to person, place, time, and associations. Hypotheses as to etiologic factors are then generated to explain observed variations in incidence. There are, however, many barriers to ascertaining accurate incidence data concerning Crohn disease.[10] Most locations do not have true population-based registries, so surrogates such as hospitalization figures are sometimes used to estimate incidence. Differences in diagnostic facilities and disease definition can give the false impression of discrepant incidence rates. Improving case ascertainment leads to an artificial increase in incidence. Some patients now diagnosed as having Crohn disease may have been more likely labeled as having ulcerative colitis in the past. Despite these confounding factors, there is a general consensus about several epidemiologic trends.[10]

Trends in Time

What has come to be known eponymously as Crohn disease was first described as "regional ileitis" in 1932, although it was considered likely that the same pathologic and clinical entity had been the subject of published case reports even in the early nineteenth century.[11] The occurrence of Crohn disease increased sharply in all age groups in most Western populations between the 1950s and 1980s. Whether it has since leveled off or continues to rise is in dispute.[10]

Increases in childhood and adolescent Crohn disease have paralleled overall population trends. The incidence of Crohn disease doubled among children in Wales from 1983 to 1993.[12] A threefold rise in the incidence of Crohn disease among Scottish children between 1968 and 1983 and a continued rise at the same rate between 1981 and 1992 have been reported.[13,14]

Geographic Trends

Geographic variability of inflammatory bowel disease (IBD) is striking.[10] The worldwide distributions of Crohn disease and ulcerative colitis are similar; both are most prevalent in North America, northwestern Europe, especially Scandinavia, and the United Kingdom.[10] Countries in southern Europe, South Africa, and Australia have somewhat lower incidence rates. A carefully designed recent collaborative European study of prospectively accrued cases confirms that incidence rates for both ulcerative colitis and Crohn

disease are higher in northern than in southern regions, but the north-south gradient in incidence rates is more modest than previously suspected.[15] IBD is relatively rare in Asia, Africa, and South America. In continental Europe, the occurrence of ulcerative colitis including proctitis in adults still exceeds that of Crohn disease at a ratio of 2:1, whereas the incidence of Crohn disease has become relatively greater than that of ulcerative colitis in parts of North America and the United Kingdom.[10,16]

Recent studies reporting the incidence of pediatric-onset illness in countries where IBD is most common are summarized in Table 41.1-1.[12–14,17–21] Reported incidence rates may be significantly influenced by even slight variations in the definition of "childhood" because of the steep rise in age-specific incidence during the teenage years.[10]

Trends in Age and Gender

Peak incidences of Crohn disease are observed in late adolescence or young adulthood. A second smaller peak is observed in the sixth decade.[10] There is no convincing evidence that age at onset is decreasing. The incidence of pediatric Crohn disease generally exceeds that of pediatric ulcerative colitis, although among children very young at presentation, ulcerative colitis is diagnosed more commonly than is Crohn disease.[12,21,22]

For Crohn disease overall, the incidence among females exceeds that among males by 20 to 30%.[10] In contrast, however, studies restricted to pediatric-onset Crohn disease document a male-to-female preponderance.[12,21] As summarized in Table 41.1-2, demographic data from a recently completed survey of new diagnoses of IBD among patients less than 16 years in the United Kingdom and Ireland are strikingly similar to relatively population-based data from the urban center of metropolitan Toronto, Canada, concerning children and adolescents diagnosed with IBD between 1980 and 1996.[12,21]

Trends among Races and in Ethnic Groups

Both ulcerative colitis and Crohn disease affect whites more than Asians and African blacks. Individuals of Jewish descent appear to be particularly susceptible to IBD.[23,24] Compared with Sephardic or Oriental Jews, Ashkenazi Jews have an increased risk.[23,24] Their incidence rate for IBD varies tremendously around the world, in parallel with but always remaining three to four times greater than the local non-Jewish population risk.[24] The persistence of increased risk across different time periods and geographic areas provides indirect evidence that there is a genetic predisposition to developing IBD.

ETIOPATHOGENESIS

It is unlikely that a simple cause and effect relation accounts for the majority of Crohn disease cases. Rather, it is hypothesized that the chronic immune-mediated intestinal injury results from complex interactions between predisposing genetic factors and exogenous or endogenous triggers, likely microbial in origin.[6,7] The proposed multifactorial etiopathogenesis is summarized schematically in Figure 41.1-1. Impressive progress has been made in elucidating the genetic basis of Crohn disease susceptibility, but, to date, the precise role played by the intestinal microflora in triggering and perpetuating chronic inflammation remains elusive.

GENETIC SUSCEPTIBILITY

Observations from Family Studies

The familial occurrence of Crohn disease is well recognized.[25–29] A positive family history in a first-degree relative remains the major identified risk factor for its development.[29] Familial aggregation could be explained by shared environmental or by genetic factors. However, the relative rarity in spouses compared with first-degree relatives and, most convincingly, data from studies comparing disease concordance in monozygotic versus dizygotic twins argue for the importance of genetic factors.[30,31]

A high (44.4–58%) rate of concordance for Crohn disease among monozygotic twins versus dizygotic twins (0–3.8%) was reported in Swedish and Danish studies, respectively, based on unselected twin registries.[30,31] If only environmental factors were involved in Crohn disease, the observed concordance rates between dizygotic twins and monozygotic twins would be expected to be the same. Conversely, because monozygotic twins share identical genomic material and yet are not 100% concordant for Crohn disease, no combination of genes is sufficient for the development of Crohn disease. Rather, some environmental trigger is also required for the disease to be expressed.

TABLE 41.1-1 RECENT INCIDENCE DATA FOR INFLAMMATORY BOWEL DISEASE IN CHILDREN AND ADOLESCENTS

LOCATION	AGE CRITERIA	CALENDAR YEARS OF STUDY	INCIDENCE OF PEDIATRIC CD (PER 100,000/YR)	INCIDENCE OF PEDIATRIC UC (PER 100,000/YR)
Scotland[13,14]	≤ 16 yr at symptom onset	1981–1983	2.3	1.6
		1990–1992	2.8	
South Glamorgan, Wales[12]	< 16 yr at diagnosis	1989–1993	3.1 (95% CI 1.8–5.3)	0.7
Nord-Pas-de-Calais, France[17]	≤ 15 yr at diagnosis	1984–1989	2.1	0.5
Western Norway[19]	≤ 15 yr at diagnosis	1984–1985	2.5	4.3
Metropolitan Toronto, Canada[20]	≤ 17 yr at diagnosis	1991–1996	3.7	2.7
United Kingdom and Ireland[21]	< 16 yr at diagnosis	1998–1999	3.0	2.2*
Copenhagen County, Denmark[18]	< 15 yr at diagnosis	1962–1987	0.2	2.0

CD = Crohn disease; UC = ulcerative colitis.

TABLE 41.1-2 COMPARISON OF DEMOGRAPHIC DATA AT TIME OF DIAGNOSIS OF CROHN DISEASE*

	GREATER TORONTO AREA, 1980–1996	UNITED KINGDOM AND IRELAND, 1998–1999
Total number of children diagnosed with IBD	787	739
Crohn disease		
Number (% of total)	486 (61.8)	379 (58)
Gender	62% male	62% male
Age at diagnosis (yr)	12.7 ± 2.56 (mean ± SD)	12.9 (10.8–14.3) Median (interquartile range: Q1–Q3)

IBD = inflammatory bowel disease.
*The Toronto, Canada, data concern children prospectively registered at the time of diagnosis in The Hospital for Sick Children pediatric inflammatory bowel disease database. The United Kingdom and Ireland data represent the results of 13-month surveillance of incident inflammatory bowel disease cases.[21]

The relative importance of genetic versus environmental factors, or heritability, is commonly expressed as λs, the prevalence in siblings divided by population prevalence.[29] For Crohn disease, the overall λs has been calculated in several studies worldwide to range between 10 and 35.[29] Hence the relative contribution of genetic factors to the pathogenesis of Crohn disease is greater than in schizophrenia, asthma, or hypertension and is at least equivalent to that identified in insulin-dependent diabetes.

Familial aggregation is more common among Jewish versus non-Jewish patients.[32,33] The age-adjusted empiric risks for developing IBD during a lifetime were calculated for first-degree relatives of Jewish and non-Jewish white probands with Crohn disease in a study from southern California.[32] The age-adjusted lifetime risks for siblings of Jewish and non-Jewish probands with Crohn disease were, respectively, 16.8% and 7.0%.[32]

Crohn disease and ulcerative colitis are observed to coexist in the same family with a frequency higher than just the co-occurrence by chance alone.[25–29,33] Nevertheless, concordance within a family for the type of IBD is much more common than discordance.[25–29,33] These observations indicate that the two diseases share at least some common etiologic factors. The occurrence of Crohn disease in offspring of couples both affected by ulcerative colitis supports the same conclusion.[34]

Genetic factors may be particularly important in the development of early-onset IBD. Polito and colleagues reported the proportion of patients with relatives affected with IBD according to the age at diagnosis in the proband.[35] Thirty percent of 177 patients diagnosed under age 20 years had a positive family history. The percentage decreased to 18% for those diagnosed between 20 and 39 years of age (n = 311) and to 13% among those diagnosed after age 40 years (n = 67).[35] Among a cohort of 770 probands with pediatric-onset IBD in Toronto, Canada, 16% had a first-degree relative (parent and/or sibling) who was also affected.[33] Thirty percent of the Jewish children with Crohn disease had one or more first-degree relatives with IBD.[33]

It has been observed that Crohn disease develops at a younger age in offspring in comparison with their affected parents.[36–38] Genetic "anticipation" refers to the tendency of a disease to develop at an earlier age and with increased severity in subsequent generations. In several monogenic neurodegenerative disorders, such anticipation is explained on a molecular basis by an increased number of trinucleotide repeats within the disease gene.[39] Although some investigators have proposed the same mechanism in Crohn disease,[36] earlier exposure to an environmental trigger and ascertainment biases are more plausible explanations.[37,38]

The number of genes that may confer susceptibility to IBD is still unknown. Initial segregation analyses led investigators to hypothesize that a major autosomal recessive gene may account for a proportion of the genetic predis-

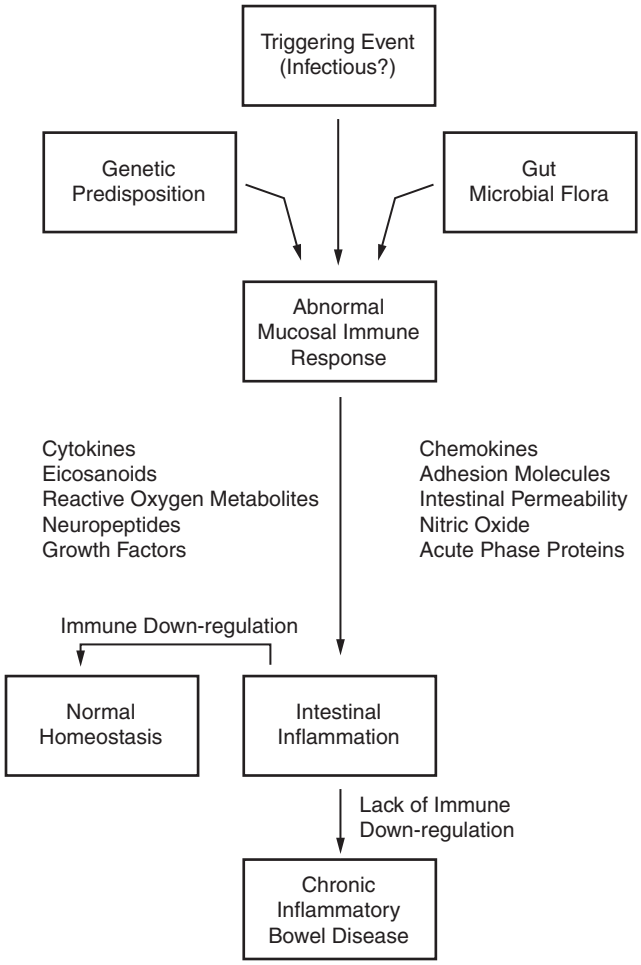

FIGURE 41.1-1 Multifactorial etiopathogenesis of Crohn disease. It is postulated that in a genetically susceptible individual, interacting environmental factors and the host intestinal microbial flora, in the presence of a yet unspecified triggering event, activate an aberrant immune response, the end result of which is chronic intestinal inflammation.

position to Crohn disease.[40] It is usually accepted, however, that IBD involves multiple susceptibility loci, as well as genetic heterogeneity (whereby different genes result in a similar disease phenotype), and both gene-gene and gene-environment interactions in a complex system.[29,41,42]

Genetic Studies in Crohn Disease

Two complementary strategies are used to search for the genetic determinants of a disease trait: linkage studies and candidate gene analysis. In the former, systematic screening of the entire human genome using highly polymorphic markers consisting of di- and trinucleotide repeats provides a strategy for localizing genes without prior hypotheses about their nature. The intrafamilial segregation of these microsatellite marker alleles is compared with segregation of the disease trait within a family. The markers have no direct relationship to disease pathogenesis, but when there is an excess of a marker allele shared among individuals with the disease, the disease gene and the marker locus are presumed to be transmitted together by virtue of being in proximity on the same chromosome.[43] Such linkage analyses have been successfully performed for numerous mendelian disorders, leading to the localization and further identification of the predisposing gene. However, the application of genome scanning to the study of complex disorders is relatively new and has much less often been fruitful.[43]

The candidate gene approach to identification of susceptibility genes requires determination of the frequency of different alleles at a polymorphic locus on a putative disease gene in patients versus ethnically matched controls (case-control studies). If a statistically significant difference is observed between the two groups, the allele that is more prevalent in the patient group is said to be associated with the disease. However, spurious associations may be generated by ignoring differences between the control and the disease groups that are not related to the disease. To overcome the bias of improper matching, tests that incorporate analysis of unaffected parents have been proposed. As an example, in transmission disequilibrium testing, the frequency with which an allele is transmitted from a usually healthy parent to an affected child is compared with the theoretically expected value of 0.5.[44] Significant departure from this expected value confirms an association between the allele and the disease.

Because the pathophysiologic processes leading to IBD are complex, the number of potential candidate genes is immense. Without direction from linkage studies, association studies would only very fortuitously successfully identify susceptibility genes. However, case-control candidate gene studies or transmission disequilibrium testing at loci identified by linkage studies can be complementary to genome scanning. Indeed, the application of the above-described strategies to Crohn disease has been rewarded with enormous recent advances.[1,2]

Identification of CARD15/NOD2 as a Crohn Disease Susceptibility Gene

Hugot and colleagues reported the first genome scan in families with two or more siblings affected with Crohn disease and thereby identified the pericentromeric region of chromosome 16 as a possible locus of a Crohn disease gene.[3] Linkage to this region, named IBD1, was subsequently confirmed in a multicenter replication study undertaken by the International Inflammatory Bowel Disease Genetics Consortium.[45] The eventual identification at this locus of *NOD2*, further renamed caspase recruitment domain protein 15 (CARD15) by an international nomenclature committee, as the first Crohn disease susceptibility gene marked the first time a gene in any complex disorder had been first localized by linkage studies and then positionally cloned.[1,3] At the same time, Ogura and colleagues successfully used a candidate gene approach to gene identification.[2] They selected *NOD2/CARD15* as a potential Crohn disease gene based on knowledge of its role in the recognition of bacterial components and on the gene location within the IBD1 region.

The 12-exon *NOD2/CARD15* gene encodes an intracellular protein, structurally related to the R proteins in plants, which mediate host resistance to microbial pathogens.[4] As illustrated in Figure 41.1-2, the protein product is composed of 1,040 amino acids with several functional domains: two caspase recruitment domains (CARD1 and CARD2), a nucleotide binding domain (NBD), and a leucine-rich repeat (LRR) domain.[4] The LRR domain functions as a pattern recognition receptor for microbial components. The NBD mediates protein self-oligomerization, which is required for activation.[4] CARDs are domains involved in apoptosis pathways and in nuclear factor-κB (NF-κB) activation.

Sequencing of the *NOD2/CARD15* gene in Crohn disease patients revealed a cytosine insertion at position 3020 in exon 11 (Leu1007fsinsC) that gives rise to a stop codon and a truncated NOD2 protein.[1,2] This frameshift mutation and two other common missense mutations (Arg702Trp, Gly908Arg), all within or near the LRR domain of *NOD2/CARD15* (see Figure 41.1-2), have been highly associated with Crohn disease but not with ulcerative colitis.[1,2,5] This lack of an association with ulcerative colitis is consistent with previous negative linkage data at the IBD1 locus.[45] Allelic frequencies for Arg702Trp, Gly908Arg, and Leu1007fsinsC are consistently higher in white Crohn disease patients compared with controls.[41] In addition to the three major risk alleles, a number of extremely rare ("private") amino acid polymorphisms, particularly within or near the LRR domain, have been defined, each present in only a few families.[1,9] These rare ("private") mutations appear, nevertheless, to be similarly associated with disease

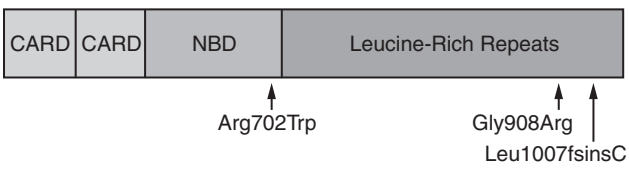

FIGURE 41.1-2 Structure of the NOD2/CARD15 protein. The three common Crohn disease–associated polymorphisms are located in the leucine-rich repeat domain. CARD = caspase recruitment domain; NBD = nucleotide binding domain.

pathogenesis. Little is known about the presence of *CARD15* mutations in ethnic groups other than whites. In studies of Japanese Crohn disease patients, none were carriers for any of the three major risk alleles.[46,47] A unique amino acid polymorphism has been identified in blacks.[41,48]

Having one copy of a risk allele confers a relatively small (two- to fourfold) increased risk for developing Crohn disease, whereas having two copies increases the risk 20- to 40-fold, indicating that *NOD2/CARD15* functions to a large extent in an autosomal recessive fashion.[1,5] Patients carrying two variant alleles are characterized by a younger age at onset.[9] These observations are, interestingly, in accordance with previous segregation analyses, which suggested that a major recessive gene might play a role in a subset of patients, particularly with early-onset Crohn disease.[40] Approximately 8 to 17% of patients carry two copies of the major *NOD2/CARD15* risk alleles (compared with less than 1% in white control populations).[41] Twenty-seven to 32% of Crohn disease patients carry one major risk allele, and roughly half carry one major or one rare ("private") variant allele (compared with about 20% of white controls).[9,41]

Several phenotypic correlations have emerged as large patient populations have been genotyped for the Arg702Trp, Gly908Arg, and Leu1007fsinsC *NOD2/CARD15* polymorphisms.[8,9,49–54] First, *NOD2/CARD15* polymorphisms are associated with both sporadic and familial Crohn disease.[1,2,5,9] Second, in multiple studies, a significant association has been found between ileal disease and the carriage of one or more *NOD2/CARD15* risk variant alleles.[8,9,49–54] Double-dose carriers are very uncommonly observed in colon-only Crohn disease.[8,9,50] Finally, some studies have demonstrated an association between *NOD2/CARD15* risk alleles and a stricturing phenotype.[50,51,53]

The mutational spectrum of *NOD2/CARD15* is favorable for genetic analyses because the three major polymorphisms represent more than 80% of the variant alleles and are easily determined in laboratories involved in molecular diagnosis.[1,9] As yet, however, knowledge of *NOD2/CARD15* status has little role in clinical practice. The lack of any association between *NOD2/CARD15* polymorphisms and ulcerative colitis initially suggested that *NOD2/CARD15* genotyping could help to classify indeterminate colitis, but this is precluded by the low frequency of *NOD2/CARD15* mutations in Crohn disease patients with an ulcerative colitis–like phenotype. To date, *NOD2/CARD15* status has not correlated with any treatment responsiveness, but only the response to infliximab therapy has hitherto been studied.[55,56] The usefulness of *NOD2/CARD15* genotyping in predicting outcomes needs to be studied in future clinical trials.

As expected for a complex genetic trait, *NOD2/CARD15* is neither necessary nor sufficient for disease development. The odds ratio of disease development is in the range of 20 to 40 for carriers of two Crohn disease–associated polymorphisms compared with carriers of two wild-type *NOD2/CARD15* alleles. Given a rough prevalence of 1 in 1,000 inhabitants in Western countries, it can be easily calculated that the probability of developing the disease (penetrance) is no more than 0.04 for the group at highest risk. With such a low risk, and in the absence of any preventive action, screening of family members is not currently recommended. It has been estimated, moreover, that the three main *NOD2/CARD15* polymorphisms explain no more than 20% of the genetic predisposition Crohn disease.[41] Such observations are expected for a complex genetic disorder, in which the disease results from the complex interplay between several genetic and environmental risk factors.

Search for Other Crohn Disease–Associated Genes

The number of individual genes that contribute to the overall susceptibility to Crohn disease is, as yet, unknown. Since the initial identification of IBD1 on chromosome 16q, several other genome-wide linkage studies have identified additional IBD susceptibility loci, indicating the complexity of IBD.[57–62] As recently reviewed,[41] significant linkages have been reported on chromosomes 1p, 5, 6, 12, 14, and 19 and suggestive linkages on chromosomes 1q, 3, 4, 7, 10, 16p, 22, and X.[41,57–62] One of the lessons learned from animal models of IBD is that entirely different genetic abnormalities can lead to similar clinical features of intestinal inflammation.[63] Genetic heterogeneity in Crohn disease (the ability of different genes to result in a similar disease phenotype) could well contribute to the discrepancies observed between linkage studies undertaken in different patient populations.[29,41,64] The evidence of two X chromosomal linkages in the huge number of affected sibling pair families studied by Hampe and colleagues[58] is interesting in light of the reported increased incidence of Crohn disease in girls with Turner syndrome.[65]

From localization to actual identification of other susceptibility genes is still a long walk. On chromosome 5q31-33 (IBD5),[60] significant associations have been reported between Crohn disease and several genetic haplotypes in a very narrowed region, which includes a cluster of cytokine genes.[66]

The list of genes studied via association (case control) studies in relation to IBD is growing rapidly. Genes considered and studied as candidates have mainly been those coding for factors involved in regulation of immune and inflammatory processes or maintenance of mucosal barrier function. Major histocompatibility complex (MHC) class II allelic associations are more robust for ulcerative colitis than for Crohn disease, although susceptibility associations have been found for human leukocyte antigen (HLA)-DRB1*0701 and HLA-DRB3*0301 and protective association for HLA-DRB1*1501.[8,67] Allelic variation in the promoter region of the tumor necrosis factor-α (TNF-α) gene within the MHC class III region has been associated with susceptibility to and progression of Crohn disease.[68,69] Other reported associations include polymorphisms in the intercellular adhesion molecule 1.[70] Most of the reported associations do not clearly indicate functional alterations in the gene.

ENVIRONMENTAL INFLUENCES

Environmental factors must also be important in the development of Crohn disease, as evidenced by the rapidly increasing incidence in recent decades[10] and by the lack of complete concordance for disease status among monozygotic twins.[30,31] Environmental influences, if shared by family members, may also contribute to familial aggregation, as is supported by a recent analysis of birth order of affected siblings in multiplex families.[71]

Search for a Specific Microbial Trigger

Over the past 30 years, there has been an intensive search for the antigens that trigger the immune response. The fundamental question regarding the pathogenesis of Crohn disease has been framed as follows: does the chronic, recurring inflammatory activity reflect an appropriate response to a persistently abnormal stimulus (eg, a persistent causative agent in the intestinal lumen) or an abnormally prolonged response to a ubiquitous stimulus?[6] Although the most widely held theory is that Crohn disease constitutes a dysregulated immune response to common bacterial antigens, the search for specific pathogens has not been abandoned. An infectious etiology for Crohn disease, with a direct cause-and-effect relationship between a single microorganism and inflammation in a genetically predisposed host, still remains plausible. The relationship between microbes and defined clinical entities is often ambiguous, but diseases of unknown etiology are unexpectedly proven to be infectious. The most striking example is peptic ulcer disease and *Helicobacter pylori*. A number of putative infectious agents have been proposed and discounted as etiologic factors since Crohn disease was first identified as an entity distinct from tuberculous ileitis.

Mycobacteria. *Mycobacterium paratuberculosis* causes Johne disease, an intestinal disorder in ruminants that clinically and histologically resembles Crohn disease. Mycobacteria (named *M. Linda* after the patient) isolated from a Crohn disease surgical specimen were administered orally to a young goat and caused a disease similar to Johne disease.[72] It is quite possible, however, that this organism, although pathogenic for goats, is merely a nonpathogenic secondary agent in humans. Despite intensive efforts, *Mycobacterium* species similar or identical to *M. paratuberculosis* can be cultured from relatively few patients with Crohn disease. Some, but not all, investigators have identified fragments of its deoxyribonucleic acid (DNA) by polymerase chain reaction more commonly in Crohn disease tissue than in tissue from patients with ulcerative colitis or controls.[73] Current evidence suggests that *M. paratuberculosis* is an environmental contaminant that preferentially invades the deeply ulcerated mucosa of Crohn disease patients to a greater extent than that of controls. The results, however, do not exclude pathologic infection of a subgroup of Crohn disease patients.

Viruses. Interest in a viral etiology of Crohn disease was rekindled by Wakefield and colleagues, who demonstrated evidence of persistent measles infection in foci of granulomatous vasculitis in the intestine of patients with Crohn disease.[74] It has been proposed that measles infection early in life leads to microvascular thrombosis, multifocal gastrointestinal infarction, and, eventually, gross pathologic sequelae such as inflammation, fibrosis, and strictures.[75] This has been tied in with a report of a cohort effect of a measles epidemic in childhood with subsequent Crohn disease and a striking report of three cases of serious Crohn disease in the children of three of four mothers affected with measles during pregnancy.[76] The same group of investigators reported that the first children participating in the measles vaccination program in the United Kingdom were more likely to subsequently develop Crohn disease than were nonvaccinated children.[77] Other investigators, however, have been unable to confirm either the epidemiologic observations or the identification of persistent measles virus infection by immunohistochemical staining of tissue from patients with Crohn disease.[78,79]

Role of Enteric Flora

The recent recognition that altered structure of the *NOD2/CARD15* receptor confers susceptibility to Crohn disease clearly links microbes to its pathogenesis.[2] Indeed, although Crohn disease is not likely usually due to a single mucosal pathogen, several lines of evidence indicate the crucial involvement of the intestinal microflora.[80–83] Increased numbers of bacteria have been reported in both inflamed and noninflamed colonic segments in patients with Crohn disease compared with noninflamed and inflammatory disease controls.[80]

Patients with ileal resections and a diverting ileostomy excluding the neoterminal ileum fail to develop recurrent disease until reanastomosis is performed.[81] Infusion of autologous luminal contents in excluded normal ileal loops of patients with Crohn disease rapidly induces new inflammation, indicating that fecal component(s) may promote disease flare-up.[82] Inflammation is prevented or lessened by a germ-free environment in several knockout and transgenic animal models of IBD.[83,84]

Role of Diet

It is logical to attempt to attribute the changing incidence of gastrointestinal disorders to different dietary exposures. However, no specific dietary toxin or antigen has been incriminated. The rarity of IBD has limited traditional epidemiologic methods of determining causation to case-control studies, which have failed to provide meaningful insight into disease pathogenesis. Persson and colleagues reviewed studies examining the reported preillness intake of refined sugar, cereals, fiber, and milk products of patients with Crohn disease or ulcerative colitis compared with that of controls.[85] An increased intake of refined sugar before the development of symptomatic Crohn disease has been fairly consistently reported, suggesting perhaps a modulating role, but the methodologic weaknesses of study design must be recognized.[85] The association may represent a behavioral adaptation to disease rather than a cause of disease.

Recently, nutritional factors modulating the risk of IBD development have been examined. In a correlation study from Japan, the increasing incidence of Crohn disease in this racially homogeneous population was shown to parallel increasing daily intake of animal protein, total fat, and animal fat, especially ω-6 polyunsaturated fatty acids (PUFAs) relative to ω-3 PUFAs.[86] These trends indicating "Westernization" of diet in Japan were determined from sequential population surveys of dietary habits. Omega-3 PUFAs found in marine oils have an anti-inflammatory effect through modulation of proinflammatory cytokine synthesis.[87]

Risk Factors: Early-Life Exposures

The finding of a birth cohort effect instead of a period effect in two independent Swedish studies indicates that events early in life influence the risk of developing IBD.[88,89] Maternal or neonatal infection has been investigated as the underlying cause of this clustering phenomenon.[90] Breastfeeding in infancy may reduce the risk of developing Crohn disease.[91]

Other Modulating Factors

Smoking. A clear dichotomy between ulcerative colitis and Crohn disease is indicated by the opposing effect of cigarette smoking on the two disorders.[92] Smoking decreases and cessation of smoking increases the risk of developing ulcerative colitis.[92] Smoking is a risk factor for Crohn disease, with a point estimate of between 2 and 5.[92] The risk for former smokers does not differ from the risk in people who have never smoked, indicating that smoking is not an initiator of Crohn disease but rather a promoter. Passive exposure to smoking and active smoking may be influential.[93] The components of tobacco responsible for these observations are uncertain, but most attention has been focused on nicotine. Cigarette smoking has been shown to cause morphologic injury to endothelial cells, leading to the formation of microthrombi. Hence, the increased risk of Crohn disease among smokers has been hypothesized to relate to potentiation of multifocal gastrointestinal infarction.

Oral Contraceptives. Oral contraceptive use has been implicated as a risk factor for Crohn disease, but the results are not as consistent as those for smoking, and the risk estimates are generally lower. In some studies, the increased risk has only been found in subgroups of smoking patients.[94] Oral contraceptive use may modestly increase the risk of Crohn disease 1.5 and 2.6 times in current smokers. It is biologically plausible that oral contraceptive use might further promote Crohn disease through similar effects on the mesenteric vasculature.

HOST-ENVIRONMENT INTERACTIONS

The intestinal inflammation of Crohn disease may be viewed as an exaggeration of the "physiologic" inflammatory response always present in the normal lamina propria of the intestine and colon. An enormous antigenic load is regularly presented through the lumen of the gastrointestinal tract, but an intact mucosal barrier and regulatory mechanisms normally prevent the immune and inflammatory responses important in defense against pathogenic agents from proceeding to cause tissue injury. A defect in mucosal barrier function, in antigen processing, or in immunoregulation could result in a chronic inflammatory state, lymphocyte proliferation, cytokine release, recruitment of auxiliary effectors such as neutrophils, and eventual tissue damage. Elucidation of the genetic basis of Crohn disease has the potential to uncover the primary mechanisms underlying its development. Identification of the *NOD2/CARD15* susceptibility gene has provided a tangible basis for investigating the interactions between host and environment that culminate in chronic inflammation.

Defective Mucosal Barrier

Mucosal permeability is increased in Crohn disease, but whether the defect is primary or secondary remains controversial. Approximately 10% of asymptomatic family members of Crohn disease patients exhibit increased permeability, and an additional subset have enhanced permeability after exposure to nonsteroidal anti-inflammatory drugs.[95,96] Whether this abnormal permeability is indicative of subclinical intestinal inflammation or represents a genetically determined predisposing factor is unclear. There is little doubt, however, that excessive permeability, allowing macromolecular uptake of bacterial and other luminal antigens, plays a role in perpetuating the inflammation in IBD.

Immunoregulatory Abnormalities

In general, immune-mediated inflammation can result from activation of innate or adaptive immune responses, which are tightly linked. Adaptive immune responses are initiated when antigen is presented to a T lymphocyte by an antigen-presenting cell. The innate immune system regulates the immediate response to microbial pathogens through "pattern recognition" receptors, which recognize bacterial products and constituents.

Defective Innate Immunity. *NOD2/CARD15* belongs to a family of such pattern recognition receptors located intracellularly, in contrast to Toll-like receptors located on the cell membrane.[97] As expected for a gene involved in innate immunity, *NOD2/CARD15* is mainly expressed in the monocyte-macrophage lineage (including dendritic cells) and granulocytes, cells present in Crohn disease lesions and involved in granuloma formation. Epithelial cells are able to express NOD2/CARD15 when activated, but the biologic relevance of this observation remains to be clarified.

Initially, lipopolysaccharide was thought to be the bacterial component recognized by the *NOD2/CARD15* receptor, but recent work has concluded instead that it is muramyl dipeptide, a component of peptidoglycan, that is associated with various bacteria and frequently contaminates preparations of lipopolysaccharide.[98] As illustrated in Figure 41.1-3, stimulation of *NOD2/CARD15* with bacterial proteins results in activation of the NF-κβ signaling cascade. Such activation occurs through receptor interacting protein 2 (RIP2, also

called RICK), a serine/threonine kinase that phosphorylates the inhibitor of NF-κB kinase and therefore allows the transport of NF-κβ to the nucleus.[99] Moreover, *NOD2/CARD15* may be up-regulated by proinflammatory cytokines, such as TNF-α, via a NF-κβ binding element in its promoter region, contributing to amplification of the inflammatory process.[100]

The recognition of *NOD2/CARD15* as a susceptibility gene identifies a primary abnormality in Crohn disease for the first time. Precisely how *NOD2/CARD15* polymorphisms confer susceptibility cannot as yet be definitively answered. The presence of caspase activation and recognition domains indicates that *NOD2/CARD15* plays a role in apoptosis. However, the Crohn disease–associated *NOD2/CARD15* polymorphisms are located in the LRR domain of the gene or in its vicinity, suggesting a defect in host-bacteria interaction, as had long been hypothesized. It is surprising, however, that the *NOD2/CARD15* Leu1007fsinsC frameshift mutation appears in functional experiments to be associated with a loss of NF-κβ activation in the presence of bacterial components.[2,101] In contrast, distinct polymorphisms in the *NOD2/CARD15* gene are associated with increased NF-κβ activation in Blau syndrome, another granulomatous condition.[102] Uveitis, arthritis, and skin rashes, but no digestive tract involvement, characterize this rare dominant mendelian trait.[102] It is postulated that Blau syndrome results from basal overactivation of the *NOD2/CARD15* pathway, not requiring interaction with bacterial components and by direct consequence without digestive lesion.[102]

The loss of function associated with Crohn disease–associated *NOD2/CARD15* polymorphisms is not as yet reconciled with the excess of NF-κβ activation observed in intestinal lesions. It is suggested that the defect in innate immunity may secondarily trigger an aberrant T-cell inflammatory response, leading to abnormal cytokine production, deregulated NF-κβ activation, and tissue damage.[63]

It remains to be seen whether other susceptibility genes, which undoubtedly exist, also code for proteins involved in the interpretation of the microbial environment by the innate immune system.

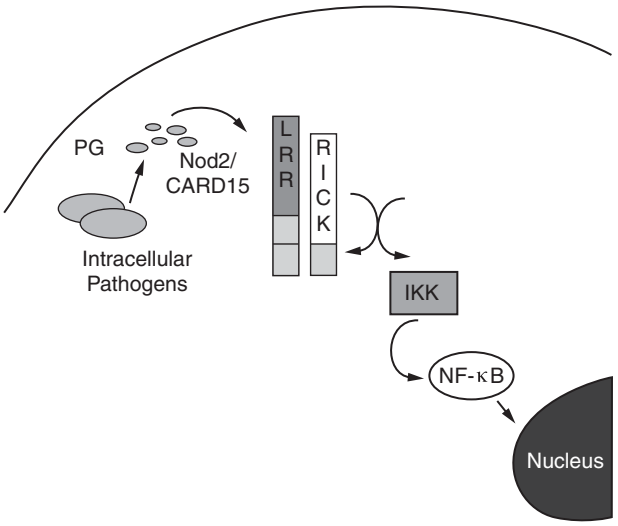

FIGURE 41.1-3 NOD2/CARD15 function in the innate immune response. Stimulation of NOD2/CARD15 by bacterial components, particularly peptidoglycan (PG), results in activation of the nuclear factor-κB (NF-κB) signaling cascade. Such activation occurs through RICK, a serine/threonine kinase that phosphorylates IKK (inhibitor of NF-κB kinase), thereby allowing transport of NF-κB into the nucleus. Crohn disease–associated polymorphisms in the *NOD2/CARD15* gene are associated with a loss of NF-κB activation in the presence of bacterial components. LRR = leucine-rich repeat; RICK = receptor interacting protein 2.

Adaptive Immune Response. Until the discovery of the *NOD2/CARD15* gene, most investigations of the pathogenic mucosal immune response in Crohn disease focused on the role of T cells, which are clearly important effectors. The pathophysiology of chronic intestinal inflammation from T-cell activation to tissue injury is summarized schematically in Figure 41.1-4. T-cell activation occurs on presentation of antigen by a macrophage or other antigen-presenting cell to a $CD4^+$ T cell. The antigen-specific activation of $CD4^+$ T cells occurs through binding of the CD4 molecule to MHC class II molecules bearing processed antigen on the surface of the activated macrophage. Following activation, $CD4^+$ T lymphocytes can differentiate into two subpopulations designated T helper 1 (Th1) and 2 (Th2) cells, which produce, respectively, predominantly interferon-β, interleukin (IL)-1, TNF-α, and IL-6 (Th1 cytokines) or IL-4, IL-5, and IL-10 (Th2 cytokines). Whether Th1 or Th2 responses predominate appears to depend on the specific costimulatory signal, the nature and concentration of the antigen, and the prevailing cytokine milieu.[63] Intracellular bacteria, which activate macrophages, promote Th1 cell differentiation by stimulating the synthesis of IL-12, the major Th1-inducing cytokine. Th1 responses predominate in Crohn disease. Amplification or suppression of the inflammatory response by T cells and macrophages depends on the relative balance of proinflammatory and anti-inflammatory immunoregulatory cells and mediators.[63] The unrestrained intestinal Th1 activation in Crohn disease appears to be due to defective regulation via regulatory T-cell populations and to T-cell resistance to normal apoptotic signals.[7,103] Tissue damage results from downstream effects of activated Th1 cells. Th1 cytokines, such as TNF-β, have many functions, including induction of the expression of adhesion molecules, thereby contributing to the recruitment of monocytes, lymphocytes, and granulocytes. Cells recruited to the mucosa release a vast number of substances with nonspecific inflammatory but directly injurious properties. These include arachidonic acid metabolites (prostaglandins, thromboxane, leukotrienes), free radicals (reactive oxygen metabolites and nitric oxide), platelet activating factor, and various proteases.

Control of Mucosal Immune Response. The mucosal immune system must tightly control the balance between responsiveness and nonresponsiveness (tolerance) to the millions of antigens continuously passing along the mucosal surface. The ability to distinguish between commensal and pathogenic organisms is vital to a normal mucosal immune system. Attempting to explain all of the epidemiologic and pathophysiologic observations, as dis-

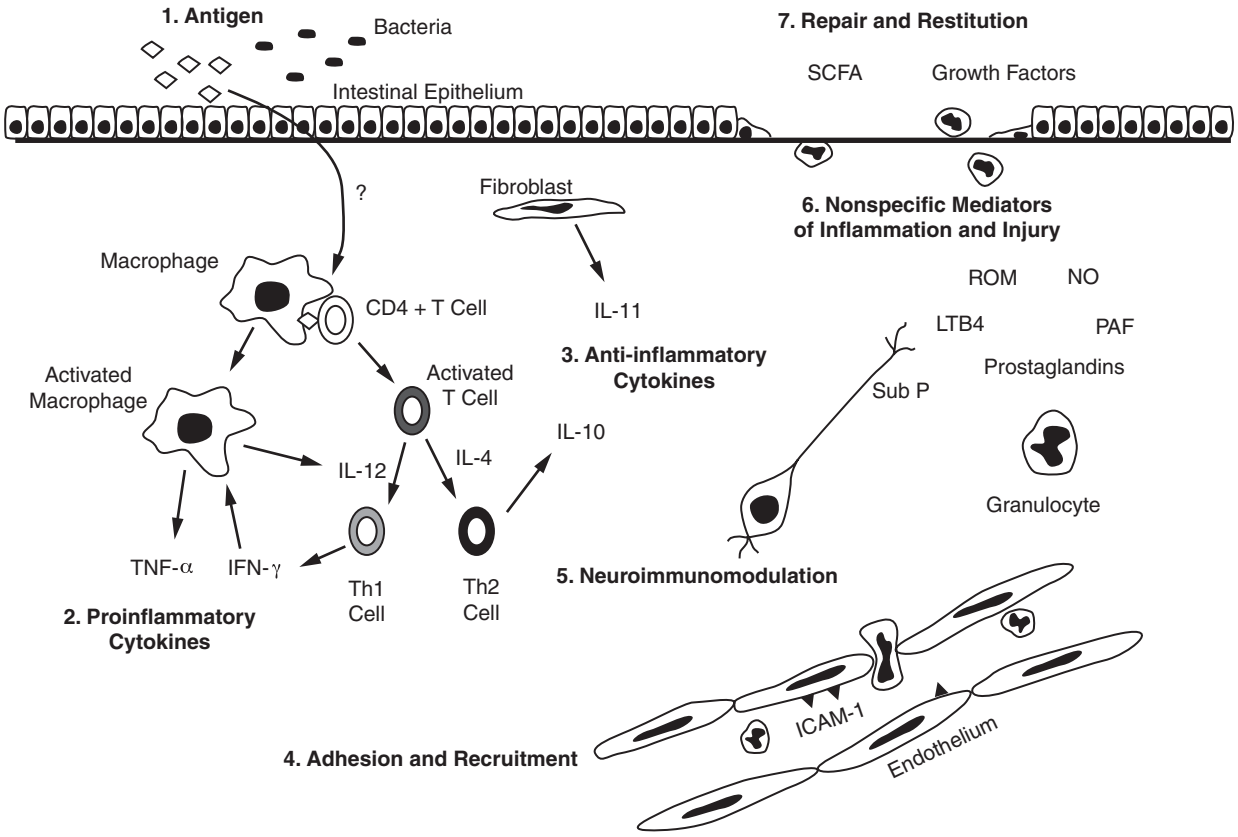

FIGURE 41.1-4 Proposed pathophysiology of chronic intestinal inflammation. Numbers in parentheses indicate sites for therapeutic interventions. The persistent mucosal inflammation in inflammatory bowel disease is triggered by antigen (1) believed to be bacterial in origin. Macrophages process antigen and present it in the context of human leukocyte antigen class II to CD4+ T cells. On activation, macrophages elaborate the proinflammatory cytokines (2) tumor necrosis factor-α (TNF–α) and interleukin (IL)-12, inducing T helper 1 (Th1) responses. Alternatively, elaboration of IL-4 may promote differentiation toward T helper 2 (Th2) responses and expression of the anti-inflammatory cytokine (3) IL-11. Cells are recruited from the periphery (4) via coordinated expression of integrins, chemokines, and adhesion molecules such as intercellular adhesion molecule 1 (ICAM-1). Elaboration of neutropeptides, such as substance P (Sub P), may modify the local responses (5). A variety of nonspecific mediators of inflammation and injury (6) may affect tissue destruction directly. Such mediators include reactive oxygen metabolites (ROM), nitric oxide (NO), leukotriene B_4 (LTB_4), platelet activating factor (PAF), and prostaglandins. Finally, host responses may induce nonspecific mechanisms of restitution of the wound and repair (7). Short-chain fatty acids (SCFA) and growth factors may contribute to this process. cussed above, it has been hypothesized that Crohn disease may be a disorder of mucosal immune interpretation of the microbial environment.[7] Genetic variants increasing susceptibility to Crohn disease and other chronic inflammatory disorders, such as allergies and asthma, may have persisted and expanded in human populations owing to a beneficial effect in mediating host-microbial interactions in an unsanitary world.[7] The survival advantage previously afforded by enhanced mucosal immune reactivity becomes a risk factor for immune-mediated disease as lifestyle and environmental conditions change.[7,104] Environmental factors, hence, may exert their influence and account for the changing incidence of Crohn disease at the level of immune regulation rather than via a transmissible infectious agent.[7]

PATHOLOGY

Anatomic Distribution

Crohn disease is a panenteric inflammatory process. Endoscopy with biopsies commonly identifies histologic abnormalities throughout the gastrointestinal tract. Nevertheless, classification according to the distribution of gross disease evident radiologically or macroscopically at endoscopy still guides treatment and may be useful prognostically. In comparison with the continuous distribution of ulcerative colitis, Crohn disease is characteristically segmental, with spared areas throughout the intestinal tract. The terminal ileum is the most commonly affected site.

During the most recent decade (1990–1999) at The Hospital for Sick Children, Toronto, 386 children and adolescents were evaluated at initial presentation by colonoscopy and small bowel radiography. Twenty-nine percent have had terminal ileal with or without cecal disease, 9% more isolated proximal (ileal or jejunal) disease, 42% ileocolonic inflammation, and 20% colon-only involvement. The extent of the disease was evaluated by colonoscopy and small bowel radiography. Data from 12 pediatric series, as pooled by Barton and Ferguson, were similar.[105] Crohn disease was localized to the small intestine (breakdown of terminal ileum versus diffuse or more

proximal small intestine not given) alone in 38%, in combination with the colon in another 38%, and in the colon only in 20%. Upper endoscopy with biopsy, if routinely performed, frequently reveals at least microscopic involvement of the esophagus, stomach, or duodenum, but gastroduodenal disease is only rarely the sole or predominant site of Crohn disease.[106]

Macroscopic Appearance

Gross inspection of the bowel in well-established Crohn disease reveals marked wall thickening. Mural thickening is the result of chronic inflammation and edema in all layers and is accompanied by luminal narrowing. The mesentery is thickened and contracted and may fix the intestine in one position. Mesenteric lymph nodes are frequently enlarged. Fat extends from the mesentery and "creeps" over the serosal surface of the bowel. The transmural inflammation may cause loops of intestine to be matted together. Fistulae are thought to arise when inflammation extends through the serosa into adjacent structures, such as another loop of bowel, the urinary bladder, or the vagina. Alternatively, a fistulous tract ends blindly in an inflammatory mass (phlegmon) adjacent to the bowel. Stricture formation may occur as a result of fibrous tissue proliferation involving first the submucosa and then the deeper layers of the bowel wall.

The earliest lesion of Crohn disease is the aphthous ulcer, which typically occurs over Peyer patches in the ileum and over lymphoid follicles in the colon. As the disease progresses, aphthoid ulcers enlarge and become stellate and, eventually, deeper longitudinal and transverse linear ulcers. Remaining islands of nonulcerated mucosa give a "cobblestone" appearance. Fissures develop from the base of ulcers and extend through the muscularis to the serosa. Free perforation is uncommon because serositis induces the adherence of other bowel loops into which the fissure extends. Bowel inflammation and ulceration are characteristically punctuated by "skip areas" of grossly and even microscopically normal mucosa.

Microscopic Findings

Mucosa that is thought to be normal grossly often reveals abnormalities such as edema and an increase in mononuclear cell density in the lamina propria. Microscopic inflammation in such relatively uninvolved sites is often strikingly focal.[107] Even within one histologic section, inflammation may be immediately adjacent to an uninflamed microscopic skip area. Mucosal changes may resemble ulcerative or infectious colitis with infiltration of the crypts by polymorphonuclear leukocytes (cryptitis or crypt abscesses) and distortion of crypt architecture. However, the presence of fibrosis and histiocytic proliferation in the submucosa suggests Crohn disease. The pathologic hallmark is transmural extension to all layers of the bowel wall and adventitia.[107]

Granulomas are not always found in pathologic specimens from patients with Crohn disease. The likelihood of finding granulomas in biopsy specimens is a function of the number of specimens taken, the number of sections examined, and the definition of a granuloma. Granulomas occur more commonly in the submucosa than in the mucosa. Hence, they are observed in 60% of surgical specimens but, less frequently, in 20 to 40% of mucosal biopsies (Figure 41.1-5).[107] Granulomas can also be found in lymph nodes, mesentery, and peritoneum. Intestinal granulomas can be found in a number of infectious diseases, including tuberculosis, fungal infections, chlamydial infections, and yersiniosis, as well as in sarcoidosis and foreign-body reactions. Granulomas in Crohn disease lack the caseating necrosis evident in tuberculosis.

CLINICAL PRESENTATION

The prevalence of individual symptoms among children and adolescents at the time of their diagnosis with Crohn disease is outlined in Table 41.1-3. As is evident in the table, the reported common symptoms during a year of prospective surveillance for pediatric Crohn disease in the United Kingdom and Ireland[22] were remarkably similar to

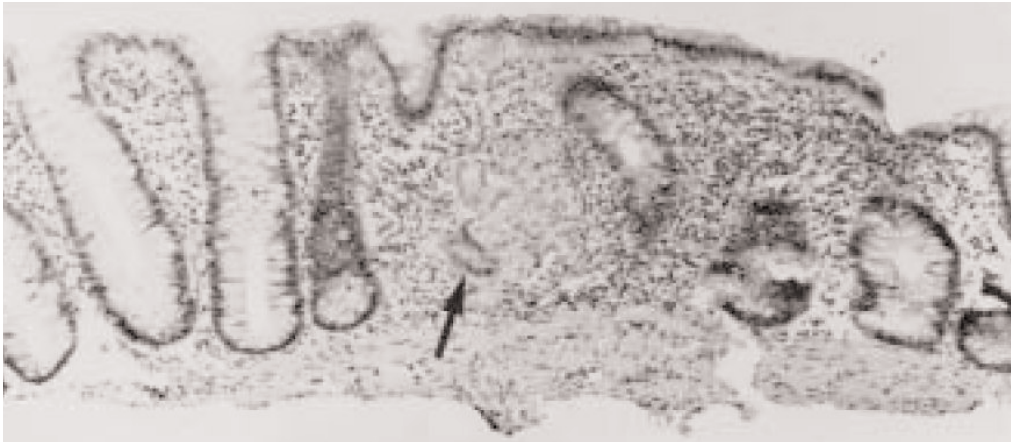

FIGURE 41.1-5 Colonic biopsy specimen from a child with active Crohn disease. Notice the distortion of the crypt architecture with a prominent noncaseating granuloma and giant cells (*arrow*) amid increased acute and chronic inflammation in the lamina propria (hematoxylin and eosin; × 40 original magnification).

TABLE 41.1-3 PREVALENCE OF INDIVIDUAL SYMPTOMS AT THE TIME OF DIAGNOSIS OF CROHN DISEASE*

Skin lesions	8	1

IBD = inflammatory bowel disease.
*Prospectively recorded single-center data from The Hospital for Sick Children, Toronto, during a 10-year period, 1990–1999, are compared with multicenter data reported by pediatric gastroenterologists as part of the United Kingdom/Ireland Inflammatory Bowel Disease Surveillance Project.[21]

those prospectively recorded during the past decade (1990–1999) among newly diagnosed children in Toronto. The mean interval between development of these presenting symptom(s) and diagnosis at The Hospital for Sick Children, Toronto, was 5.5 months. Several observations warrant emphasis.

In comparison with those of ulcerative colitis, the initial symptoms of Crohn disease are more subtle and varied, in part a reflection of its diffuse and diverse anatomic localization. A careful physical examination may detect clues to underlying Crohn disease when the presenting symptoms such as abdominal pain without other overt intestinal symptoms, isolated anemia, or weight loss do not immediately suggest IBD. A plateau in linear growth, delayed pubertal development, perianal lesions, and finger clubbing are tell-tale signs that may be easily overlooked unless specifically sought.

Classic Presentation

The constellation of abdominal pain, diarrhea, poor appetite, and weight loss constitutes the classic presentation of Crohn disease in any age group. As shown in Table 41.1-4, this symptom complex (with and without extraintestinal manifestations of IBD) comprises the mode of presentation in nearly 80% of children and adolescents. Abdominal pain is the most common single symptom at presentation. It is often periumbilical but may localize to the right lower quadrant or diffusely to the lower abdomen with colonic disease. Diarrhea, although common, need not be present, especially when disease is confined to the small intestine. Diarrhea, especially in the absence of significant left-sided colonic disease, is often not grossly bloody, unless there is bleeding from a perianal fissure. The less common modes of presentation in Table 41.1-4 deserve comment because they are more likely to be associated with diagnostic confusion and delay.

Growth and Pubertal Delay

Crohn disease may present as short stature. Impairment of linear growth and concomitant delay in sexual maturation may precede the development of intestinal symptoms and dominate the presentation.[108] Impaired growth in a young adolescent becomes strikingly obvious as healthy peers experience the rapid increase in height associated with normal puberty. Affected adolescents are often normal weight for height but low height for age, that is, stunted. As is discussed in detail later in this chapter, there is evidence that *both* chronic undernutrition secondary to anorexia *and* proinflammatory cytokines produced by the inflamed intestine contribute to the observed alterations in growth.[109,110]

Perianal Disease

Perianal lesions may be the isolated presenting feature of Crohn disease and an accompanying sign of other gastrointestinal symptoms. Perianal fistulae, large tags, or recurrent perianal abscesses in any child warrant investigation to exclude Crohn disease.

TABLE 41.1-4 MODES OF PRESENTATION OF CROHN DISEASE*

MODE	N (%)
Classic presentation (abdominal pain, diarrhea, weight loss ± extraintestinal manifestations)	235 (78.6)
Growth failure predominating	10 (3.3)
Extraintestinal manifestations predominating	25 (8.4)

*Data from The Hospital for Sick Children, Toronto, from 1980–1989.

Anemia

Iron deficiency anemia, unless explained by abnormal menstrual losses, reflects gastrointestinal blood loss until proven otherwise. Crohn disease is one condition that must be included in the differential diagnosis, even if other suggestive symptoms are not readily apparent.

Weight Loss

With similar subtlety, Crohn disease can masquerade as anorexia nervosa when weight loss predominates.

EXTRAINTESTINAL MANIFESTATIONS

Inflammatory extraintestinal manifestations of Crohn disease are more common with colonic disease than with isolated small bowel disease.[111,112] The most common target organs are the skin, joints, liver, eye, and bone.[111,112] At least one extraintestinal manifestation is seen in about 25 to 35% of adult patients with IBD.[111] The prevalence would likely be higher in children if fever was included. As previously reviewed, inflammatory extraintestinal manifestations in children most often parallel the activity of intestinal inflammation, but some follow an independent course.[112] Appreciation of this relationship determines whether specific therapy of the extraintestinal lesion is required. Other complications, although not inflammatory themselves, result directly from the presence of diseased bowel. These include nephrolithiasis and ureteral obstruction. Growth impairment is discussed separately and in detail because of its extreme significance and its multifactorial pathogenesis.

Joints

Arthritis is less common than arthralgias, but together they constitute the most common extraintestinal manifestations of Crohn disease (15%) in young patients.[112] As exemplified in Table 41.1-4, arthritis is the most likely of the extraintestinal manifestations to precede gastrointestinal manifestations of Crohn disease and dominate the clinical presentation. Typically, a few large joints are involved, especially the knees, hips, and ankles.[112,113] The appropriately named episodes of "colitic arthritis" tend to reflect inflammatory activity in the intestine and settle without deformity as the bowel disease is treated. An exception is the arthritis of juvenile ankylosing spondylitis, which occurs more frequently in IBD than in the general population and not only in those positive for HLA-B27.[112,113] Peripheral arthritis of the hips or sacroiliac joints precedes the spinal arthropathy, often requires specific anti-inflammatory treatment, and may progress independently of the bowel disease.[113]

Skin

The most commont cutaneous manifestations (with frequencies of occurrence based on a large adult series of Crohn disease patients) are erythema nodosum (8–15%) and pyoderma gangrenosum (1.3%).[111] Erythema nodosum tends to occur when the intestinal disease is active but does not necessarily indicate its severity. Pyoderma gangrenosum often runs its own course and requires specific medical treatment.[112]

Eye

Ocular lesions appear to be less common in young patients than in adults, but acute episcleritis. uveitis, and, rarely, orbital myositis do occur.[112] Asymptomatic uveitis has been described in Crohn disease predominantly when only the colon is involved, but there is no convincing evidence that it progresses to destructive ocular disease.[114]

Hepatobiliary

Primary sclerosing cholangitis (PSC) is associated most often with ulcerative colitis but may also occur with Crohn disease involving the colon. PSC preceded the clinical onset of the bowel disease in 50% of 17 predominantly adolescent patients (ulcerative colitis in 14, Crohn disease of the colon in 3) with the PSC-IBD combination identified in Toronto.[115]

Pancreas

Acute pancreatitis may occur, albeit rarely, as an extraintestinal manifestation of either ulcerative colitis or Crohn disease.[116] It can also be a direct complication of duodenal Crohn disease, PSC, or drug therapy (azathioprine, 6-mercaptopurine [6-MP], and 5-aminosalicylic acid [5-ASA]).

Renal

Renal complications of Crohn disease are not themselves inflammatory in nature but rather result from the presence of diseased bowel. These include ureteric obstruction and hydronephrosis from thickened, chronically inflamed bowel and an increased incidence of urinary stones.[117] Oxalate, urate, and phosphate stones may occur. In normal persons, oxalate in the lumen is bound to calcium, and the poorly absorbed calcium oxalate is excreted in the feces. However, when the ileum is diseased or has been resected, increased luminal concentrations of malabsorbed fatty acids compete for calcium. Oxalate absorption and subsequent renal excretion are therefore increased.

Vascular

Hypercoagulability from thrombocytosis, hyperfibrinogenemia, elevated factor V and factor VII, and depression of antithrombin III is seen in some patients with IBD.[118] Vascular complications have included deep vein thrombosis, pulmonary emboli, and cerebrovascular disease.[118]

Bone

Decreased bone density is increasingly recognized in Crohn disease.[119–122] The pathogenesis is multifactorial, but a major contributory factor appears to be inhibition of bone formation by cytokines.[123] As recently reported, bone density was reduced to osteoporotic levels in 25% of newly diagnosed children with Crohn disease prior to any corticosteroid therapy.[124] Rapid increments in bone mass are normally acquired during puberty, and peak bone mass attained is an important determinant of risk for subsequent osteoporosis in later life. Hence, childhood-onset Crohn disease may be a particular risk factor for long-term morbidity from clinical osteoporosis. Monitoring of bone densitometry and modification of other risk factors (exercise,

reduction in steroid use, hormonal treatment of chronic secondary amenorrhea in adolescent girls, calcium and vitamin D supplementation) are recommended. Treatment with bisphosphonates is now common among adult patients with Crohn disease and significantly decreased bone density, but experience with these agents in children has been very limited to date.

DISEASE COMPLICATIONS

Malnutrition

Weight loss and emaciation are the most prevalent nutritional disturbances in IBD. At the time of first diagnosis, approximately 85% of pediatric patients with Crohn disease have lost weight.[125] Multiple factors contribute to malnutrition. However, reduced intake, rather than excessive losses or increased needs, is the major cause of the caloric insufficiency. The child or adolescent may voluntarily refrain from eating to avoid aggravation of abdominal cramps and diarrhea. Moreover, disease-related anorexia may be profound. Cytokines produced by the inflamed bowel are likely responsible; TNF-α has been shown to produce anorexia.[110]

Intestinal malabsorption may factor in the equation leading to energy imbalance but is seldom a major cause. In Crohn disease involving the ileum, the processes of fat digestion and absorption may be altered either by loss of gut surface area owing to inflammation or by depletion of the circulating bile salt pool owing to bile acid malabsorption in the diseased ileum or deconjugation by bacteria. In a study years ago of adults prior to intestinal resection, Filipsson and colleagues found predominantly mild steatorrhea in 24% of patients with ileal disease, 26% of those with ileocolonic involvement, and 17% of those with Crohn colitis.[126]

Increased energy expenditure associated with active inflammation has been suggested as a further mechanism accounting for the frequency of malnutrition. In general, resting energy expenditure (REE) does not differ from normal in patients with inactive disease but can exceed predicted rates in the presence of fever and sepsis.[127] Furthermore, in comparison with comparably malnourished patients with anorexia nervosa, a lack of compensatory reduction in REE has recently been described in adolescents with Crohn disease.[128] A reduction in REE is a normal biologic response to conserve energy. Production of inflammatory mediators may explain the lack of REE adaptation in patients with Crohn disease and further augment the ongoing malnutrition.

Growth Impairment

Chronic malnutrition translates into impairment of linear growth and pubertal development in pediatric IBD. Inflammatory disease occurring during early adolescence is likely to have a major impact on nutritional status and growth because of the very rapid accumulation of lean body mass that normally occurs at this time. Further, boys are more vulnerable to disturbances in growth than girls are because their growth spurt comes at a later stage of normal pubertal development and is ultimately longer and greater.

Prevalence. Several recent studies have characterized the growth of children with Crohn disease as treated in the 1980s and into the 1990s.[129–133] These studies are important as a benchmark of outcomes with traditional therapy. It is to be hoped that the now better understanding of the pathogenesis of growth impairment, together with the greater efficacy of immunomodulatory and emerging biologic therapies in treating intestinal inflammation, may lead to enhanced growth of young patients diagnosed in the present decade.

As summarized in Table 41.1-5, the percentage of patients with Crohn disease whose growth is affected varies with the definition of growth impairment and with the nature of the population under study (tertiary referral center versus population based).[129–133] It has nevertheless been consistently observed that impairment of linear growth is common prior to recognition of Crohn disease and during the subsequent years and that height at maturity has often been compromised.[129–133] Height velocity is the most sensitive parameter by which to recognize impaired growth. It is important to obtain preillness heights so that the impact of the IBD can be fully appreciated. The greater the height deficit at diagnosis, the greater the demands for catch-up growth. This emphasizes the need for early recognition of Crohn disease in young patients and for new approaches to optimize the catch-up growth of those diagnosed late.

Pathophysiology. As summarized in Table 41.1-6, several interrelated factors contribute to growth impairment in children with Crohn disease. Chronic undernutrition has long been implicated and remains an important and

TABLE 41.1-5 PREVALENCE OF LINEAR GROWTH IMPAIRMENT IN PEDIATRIC CROHN DISEASE

STUDY	TIME OF ASSESSMENT	PATIENTS STUDIED	DEFINITION OF LINEAR GROWTH IMPAIRMENT	PERCENTAGE WITH GROWTH IMPAIRMENT
Kanof et al[108]	At diagnosis	Prepubertal (Tanner 1 or 2) patients (n = 50)	Decrease in height velocity	88
Kirschner[133]	At diagnosis		Decrease in height centile > 1 SD	36
Griffiths[129]	During follow-up	Prepubertal (Tanner 1 or 2) patients (n = 100)	Height velocity ≤ 2 SD for age for ≥ 2 yr	49
Hildebrand[130]	Before diagnosis or during follow-up	Population-based cohort of 46 children	Height velocity ≤ 2 SD for age for 1 yr	65

TABLE 41.1-6 FACTORS CONTRIBUTING TO GROWTH ABNORMALITIES IN CHILDREN WITH CROHN DISEASE

FACTOR	REASON
Cytokines produced by chronically inflamed intestine	Direct role of inflammatory cytokines in linear growth inhibition (IGF-1 inhibition; interference with kinetics of bone growth)
Insufficient caloric intake	Food avoidance because of exacerbation of gastrointestinal symptoms by eating; cytokine-mediated anorexia
Stool losses	Mucosal inflammation leading to protein-losing enteropathy; steatorrhea if extensive
Increased nutritional needs	Fever, chronic deficits
Corticosteroid treatment	Inhibition of IGF-1

IGF-1 = insulin-like growth factor 1.

remediable cause of growth retardation.[109] A simple nutritional hypothesis fails, however, to explain all of the observations related to growth patterns among children with Crohn disease. Within the past decade, the direct growth-inhibiting effects of proinflammatory cytokines released from the inflamed intestine have been increasingly recognized and are now the focus of very intriguing research.[110,123,134] It is postulated that inflammatory mediators, such as TNF-α and IL-6 secreted from the diseased gut, may interfere with growth plate kinetics and thereby suppress linear growth.[110,123] Daily corticosteroid use may also inhibit growth, but it is often difficult to separate the relative contributions of disease activity from corticosteroid use in the pathogenesis of slow linear growth in pediatric Crohn disease.[129,132]

Insulin growth factor 1 (IGF-1), produced by the liver in response to growth hormone stimulation, normally mediates growth hormone's effects on the growth plate of bones. An association between impaired growth in Crohn disease and low IGF-1 levels is well recognized.[135] Malnutrition,[135] cytokines,[134,136] and chronic daily corticosteroid therapy[137] may all suppress IGF-1 production. Recently, transgenic mice with defective growth were found to overexpress IL-6.[134] Antibody to IL-6 partially corrected the growth defect, whereas administration of IL-6 led to a decrease in IGF-1 before food intake was affected. Further, IGF-1 levels were negatively correlated with IL-6 among children with juvenile rheumatoid arthritis. These findings suggest that an IL-6–mediated decrease in IGF-1 production may represent a major mechanism by which chronic inflammation leads to stunting of growth.

From the foregoing discussion, it is clear that enhancement of linear growth is best achieved through control of intestinal inflammation without chronic corticosteroid therapy and assurance of adequate nutrition.[138]

Perianal Disease

Perianal abscesses and fistulae occur in one-third of patients over time, more frequently in association with colorectal disease in comparison with small intestinal disease.[139] When skin tags and fissures are included, the prevalence of perianal disease among pediatric patients at tertiary care centers is 14 to 62%.[139] Tags and fissures are often asymptomatic, but large inflamed tags, deeper fissures, perianal fistulae, and abscesses may contribute significantly to the morbidity of Crohn disease. A recent analysis suggests that the IBD5 risk haplotype at the chromosome 5q31 locus is associated with perianal lesions, providing further molecular evidence of a genetic basis for the clinical heterogeneity of Crohn disease.[140] This putative association will need to be re-examined when an actual gene is identified at this locus.

INVESTIGATION AND DIAGNOSIS

There is no single test that can confidently confirm the suspicion of Crohn disease. The diagnosis is made based on a compatible clinical presentation, substantiated by radiologic assessment of the small bowel, endoscopy of the ileocolon with pathologic examination of mucosal biopsies, and exclusion of other causes of chronic intestinal inflammation. *Salmonella*, *Shigella*, *Campylobacter jejuni*, enteropathogenic *Escherichia coli*, and *Clostridium difficile* infections are excluded with stool cultures. Serologic techniques are important in the diagnosis of *Yersinia* infections and amebiasis. Intestinal tuberculosis and schistosomiasis should be excluded when risk factors exist.

Ultrasonography has been used as a noninvasive screening test for suspected Crohn disease. Radiology and ileocolonoscopy (with mucosal biopsies for histologic assessment) are used to define the nature and extent of intestinal inflammation and to distinguish ulcerative colitis from Crohn disease. Differentiation of isolated colonic Crohn disease from ulcerative colitis is made on the basis of macroscopic and microscopic criteria. When features of both types of IBD are present, the designation of indeterminate colitis is applied, pending clarification with time and subsequent evaluations.[141]

Some clinicians recommend upper gastrointestinal endoscopy with biopsies as an adjunctive tool in differentiating the type of colitis, but caution must be exercised in interpreting all gastric or duodenal inflammmation as indicative of Crohn disease.[142] Nonspecific histologic gastritis is common in ulcerative colitis and in Crohn disease; focal antral gastritis may be more specific for Crohn disease[142]; the finding of granulomata on gastric antral biopsy may clarify a diagnosis of Crohn disease in an otherwise indeterminate colitis.[142] Technologic advances in magnetic resonance imaging (MRI) or ultrasonography, which allow assessment of the depth of intramural inflammation, may provide adjunctive information facilitating differentiation of Crohn colitis from ulcerative colitis.[143,144] However, in a pilot study of MRI of the colon in children with IBD, there was poor interobserver reliability between radiologists and poor correlation with diagnosis based on conventional endoscopic and histologic criteria.[145]

Serologic Tests in the Diagnosis of IBD

Recently, antineutrophil cytoplasmic antibodies (ANCAs) and anti-*Saccharomyces cerevisiae* antibody (ASCAs) have been recommended as tools to facilitate screening for IBD among children with suggestive symptoms and to differentiate ulcerative colitis from Crohn disease.[146]

ASCAs are immunoglobulin (Ig)G and IgA antibodies that recognize mannose sequences in the cell wall of *S. cerevisiae* strain Su1. ASCA is detected in 55 to 60% of children and adults with Crohn disease and in 5 to 10% of controls with other gastrointestinal disorders, findings indicating good specificity but relatively poor sensitivity.[146–148] The specificity of the antibody response makes it unlikely that the elevated titers result merely from increased intestinal permeability. It is possible that *S. cerevisiae* shares antigenic determinants with another organism of true etiopathogenetic significance in Crohn disease. An increased prevalence in relatives is reported.[149] Whether such clustering is due to genetic or environmental factors is unknown.

ANCAs, originally described in Wegener granulomatosis and necrotizing vasculitis, are IgG antibodies directed against cytoplasmic components of neutrophils. The association with IBD of a subset of ANCA with a perinuclear staining pattern on immunofluorescence studies (pANCA) was first recognized for ulcerative colitis.[150] The specificity of perinuclear staining for IBD can be confirmed by its disappearance after desoxyribonuclease digestion of neutrophils. Studies in both adult and pediatric patients have consistently supported the specificity of pANCA for IBD versus infectious colitides and other gastrointestinal disorders.[148,151,152] However, sensitivity is poor because pANCA is positive in only 50 to 65% of pediatric patients with ulcerative colitis.[148,152] ANCAs are produced by B cells in the lamina propria of the colonic mucosa but do not appear to contribute directly to tissue injury in IBD. Rather, pANCA is considered a marker of the immunologic disturbance that underlies the development of chronic colonic inflammation. Further, there is evidence that HLA class II genes influence ANCA status.[153] Hence, ANCA may prove to be a marker of heterogeneity of genetic susceptibility to IBD.[153]

The relatively low sensitivities of serology for Crohn disease and ulcerative colitis argue against there being any additional value for ASCA or ANCA as routine or first-line screening tests for IBD compared with clinical acumen and the equally sensitive (albeit less specific) measurement of acute-phase reactants. Moreover, the need to perform definitive radiologic and endoscopic studies to guide therapy by defining the extent and nature of disease will not be averted by positive serologic tests.

Combined ANCA or ASCA testing has recently been recommended to help differentiate Crohn disease from ulcerative colitis.[146] However, differentiation of Crohn disease from ulcerative colitis is clinically problematic only when inflammation is largely confined to the colon. pANCA is positive in up to 35% of patients with colonic Crohn disease, and ASCA is less often detected in patients with Crohn disease confined to the colon.[147,148,154,155] Hence the utility of serology is less in the setting where it is needed most. In the one published study clearly reporting sensitivity, specificity, and predictive values of combined serologic testing, the sensitivity of ASCA+pANCA– serology for Crohn colitis versus ulcerative colitis was only 32%.[147] However, the specificities of ASCA+pANCA– serology for Crohn colitis and pANCA+ASCA– serology for ulcerative colitis are high, so the predictive values are also high in the presence of a positive test.

TREATMENT

Basic Principles Governing Treatment

The challenge in treating each child or adolescent with Crohn disease is to employ pharmacologic, nutritional, and, where appropriate, surgical interventions, not only to decrease mucosal inflammation and thereby alleviate symptoms but also to optimize growth, normalize pubertal development, facilitate normal social development, and avoid long-term disease-related complications.

Growth is a measure of the success of therapy. Based on the pathogenesis of growth impairment in Crohn disease, as discussed above and summarized in Table 41.1-7, optimization of treatment of intestinal inflammation and provision of adequate nutrition are of paramount importance in preventing or remedying growth impairment.[138] Control of gastrointestinal symptoms by long-term corticosteroid use, which impedes linear growth, does not constitute successful medical management. Optimal treatment of intestinal inflammation encompasses, as is discussed in detail in subsequent sections, immunomodulatory therapy, biologic therapies, nutritional therapies, and, if appropriate, resection of diseased bowel.

The natural history and severity of Crohn disease vary greatly among patients. Increasingly, gastroenterologists are acknowledging the heterogeneity of disease and the varying treatment responsiveness of individual patients. The identification of genetic or other markers predictive of disease behavior would constitute a significant advance, allowing early selection of the most appropriate treatment plan for individual patients.

Crohn disease has traditionally been thought of as a disease characterized by exacerbations and remissions. It must be acknowledged, however, that the term "remission," as generally applied, is a clinical concept. The persistence of endoscopic and histologic lesions, despite resolution of symptoms and biochemical abnormalities with corticosteroid therapy, has been well documented.[156,157] With emerging biologic agents and optimal use of immunomodulatory drugs, healing of intestinal lesions may, however, become a more achievable goal.

Nutritional Support

Nutritional support is a vital component of the management of patients with Crohn disease. Management goals must include correction and prevention of nutritional deficits and control of symptoms.

General Dietary Measures. For children and adolescents, the most important advice is to consume a diet liberal in protein with calories sufficient to maintain or

TABLE 41.1-7 SUMMARY OF EVIDENCE-BASED PHARMACOLOGIC TREATMENT OF CROHN DISEASE

TYPE OF CROHN DISEASE	ACTIVE DISEASE	MAINTENANCE OF REMISSION
ILEAL OR OTHER SMALL BOWEL DISEASE		
Mild	Oral 5-ASA (50–100 mg/kg/d up to 4 g/d) (Pentasa or Salofalk most suitable)	(Oral 5-ASA frequently used, but RCT data combined in meta-analysis do not support a benefit when compared with placebo)
Mild or moderate	Controlled ileal release budesonide (9 mg/daily) for ileal and/or right colonic inflammation	
Moderate or severe	Conventional corticosteroids (1 mg/kg/d up to 40–60 mg/d prednisone)	6-MP (1.5 mg/kg/d)* Azathioprine (2 mg/kg/d)* Methotrexate
Otherwise refractory and extensive	Infliximab	Infliximab
COLONIC DISEASE		
Mild to moderate	Oral 5-ASA (Asacol or Dipentum most suitable) Sulfasalazine† ?5-ASA enemas‡ Metronidazole (10–20 mg/kg/d up to 1 g daily) Ciprofloxacillin (20 mg/kg/d)	(Oral 5-ASA or sulfasalazine frequently used; RCT data combined in meta-analysis do not support a benefit when compared with placebo)
Moderate or severe	Conventional corticosteroids (1 mg/kg/d up to 40–60 mg/d prednisone) Methotrexate	6-MP (1.5 mg/kg/d)* Azathioprine (2 mg/kg/d)* Methotrexate
Otherwise refractory	Infliximab	Infliximab
PERIANAL

5-ASA = 5-aminosalicylic acid; 6MP = 6-mercaptopurine; RCT = randomized controlled trial.
*Delayed onset of action.
†May have an adjunctive role with corticosteroids.
‡Not subjected to controlled clinical trial.

restore weight and to support growth in children and adolescents. For children, recommendations for daily intakes of total calories and protein should be made according to their height for age and need for catch-up growth. Liquid dietary supplements may help motivated patients achieve these goals, although in young patients, these will often simply displace ingested calories from regular food without increasing total caloric intake.

Except in specific circumstances (eg, a low-residue diet to reduce obstructive symptoms in the setting of small intestinal stricture), a full diet for age is most appropriate.

Intensive Nutritional Support. Intensive nutritional support rather than simple dietary counseling to increase caloric intake is required when patients are significantly malnourished or when growth is retarded.[109,158,159] Adjunctive nutritional support in these contexts may be provided by enteral nutrition using formulated food or via parenteral nutrition using a centrally placed intravenous catheter. Nocturnal nasogastric infusion of formulated food has come to constitute the preferred and more frequent approach by virtue of its lower complication rates and easier and less costly administration.[158,159]

PHARMACOLOGIC TREATMENT

Drugs constitute the mainstay of treatment of children and adolescents with Crohn disease, although enteral nutrition using formulated food is commonly and effectively employed as an alternate primary therapy of active inflammation in some parts of the world, particularly in the United Kingdom. Table 41.1-7 summarizes validated pharmacologic options for the treatment of active inflammation and the maintenance of clinical remission based on the nature and localization of disease. Multicenter randomized controlled trials conducted predominantly among adults have helped establish the effectiveness of these therapies. For several of the commonly employed drugs, meta-analyses of individual controlled trial data have been performed. The efficacy of combination therapy (ie, more than one drug used in adjunctive fashion) has seldom been addressed in the clinical trial setting. Pharmacokinetic and dose-ranging studies have hitherto seldom been conducted in children; recommended dosages in Table 41.1-8 are based on extrapolation from adult studies.

The pharmacokinetics, mechanism of action, and potential adverse effects of individual drugs are discussed and the evidence of their therapeutic efficacy critically appraised in the forthcoming sections. The challenge at the present time is to wisely employ immunomodulatory and emerging biologic therapies, with the goal of improving outcomes, particularly for the subgroup of pediatric patients with otherwise chronically active, extensive, and disabling disease, formerly all too often associated with compromised growth.[129]

Systemic Corticosteroids. Corticosteroids have traditionally been the mainstay of treatment of active Crohn dis-

TABLE 41.1-8 SULFASALAZINE AND ORAL 5-AMINOSALICYLIC ACID ANALOGUES

GENERIC NAME	TRADE NAME	DOSAGE FORM	RELEASE MECHANISM	SITE OF RELEASE
Sulfasalazine	Azulfidine	500 mg tablets	Bacterial cleavage of diazo bond	Colon
Olsalazine	Dipentum (Pharmacia)	250 mg capsules	Bacterial cleavage of diazo bond	Colon
Mesalamine	Asacol (Proctor and Gamble, US and Canada; Tillots, UK)	400 mg tablets	pH-dependent breakdown	Distal ileum or right colon (pH > 7.0)
Mesalamine	Salofalk (Interfalk); Claversal (Smith, Kline & French, US); Rowasa (Reid-Rowell, US)	250 and 500 mg tablets	pH-dependent breakdown	From mid- to small bowel distally (pH > 5.6)
Mesalamine	Pentasa (Marion, US; Ferring, Canada; Ferring, Europe)	250 and 500 mg tablets	Timed release	Throughout small intestine and colon

ease. The various systemic glucocorticoids differ with respect to the duration of action, relative glucocorticoid potency, and relative mineralocorticoid activity. Oral prednisone in North America, the comparable prednisolone in Britain, and the slightly more potent methylprednisolone in Europe are favored. They offer the advantage of minimal mineralocorticoid effects, unlike parenteral hydrocortisone.

Pharmacology and Mechanism of Action. Prednisone is a synthetic glucocorticoid of intermediate potency. It is converted to its active form, prednisolone, in the liver. Both prednisone and prednisolone are promptly and completely absorbed in most individuals. The possibility of reduced absorption in patients with active Crohn disease of the small intestine must be borne in mind. The concept that the effects of corticosteroids at the tissue level outlast drug concentrations in serum is important to the derivation of treatment regimens. Intermittent rather than sustained high blood levels, as long as therapeutically efficacious, are preferable by virtue of causing fewer side effects.

The multifactorial mode of action of corticosteroids, although not completely understood, relates both to their inhibition of cell-mediated immunity and their anti-inflammatory effects. It has been recently demonstrated that steroids inhibit NF-κβ function, diminishing the release of inflammatory cytokines, IL-1 and IL-2.[160] Anti-inflammatory effects include decreased capillary permeability, impaired neutrophil and monocyte chemotaxis, and stabilization of lysosomal membranes. Eicosanoid production is decreased by inhibition of phospholipase, preventing arachidonic acid liberation from membranes. Additionally, steroids decrease diarrhea in inflammatory bowel disease by enhancing sodium and water absorption.

Potential Adverse Effects. The potential toxicity of systemic corticosteroids is well known and has been recently reviewed in the context of IBD.[161] Disfigurement by acne, moon facies, hirsutism, and cutaneous striae are the most commonly observed adverse effects with treatment of acute IBD and are particularly distressing to teenagers, despite assurances of reversibility following drug withdrawal. Pseudotumor cerebri, steroid psychosis, and proximal myopathy are other, fortunately rare, sequelae of steroid therapy. Corticosteroid use also may contribute to renal calculi formation via hypercalciuria. Aseptic necrosis of the femoral head is one of the most serious consequences of steroid therapy and may be mistaken for IBD arthropathy.

There are many reasons to avoid chronic corticosteroid use. Daily glucocorticoid administration suppresses IGF-1 and consequently inhibits linear growth.[137] Alternate-day corticosteroids allow IGF-1 secretion to normalize and hence do not have the same direct growth-inhibiting potential. The effects of corticosteroids on bone are of particular concern and include both enhanced bone resorption and diminished bone formation.[162] Corticosteroids decrease calcium absorption but increase urinary calcium excretion. The secondary hyperparathyroidism is associated with osteoclastic activity. Dietary supplementation with calcium and vitamin D may be of some prophylactic benefit in reducing the rate of corticosteroid-related bone calcium loss.[162] The incidence of posterior subcapsular cataracts correlates with the dose and duration of therapy. Glucocorticoids also increase intraocular pressure.

Evidence-Based Therapeutic Indications. Corticosteroids have been the most widely used pharmacologic agents for moderate or severe acute exacerbations of Crohn disease. Corticosteroid-induced clinical remission, however, is usually associated with persistence of endoscopic lesions.[156,157]

Active Disease. Steroid use in active Crohn disease of the small intestine alone or small intestine plus colon has been validated by the National Cooperative Crohn's Disease Study (NCCDS) and the European Cooperative Crohn's Disease Study (ECCDS).[163,164] Disease confined to the colon, which, interestingly, proved relatively refractory to corticosteroid therapy in the NCCDS, benefitted from combination therapy with sulfasalazine in the European study.[163,164] There are no studies directly comparing different corticosteroid dosing regimens in adults or in children. The NCCDS titrated the dose of prednisone to the level of disease activity with a daily dose range of 0.25 to 0.75 mg/kg (maximum 60 mg). The Canadian Pediatric Crohn Disease Study employed 1 mg/kg oral prednisone (maximum 40 mg) as a once-daily dose, with the option of increasing this dose briefly to 2 mg/kg/d (maximum 60 mg) if disease was refractory to the lower dose during the first 7 days of therapy. Overall, 92% of children and adolescents with active Crohn disease involving the small intestine alone or small intestine plus colon responded to this corti-

costeroid regimen.[165] In this trial, the daily prednisone dosage was tapered from 1 mg/kg/d by 5 mg each week beginning 4 weeks after attainment of clinical remission.

Maintenance of Remission. There is little justification from longitudinal placebo-controlled trials in adults for the use of low-dose corticosteroids (less than 20 mg prednisone daily in adults) to prevent relapse in patients with inactive Crohn disease.[163,164] The ECCDS did suggest a benefit to continuation of low-dose prednisolone after clinical remission of Crohn disease was induced by its use.[164] Such patients could be considered to have corticosteroid-dependent disease, as occurred in 45% of adult patients in a population-based study of outcomes in adult patients.[166] Such chronic daily corticosteroid administration is contraindicated in childhood because of the associated suppression of IGF-1 and the consequent inhibition of linear growth. Low-dose alternate-day prednisone therapy, formerly advocated for children as a strategy to maintain remission without impeding linear growth,[167] is not evidence based and has little place in current pediatric treatment alogorithms. In short, children with "corticosteroid-dependent" disease require alternative therapies.

Controlled Ileal Release Budesonide. *Pharmacology and Mechanism of Action.* Both therapeutic and adverse effects of glucocorticosteroids are mediated via the glucocorticosteroid receptor, which is uniform in all cells. To separate therapeutic from unwanted effects, glucocorticoids have been developed with a high affinity for the glucocorticosteroid receptor in the intestinal mucosa (and therefore high topical anti-inflammatory potency) but a rapid transformation to inactivated metabolites by the liver following absorption (and therefore low risk of systemic effects).[168] One such compound is budesonide, which has now been formulated into orally administered delayed-release capsule preparations to facilitate delivery to the terminal ileum and proximal colon. Microgranules of the nonhalogenated glucocorticoid bound to ethylcellulose are encapsulated by Eudragit L resin and released at a pH greater than 5.6 in one preparation.[169,170] Another delayed-release formulation more recently available in Europe releases budesonide at a pH greater than 6.[171] Budesonide possesses a high topical potency, with affinity for the glucocorticosteroid receptor 15 times that of prednisolone. Rapid metabolism in the liver to compounds with vastly lower affinity for the glucocorticosteroid receptor results in systemic bioavailability of only 10% compared with 80% for prednisolone.[168]

Adverse Effects. The major promise of oral budesonide formulated for intestinal release is decreased adverse systemic effects in comparison with classic corticosteroids. In clinical trials, no serious corticosteroid-related toxicity has been encountered, and the incidence of overall adverse effects has been less than with prednisolone.[169–178] A dose-related biochemical impairment of adrenal function as measured by basal cortisol levels and responses to adrenocorticotropic hormone stimulation has been observed, albeit also less than with conventional oral steroids.[169,170,173]

Evidence-Based Therapeutic Indications. *Active Crohn Disease.* The major clinical indication for the hitherto available oral budesonide formulations is in the treatment of Crohn disease involving the ileum and/or right colon. In one multicenter randomized placebo-controlled trial, 8 weeks of treatment of adults with 9 mg controlled ileal release (CIR) budesonide daily resulted in clinical remission in 51% of patients compared with 20% in the placebo group.[169] In two subsequent trials, the same CIR budesonide regimen induced remission in 60% and 53% of patients, respectively, compared with 60% and 66% of adult patients treated with prednisolone.[170,172] In a recently completed multicenter randomized controlled trial versus oral prednisone in children with active Crohn disease localized to the ileum and/or right colon, 55% achieved clinical remission with CIR budesonide compared with 71% with prednisolone.[173] Taken together, the extensive randomized controlled trial data and clinical experience in adults and children suggest that response rates with CIR budesonide are intuitively less than those achieved with optimal dosing of prednisone or prednisolone. Indeed, a treatment benefit for conventional corticosteroids has been confirmed in a meta-analysis.[174] Nevertheless, CIR budesonide may spare a proportion of young patients the adverse effects of short-term conventional steroids while successfully ameliorating their Crohn disease.[173]

Only the German Budesonide Study Group has studied the efficacy of an oral budesonide formulation in patients with more distal colonic disease. Comparable percentages of patients with distal colonic involvement and ileal with or without proximal colonic disease, 51% and 59%, respectively, attained clinical remission in this open-label study with the budesonide formulation designed for release at a pH greater than 6.[171]

Maintenance of Remission in Crohn Disease. Four randomized placebo-controlled studies have examined the efficacy of CIR budesonide in maintaining medically induced clinical remission.[175–178] CIR budesonide 6 mg daily in adults significantly prolonged the median duration of remission in comparison with placebo in two multicenter studies, but at 1 year following randomization, there was no difference in the percentage of patients remaining in continuous remission.[175,176] Two other placebo-controlled studies demonstrated a similar lack of efficacy at 1 year and no delay in the median time to relapse with daily doses of 6 mg or 3 mg CIR budesonide in comparison with placebo.[177,178] At present, long-term use to maintain remission in children must be considered experimental because of the marginal benefit observed among adults and the drug's hitherto unknown effect on linear growth.[179]

Sulfasalazine and Oral 5-ASA. Sulfasalazine and 5-ASA have a greater role in the management of ulcerative colitis than in Crohn disease. Indeed, the multiple oral 5-ASA formulations, designed in part to extend the scope of efficacy to include active and preventive treatment of Crohn disease, have, in this respect, proved disappointing.

Pharmacology and Mechanism of Action. Sulfasalazine consists of 5-ASA in azo-bond linkage with sulfapyridine. The sulfa moiety functions primarily as a carrier facilitating delivery of the therapeutically active 5-ASA to the colon. There it is released from the parent molecule

by bacterial cleavage of the diazo bond and acts locally in the colonic mucosa to impede the inflammatory process. The sulfapyridine component is 95% absorbed and undergoes acetylation, hydroxylation, and glucuronidation in the liver. 5-ASA is now recognized to modify neutrophil-mediated tissue damage through a multiplicity of actions, including inhibition of leukotriene biosynthesis via the lipoxygenase pathway of arachidonic acid metabolism, interference with myeloperoxidase activity, scavenging of reactive oxygen species, and inhibition of NF-κβ.[180] Even though the sulfapyridine component is therapeutically inert, there is new evidence that the complete parent molecule may act synergistically to enhance the anti-inflammatory effects of its component 5-ASA.[181]

5-ASA ingested orally in nonprotected form is rapidly absorbed in the proximal small intestine. Alternate delivery systems have been developed to facilitate transport and release of 5-ASA distally without the sulfa carrier. The plethora of available oral 5-ASA analogues differ importantly with respect to the mechanism and site of 5-ASA release.[182] The balance among release, local inactivation, and local absorption determines intraluminal drug levels at specific sites.[182,183] High 5-ASA concentrations within the intestinal wall are thought to optimize anti-inflammatory actions.

Table 41.1-8 lists the oral 5-ASA preparations currently in clinical use. These analogues are best understood in three groups. First, olsalazine, in which 5-ASA is attached to a second molecule of itself, depends, like sulfasalazine, on bacterial cleavage of the azo-bond. Other azo-bond derivatives are ipsalazide and balsalazide, which contain 5-ASA linked to an inert, unabsorbable carrier molecule. Second, the delayed-release preparations, known collectively as mesalazine in Europe and mesalamine in the United States, employ different acrylic-based resins, designed to break at a set pH, thereby making 5-ASA available to the intestinal mucosa. Finally, the timed-release formulation Pentasa contains 5-ASA in microgranules coated with a semipermeable membrane of ethylcellulose. Release occurs continually but at a rate affected by pH. The predicted sites of intestinal release are given in Table 41.1-8. However, 5-ASA preparations that require specific alterations in pH for release may not, for example, be distributed uniformly in patients with IBD, in whom the pH of luminal contents has been shown to differ from that of normal subjects.[184]

Potential Adverse Effects. Potential toxicity of sulfasalazine is considerable.[185] Overall, 20 to 25% of patients experience adverse reactions that either limit drug dosage or preclude use entirely. Undesirable effects fall into two categories, dose related and idiosyncratic or hypersensitivity, but the majority of both types seem attributable primarily to the therapeutically unimportant sulfapyridine component.[185] Dose-dependent adverse effects include nausea, vomiting, headaches, and mild hemolysis. The dose of sulfasalazine at which such reactions occur varies among individuals, partly reflecting acetylator status and its effect on sulfapyridine metabolism. Temporary interruption of therapy followed by a more gradual increase in dosage may avoid a recurrence of dose-dependent adverse effects. Glucose-6-phosphate dehydrogenase deficiency aggravates hemolysis and is therefore a contraindication to sulfasalazine administration. Idiosyncratic adverse reactions demand cessation of therapy rather than dose reduction. These, fortunately, are much less common than the dose-dependent effects and usually occur at the initiation of therapy. Fever, exanthems including Stevens-Johnson syndrome, pulmonary fibrosis, hepatotoxicity, and, rarely, agranulocytosis have all been reported. A known hypersensitivity to sulfonamides is a contraindication to sulfasalazine therapy. The infrequent occurrence of exacerbation of colitic symptoms is considered related to the 5-ASA constituent rather than to sulfapyridine.[186] Sulfasalazine also reversibly impairs male fertility.[187] Sperm morphology and motility revert to normal after discontinuation of the drug. Sulfasalazine reduces folate absorption, but supplementation to prevent anemia does not seem routinely necessary.

Eighty to 90% of patients intolerant of or allergic to sulfasalazine will tolerate oral 5-ASA.[188] Occasionally, the same adverse hypersensitivity reaction, such as fever and/or rash or exacerbation of colitic symptoms, is observed.[188] The most serious idiosyncratic reactions associated with sulfasalazine (ie, agranulocytosis, pulmonary complications) have not been reported with 5-ASA. Sulfasalazine-related impairment of male fertility resolves with a change to 5-ASA. However, several case reports of acute pancreatitis in association with mesalazine formulations have been published.[189] Olsalazine, which can act as a secretagogue in the distal ileum, causes diarrhea in 10 to 15% of patients.[190]

Evidence-Based Therapeutic Indications. *Active Disease.* In both the NCCDS and the ECCDS, sulfasalazine proved efficacious in treating inflammation involving the colon.[163,164] The European study suggested, furthermore, an adjunctive role in isolated colonic Crohn disease, which is often relatively resistant to corticosteroid therapy alone.[164] Isolated ileal Crohn disease was refractory to sulfasalazine therapy in both collaborative studies.

Timed-release and pH-dependent formulations designed to extend the scope of efficacy of 5-ASA have demonstrated, at most, modest benefit when employed at high dosages in adults with active disease.[191] For example, in one large multicenter study, 4 g of timed-release 5-ASA was superior to placebo and 1 g and 2 g of active drug, but the mean reduction in the Crohn Disease Activity Index (CDAI) even with the highest dosage was only 72 ± 13 points.[191] The best reported results have been in isolated ileitis, in which 4 g of a timed-release microgranular formulation achieved a mean change in CDAI of –123 at 12 weeks.[192] In keeping with these modest results, timed-release 5-ASA (4 g) induced clinical remission in significantly fewer patients (36%) than did CIR budesonide (69%).[193]

If children with mildly active Crohn disease are to be treated with 5-ASA or sulfasalazine, the choice of formulation should be made based on knowledge of the site(s) of intestinal inflammation to be targeted. Dosage of 5-ASA is extrapolated from adult studies; dose-ranging trials of efficacy, specifically in children, are lacking.

Maintenance of Remission. There is a paucity of data to support the efficacy of sulfasalazine in maintaining remission of quiescent Crohn disease. Neither the NCCDS

or the ECCDS demonstrated a statistically significant benefit in comparison with placebo.[163,164] The efficacy of oral 5-ASA in maintaining remission in Crohn disease has been observed in several individual randomized placebo-controlled trials, but initial enthusiasm has waned because additional data have been accrued. In an elegant meta-analysis, Camma and colleagues combined data from 2,097 patients with medically and surgically induced remission in 15 trials, including several large studies.[194] In the setting of medically induced remission, the pooled risk difference with oral 5-ASA versus placebo was not significant (–4.7%; 95% CI –9.6–2.8%). Hence, in keeping with earlier results achieved with sulfasalazine,[163,164] randomized controlled trial data in adults do not support the use of mesalamine therapy to maintain medically induced remission in patients with inactive Crohn disease.[194] Similarly, in a recently reported pediatric study, the 1-year remission rate with timed-release 5-ASA (50 mg/kg/d) initiated immediately following successful medical treatment of active disease was no different than with placebo (43% vs 37%).[195]

In the Camma and colleagues' meta-analysis, the therapeutic effectiveness of mesalamine appeared to be increased in the setting of a surgically induced remission, where the pooled risk difference was –13.1% (95% CI 0.05–0.21). As a measure of the efficacy of postoperative 5-ASA, the overall risk difference between the frequency of relapse in treated and control groups was calculated, allowing easy computation of the number of patients needing treatment to prevent one relapse.[194] Based on these data, one would need to treat eight patients following surgical resection to prevent one postoperative recurrence.[194] However, in the subsequently reported well-designed ECCDS of 318 adults, there was overall no significant difference in 18-month clinical relapse rates with timed-release 5-ASA (24.5 ± 3.6%) versus placebo (31.4 ± 3.7%) begun immediately postoperatively.[196] With these additional data in the trial literature, the number needed to treat rises to 25, and it becomes hard to defend an evidence-based recommendation for routine use of oral 5-ASA to maintain remission following intestinal resection of all grossly diseased bowel.[197] In a subgroup analysis of the ECCDS data, however, a delay in disease recrudescence was identified among patients who had undergone resection for isolated small bowel disease.[196]

Antibiotics and Probiotics. The clear implication of microbial flora in the pathophysiology of intestinal inflammation in Crohn disease has led to a resurgence of interest in the use of antibiotics and, more recently, probiotics. Supportive data are, however, relatively scarce. Metronidazole has been the most frequently studied drug, but, recently, ciprofloxacin has been employed alone or in combination.

Probiotics, defined as "living organisms, which upon ingestion, exert health benefits," belong generally to a large group of bacteria that make up the natural microflora and dwell as harmless commensals. Varieties of probiotics, which have been tested in limited fashion in inflammatory bowel disease, include lactobacilli, bifidobacteria, streptococci, nonpathogenic strains of *Escherichia coli*, and the yeast strain *Saccharomyces boulardii*.

Evidence-Based Therapeutic Indications. Metronidazole is well established, albeit not by randomized controlled trial data, in the control of perianal fistulae in Crohn disease.[198,199] In the treatment of intestinal inflammation, metronidazole was found to be at least as effective as sulfasalazine in a double-blind crossover Swedish multicenter study.[200] More recently, metronidazole was associated with a greater reduction in Crohn disease activity than was placebo, although not with a superior remission rate.[201] Two doses employed (10 mg/kg/d and 20 mg/kg/d) were comparable; the lower dose is preferred because of concerns about potential peripheral neuropathic effects with long-term use. In both studies, colonic inflammation responded better than disease confined to the small intestine.[200,201] In a small randomized study of metronidazole plus ciprofloxacin versus methylprednisolone for active Crohn disease, the clinical response rates were, respectively, 45% and 63%.[202] The combination of metronidazole plus ciprofloxacin did not enhance the efficacy of CIR budesonide in active Crohn disease involving the ileum and right colon.[203] There are supportive data for the use of metronidazole to delay recurrence after ileal resection.[204] Antimycobacterial regimens have not demonstrated benefit in comparison with placebo.[205]

The small number of IBD patients who have been treated in a randomized controlled fashion with probiotics have, to date, most often had ulcerative colitis or pouchitis. A recent combined antibiotic-probiotic regimen showed some promise in comparison with oral 5-ASA in the prevention of postoperative recurrence of Crohn disease.[206] As further trials of probiotic therapy are undertaken, it must be remembered that each strain exerts different and specialized functions. Viability and survival of organisms must be well documented; benefit of one preparation does not imply the efficacy of another.

Potential Adverse Effects. Metronidazole may cause a peripheral predominantly sensory neuropathy, which appears to be related to the dosage and duration of therapy.[207] Clinical experience suggests that paresthesiae always resolve, albeit at times very slowly, following discontinuation of metronidazole. Adolescents should be warned of metronidazole's disulfiram-like effect with alcohol ingestion. Another concern with long-term metronidazole therapy in young patients arises from its mutagenic and carcinogenic effects observed in laboratory animals. Ciprofloxacin has caused damage to growing bone in some laboratory animal species, but such adverse effects have not been observed in children despite substantial use in a variety of pediatric conditions.

Azathioprine and 6-MP. The immunomodulatory drugs azathioprine and 6-MP have become a mainstay of the management of pediatric Crohn disease, a reflection of the increased body of evidence in support of both their therapeutic efficacy and safety profile.[208] Their delayed onset of action precludes a role for azathioprine or 6-MP monotherapy in acute treatment.[208] Their importance as steroid-sparing agents in controlling intestinal inflamma-

tion and maintaining remission and thereby ameliorating growth in children is now well established.[208,209]

Pharmacology and Mechanism of Action. 6-MP is a purine analogue capable of interfering with endogenous purines, essential components of ribonucleic acid and DNA.[210] It has cytotoxic and immunosuppressive properties. Azathioprine was developed as a prodrug permitting liberation of 6-MP in tissues. The related structure of the two drugs leads one to anticipate similar clinical effects, but no directly comparative studies exist. There is some evidence from animal studies that azathioprine may have a better therapeutic index, that is, the ratio of therapeutic immunosuppressive to toxic dose.[211] The multiple mechanisms by which 6-MP and azathioprine modify immune responses are uncertain but include direct cytotoxicity, inhibition of cytokine synthesis, and, for azathioprine, additional immunologic effects of the nitroimidazoles, released from the prodrug at the same time as 6-MP.[210,211]

As shown in Figure 41.1-6, azathioprine undergoes a series of enzymatic reactions leading to the formation of 6-thioguanine nucleotide (6-TGN), considered the active but myelotoxic metabolite. Cytotoxicity results when these nucleotides are incorporated into DNA. The time to reach steady state for these cytotoxic intracellular metabolites may take up to several months, hence explaining the delayed median clinical response time of 3 to 4 months. In competing enzymatic pathways, thiopurine methyltransferase (TPMT) catalyzes the formation of 6-methylmercaptopurine ribonucleotides (6-MMPRs), metabolites that are therapeutically inactive and potentially hepatotoxic.[212]

Codominantly inherited polymorphic alleles confer high ($TPMT^H$) and low ($TPMT^L$) functional TMPT activity, which potentially impacts the therapeutic response to azathioprine and its toxicity. Approximately 89% of the population carry two wild-type $TPMT^H$ alleles ($TPMT^H/TPMT^H$) and have high TPMT activity (> 9.5 U/mL red blood cells [RBCs]); 11% are heterozygous ($TPMT^H/TPMT^L$) and have intermediate activity (5.0–9.5 U/mL RBCs); and 0.3% are homozygous for the variant $TPMT^L$ allele ($TPMT^L/TPMT^L$) and have low or undetectable activity (< 5.0 U/mL RBCs).

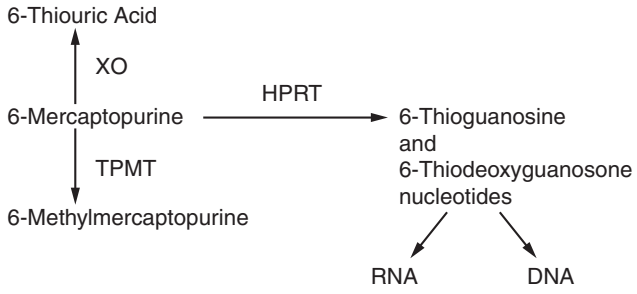

FIGURE 41.1-6 6-Mercaptopurine (6-MP) metabolism. The initial metabolism of 6-MP occurs along the competing routes catalyzed by thiopurine methyltransferase (TPMT), xanthine oxidase (XO), and hypoxanthine phosphoribosyltransferase (HPRT). Relative deficiency of TPMT or competition for XO leads to increased formation of 6-thioguanosine and 6-deoxythioguanosine nucleotides. The corporation of these nucleotides into ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) induces cytotoxicity.

Moreover, sulfasalazine and 5-ASA are recognized to inhibit TPMT activity.[212,213]

Potential Adverse Effects. Sandborn and colleagues categorized the adverse effects of azathioprine and 6-MP as allergic (dose independent) or nonallergic (dose and metabolism dependent).[214] The hypersensitivity reactions, which resolve with discontinuation of therapy, include fever, pancreatitis, rash, arthralgias, nausea, vomiting, and diarrhea. Nonallergic toxicities include severe leukopenia, thrombocytopenia, infection, hepatitis, and a theoretically increased malignancy risk.

Several groups have summarized the frequency of these acute and long-term unwanted complications of azathioprine or 6-MP administration.[214–218] Treatment was discontinued because of an adverse effect in 17 (18%) of 95 children and adolescents,[215] a higher overall percentage than in previous adult series.[214,216] The most common hypersensitivity reaction among adults and children is pancreatitis, occurring in 3 to 4% of patients and almost always within the first several weeks of starting therapy.[219] Fever and gastrointestinal intolerance manifest by vomiting necessitated cessation of treatment in 4% and 3%, respectively, of pediatric patients.[215] Bone marrow toxicity may be seen shortly after therapy is begun but also many years into therapy.[216,217] Accordingly, white blood cell counts should be monitored throughout the duration of therapy. Peripheral white blood cell counts below 2,500/mm^3 were reported in 2% of patients during more than 20 years of experience with 6-MP.[216] The British experience of 4% leukopenia with azathioprine includes two deaths, both related to bone marrow aplasia, among 714 patients with IBD.[217] Leukopenia is partly dose related, but individual susceptibility also varies, related in part to genetically determined differences in drug metabolism.[213]

It has been argued by some that TPMT activity and/or genotype be determined prior to commencing azathioprine or 6-MP as a means of avoiding serious myelosuppression. However, observed myelosuppression is, for the majority of patients, related to factors other than $TPMT^L$ activity.[213,219] Whatever the TPMT genotype, white cell counts will still need to be monitored throughout the duration of azathioprine or 6-MP therapy.[213,217,219] As an example, Colombel and colleagues reported TPMT genotype analysis in 41 Crohn disease patients, all of whom had experienced leukopenia (white cell count < 3.0×10^9/L) or thrombocytopenia (platelets < 10^9/L) leading to drug withdrawal in 83% and dosage reduction in the remainder.[219] Four patients (10%) were TPMT deficient (homozygous variant allele) and seven (17%) were heterozygous, but the remainder had wild-type activity (homozygous normal).[219] All 4 TPMT-deficient patients experienced bone marrow toxicity within 1.5 months, suggesting a role for TPMT in the prediction of early myelosuppression.[213,219] However, based on $TPMT^H$ and $TPMT^L$ allele frequencies, very low or undetectable TPMT activity would be encountered in only 3 patients of every 1,000 started on therapy. Three hundred patients would need to undergo TPMT assessment to detect one patient at short-term risk.[213]

Experience to date in IBD does not document an association of azathioprine or 6-MP use with increased risk of

subsequent malignancy, but continued observation is essential.[218] In a cohort of 775 adults treated with azathioprine for IBD, the frequency of lymphoma or other malignancy was not greater than expected among age-matched controls.[218] Infectious complications possibly attributable to or aggravated by azathioprine or 6-MP are described in 1 to 2% of patients overall.[216] One case of fatal varicella infection in a child with Crohn disease treated with 6-MP has been reported.[220] Susceptible children receiving azathioprine or 6-MP who are exposed to chickenpox should be given varicella-zoster Ig within 48 hours and have immunomodulatory agents discontinued.

Evidence-Based Therapeutic Indications. A meta-analysis of placebo-controlled trials employing azathioprine (2.0–2.5 mg/kg/d) or 6-MP (1.5 mg/kg/d) to treat active Crohn confirms the efficacy of these immunomodulatory drugs. The pooled odds ratio for response is 9.3 (95% CI 7.8–10.8).[208] Negative individual study results, which include the NCCDS,[163] are explained by withdrawal of corticosteroids immediately before commencement of azathioprine, premature outcome assessment, or employment of inadequate dosage. The meta-analysis demonstrated a requirement of 16 weeks to achieve therapeutic benefit, compatible with the hypothesis that the mode of action relates to gradual accumulation of intracellular cytotoxic metabolites. Pilot data suggesting that a large intravenous loading dose of azathioprine given at initiation of therapy might decrease the time to response were not supported in a subsequent randomized controlled trial.[221] Rather unexpectedly in light of its presumed mechanism of action, the addition of azathioprine to prednisolone therapy facilitated weaning of prednisolone dosage in a placebo-controlled 8-week trial in acute Crohn disease.[222]

Based on adult randomized controlled trial data and reported clinical experience among pediatric patients, it is reasonable to anticipate improved control of symptoms and reduced corticosteroid requirements in 60 to 70% of children and adolescents. Indicative of the now increased pediatric use of immunomodulatory drugs is the report of a placebo-controlled trial of concomitant 6-MP among newly diagnosed children treated with an initial course of prednisone.[209] In 1 year of follow-up, children treated with 6-MP experienced fewer relapses, received a lower cumulative prednisone dosage, and grew better.[209]

Direct measurement of intracellular metabolites in RBCs is feasible and is now often recommended in order that drug dosage be adjusted on an individual basis with greater safety.[223,224] There are some data from the treatment of other disorders to support the concept that individualized azathioprine or 6-MP dosing based on 6-TGN levels can improve response rates compared with conventional dosing regimens.[225,226] Data concerning 6-TGN levels and therapeutic response in IBD patients are, however, conflicting.[223,224,227,228] The earliest, preliminary, retrospective data were reported by Cuffari and colleagues in 1996.[227] Among 25 adolescent Crohn disease patients treated with 6-MP, a lack of clinical response judged by a high Harvey Bradshaw Index retrospectively calculated was associated with low RBC 6-TGN levels, but a satisfactory clinical response (low Harvey Bradshaw Index) was associated with a wide range of RBC 6-TGN levels.[227] Dubinsky and colleagues have published two observational studies concerning, respectively, 92 children and 62 adults who had been receiving 6-MP or azathioprine as treatment of their Crohn disease for at least 4 months.[223,224] RBC 6-TGN levels measured in these patients were found to correlate with a likelihood of clinical remission, as assessed by a modified Harvey Bradshaw Index less than 5 or fistula closure and steroid discontinuation. In the largest study to date conducted among 170 adults established on azathioprine or 6-MP therapy, no difference was found between whole-blood 6-TGN concentrations in patients in clinical remission compared with those with active disease.[228] Similarly, in a prospective randomized controlled trial comparing an intravenous loading dose of azathioprine with standard oral dosing, there was no correlation between RBC 6-TGN concentrations and either clinical response or occurrence of leukopenia.[221]

All studies to date in Crohn disease are observational and do not prospectively test the hypothesis that adjustment of azathioprine or 6-MP dosage to a target 6-TGN concentration will improve treatment outcomes. It would not be surprising, given the multiple possible mechanisms of action of azathioprine and its many metabolites, if a variable relationship exists between 6-TGN levels and efficacy. A double-blind multicenter trial comparing in randomized fashion azathioprine therapy at a standard 2.5 mg/kg/d dosage without subsequent metabolite monitoring versus therapy dosed according to TPMT enzyme activity and serial 6-TGN measurements is about to begin. At present, in a patient with an unsatisfactory clinical response, determination of 6-TGN and MMPR will at least detect noncompliance and may serve to influence the next therapeutic recommendation.

Methotrexate. Although methotrexate has a long history of substantial use in the treatment of rheumatoid arthritis, application to the treatment of Crohn disease has been very recent and is still limited. The onset of action appears to be more rapid than with azathioprine or 6-MP, but, otherwise, there are no comparative efficacy and safety data.

Mechanism of Action. Methotrexate inhibits the conversion of folic acid to its active form, tetrahydrofolate, which is necessary for thymidine synthesis. Thus, methotrexate impairs DNA synthesis. Additional anti-inflammatory properties may be related to a reduction in IL-1 production or induction of apoptosis of selected T-cell populations.

Potential Adverse Effects. In comparison with azathioprine and 6-MP, data establishing a safety prolife for use in IBD are sparse. Observed adverse effects in the one published multicenter trial in Crohn disease were minor: nausea and asymptomatic increases in liver enzymes.[229] Hypersensitivity pneumonitis is a rare but potentially serious complication but has not been observed in the limited experience in Crohn disease to date or reported in the much larger experience with pediatric rheumatic diseases.

Evidence-Based Therapeutic Indications. In a large placebo-controlled study that used intramuscular injections of methotrexate (25 mg weekly for 16 weeks), 39% of

patients whose Crohn disease was persistently active despite corticosteroid therapy achieved remission with methotrexate compared with 19% with placebo.[229] Clinical improvement was seen after 6 weeks of treatment. In a follow-up study, a benefit in maintaining remission in these adult patients was also observed.[230]

Eleven (78%) of 14 children and adolescents with Crohn disease previously intolerant or refractory to azathioprine or 6-MP therapy improved with methotrexate therapy.[231] These observations have now been confirmed in a larger, multicenter, but still retrospective analysis.[232]

Cyclosporine and Tacrolimus. The results from randomized controlled trials of cyclosporine in Crohn disease have been disappointing,[233–236] as is briefly summarized. In the first study conducted among adults with active corticosteroid-resistant Crohn disease, the percentage "improving" (59%) with high-dose oral cyclosporine (5–7.5 mg/kg/d) was greater than with placebo (32%), but the threshold level for judging clinical response was set very low.[233] A subsequent multicenter Canadian placebo-controlled study involving approximately 300 patients demonstrated no benefit from a mean of 4.8 mg/kg/d cyclosporine administered for 18 months.[234] One-third of patients had active disease, and two-thirds were in remission at initial randomization. Two other multicenter trials in adults yielded essentially negative results.[235,236] Oral cyclosporine was not as effective as prednisolone in newly diagnosed children with Crohn disease.[237] Intravenous cyclosporine was helpful in closing severe fistula in one study in adults.[238]

Biologic Agents: Infliximab. As the pathways involved in the pathogenesis of intestinal inflammation have been elucidated, a new class of therapeutic agents, referred to as biologics and having specific molecular targets, has been developed. These biologic therapies include cytokines, antibodies, and adhesion molecules. Infliximab, a chimeric (murine-human) monoclonal antibody directed against TNF-α, is the only biologic currently approved for treatment of Crohn disease. Infliximab has ushered in a new era in the management of pediatric Crohn disease; thus far, data from huge clinical trials in adults have influenced treatment algorithms.

Pharmacology and Mechanism of Action. Infliximab is an antibody of the IgG1 isotype that binds specifically to circulating and membrane-bound TNF-α.[239] TNF-α is a key proinflammatory cytokine possessing many properties relevant to intestinal inflammation.[240] The product of activated macrophages, it is capable of activating other macrophages and priming neutrophils, inducing proteases critical to tissue destruction, enhancing chloride secretion from intestinal epithelial cells, and inducing acute-phase reactants. It may also increase the expression of adhesion molecules, thereby contributing to the recruitment of monocytes, lymphocytes, and granulocytes. The expression of TNF-α is markedly increased in Crohn disease.[240] The efficacy of its blockade with infliximab attests to its important pathogenic role. Induction of apoptosis following infliximab binding to membrane-bound TNF-α appears to be particularly important to efficacy in Crohn disease.[241]

Evidence-Based Therapeutic Indications. In a multicenter placebo-controlled trial of three doses of infliximab in 108 adult patients with medically resistant, moderate to severe Crohn disease, 81% of patients treated with a single infusion of 5 mg/kg were significantly improved and 48% achieved remission by the end of 4 weeks.[239] In another placebo-controlled study of three infusions of infliximab (at 0, 2, and 6 weeks), 68% of patients with fistulous disease in the 5 mg/kg arm had at least a 50% reduction from baseline in the number of fistulae draining.[242] After a median 6 to 12 weeks, however, there is a predictable loss of infliximab-induced benefit in the treatment of inflammatory and fistulizing disease.[239,242] The ability of repeated infusions given at 8-weekly intervals to sustain clinical response has been demonstrated in large maintenance placebo-controlled and dose-ranging studies in adults with both inflammatory and fistulizing disease.[243,244] These studies were not designed to compare regularly scheduled infliximab infusions with episodic administration at the time of exacerbation. Mucosal healing of intestinal inflammation was observed in 30% of the adult patients with otherwise refractory inflammatory Crohn disease who underwent repeated colonoscopic examination during the ACCENT 1 trial.[243] In comparison with 5 mg/kg, doses of 10 mg/kg were associated with a longer duration of clinical response.[243]

A major efficacy-limiting problem is the development of antibodies to infliximab (ATI), previously called human-antichimeric antibodies. These are directed against the murine-TNF-α binding regions of infliximab. Their development, therefore, is associated with a shorter duration or loss of responsiveness, as well as with an increased frequency of infusion reactions.[245] Among rheumatoid arthritis patients, concomitant use of methotrexate reduced the frequency of antibody formation and had an adjunctive therapeutic effect.[246] In a retrospective analysis among adults with Crohn disease, concomitant administration of azathioprine or 6-MP was associated with a lower incidence of ATI formation and of infusion reactions, as well as with prolongation of clinical response following each infusion.[245] These observations constitute the basis for recommendations that patients treated with infliximab should also receive an immunomodulatory drug.[245] Use of an intravenous corticosteroid drug at the time of infliximab infusion is another strategy to reduce ATI formation.[247]

Potential Adverse Effects. The adverse effects of infliximab therapy have been monitored in randomized controlled trials among Crohn disease and rheumatoid arthritis and as part of postmarketing surveillance. Delayed hypersensitivity reactions are reported particularly after a long interval of no treatment. These are associated with rapid induction of high-titer ATI and are characterized by malaise, fever, and muscle ache 1 to 12 days following infusion. No end-organ damage results. Infliximab may induce anti–double-stranded DNA antibodies, which are usually low titer and infrequently associated with the clinical signs and symptoms of systemic lupus erythematosus.[248]

TNF-α is an integral component of innate and adaptive immune responses and is absolutely necessary for host defense against certain intracellular bacteria, in particular

Mycobacterium tuberculosis. It is not surprising, therefore, that infliximab treatment is associated with an increased incidence of tuberculosis, usually a consequence of reactivation of latent disease and often presenting in a disseminated form.[249] Pretreatment screening for latent tuberculosis, which would constitute a contraindication to infliximab therapy, is essential. Other infections complicating infliximab therapy are much rarer but include histoplasmosis and a case of *Listeria* meningitis in a teenager treated for Crohn disease.[250]

Clinical trial experience in adults with rheumatoid arthritis and Crohn disease raised an initial concern about an excess of lymphoma development, but reported occurrences of malignancy in postmarketing surveillance have not exceeded expected rates. However, the very recent introduction of infliximab precludes any data concerning long-term safety.

Clinical Use. Evidence-based guidelines for infliximab use among adult patients with inflammatory Crohn disease have endorsed its use among patients refractory to or intolerant of corticosteroids and conventional immunomodulatory agents.[251] Such "step-up" recommendations constitute a balance between the often dramatic short-term efficacy and the possibility of mucosal healing and the known short-term and unknown long-term adverse effects. Infliximab has a similar role in the treatment of children and adolescents with severe disease refractory to optimally employed conventional medical therapies and not amenable to localized resection.[252] Pediatric gastroenterologists must stay aware of evolving recommendations concerning treatment regimens and concomitant medications in order that efficacy be maximized and problems, including ATI formation, be minimized.

Other Biologics. Other biologic agents that have been less efficacious in Crohn disease include TNF-α receptor and CDP571, a humanized anti–TNF-α antibody of IgG4 type.[253,254] The greater efficacy achieved with infliximab is felt to be due to its ability to induce apoptosis.[241] The results with IL-10 in Crohn disease have been disappointing.[255] Recently, some diminution of active inflammation was observed with natulizimab ($\alpha_4\beta$ integrin) in a randomized controlled trial among adults.[256]

Primary Nutritional Therapy

Liquid diet therapy is an effective alternative to corticosteroids among children and adolescents with active Crohn disease. Indeed, enteral nutrition is regarded as first-line therapy for pediatric Crohn disease in centers in the United Kingdom[138] and is commonly employed in other parts of Europe and Canada.

Enteral Nutrition in Crohn Disease. *Mechanism of Action.* The mode of action of enteral nutrition as primary treatment of active Crohn disease remains conjectural. Hypotheses have included alteration in intestinal microbial flora, elimination of dietary antigen uptake, diminution of intestinal synthesis of inflammatory mediators via reduction of dietary fat, and overall nutritional repletion or provision of important micronutrients to the diseased intestine.[257] The effects of enteral nutrition on the gut microbial flora deserve further exploration in light of the now well-established role of microbes in disease pathogenesis.

Evidence-Based Therapeutic Indications. *Active Disease.* The potential role of exclusive enteral nutrition as primary therapy of active Crohn disease was discovered fortuitously. Patients given elemental formulae preoperatively experienced an improvement not only in their nutritional status as intended but also in the inflammatory activity of their disease. These observations of primary therapeutic efficacy were first confirmed in the small controlled trial conducted by O'Morain and colleagues.[258] However, in the subsequent much larger ECCDS randomized trials of enteral nutrition versus corticosteroid and sulfasalazine therapy, the drug therapy proved superior to semielemental formulae containing oligopeptides as the protein source.[259,260]

The controversy surrounding seemingly divergent outcomes has fueled several meta-analyses, each of which has concluded that there is a treatment benefit to corticosteroids in comparison with enteral nutrition.[261] Analyzing results of eight trials on an intention-to-treat basis, the pooled odds ratio for the likelihood of clinical remission with liquid diet therapy versus corticosteroids is 0.35 (95% CI 0.23–0.53).[261] Furthermore, poor compliance, although contributory, does not constitute the major explanation for the lower response rates to enteral nutrition, as is evident from secondary meta-analysis excluding dropouts for apparent intolerance.[261]

No controlled trials of enteral nutrition versus placebo or less effective drugs in active Crohn disease have been conducted. However, comparison of observed response rates to exclusive liquid diet therapy (53–82%) with usual placebo response rates (18–42%) in the controlled clinical trial setting suggests that enteral nutrition is of therapeutic benefit, when tolerated, even if efficacy does not equal that of corticosteroid treatment.[261] Moreover, a reduction in gastrointestinal protein loss, a decrease in intestinal permeability, and a reduction in fecal excretion of indium-labeled leukocytes have each been demonstrated, suggesting a direct effect on intestinal inflammation.[262,263] Open trials in children have documented endoscopic healing and decreased mucosal cytokine production following exclusive enteral nutrition.[264,265]

Factors Influencing Efficacy. *Anatomic Localization of Inflammation.* Anecdotal evidence suggests that Crohn colitis responds less well to enteral feeding than ileocolitis or isolated small bowel disease. Children with Crohn disease confined to the colon were excluded from the Canadian pediatric multicenter study.[165] The results of the ECCDS did not confirm a relationship between site(s) of intestinal inflammation and outcome, but the numbers of patients with isolated colonic disease were small even in these trials.[259,260] In one trial comparing two types of enteral nutrition, two-thirds of patients had disease confined to the colon, but excellent clinical response rates of 67% and 73% to elemental and polymeric formulae, respectively, were less observed.[266]

Formula Composition. Several clinical trials have compared the efficacy of elemental versus nonelemental formulae of varying protein and fat composition. Existing data combined in a meta-analysis do not support an advantage to elemental (amino acid based) feedings compared with more palatable polymeric formulations. The importance of fat composition to efficacy is less clear, but there may be a small treatment benefit achieved by a reduction in the content of total fat or ω-6 PUFAs.[267]

"Bowel Rest." When employed in the treatment of active Crohn disease, enteral nutrition is generally combined with "bowel rest." The necessity of complete avoidance of other food is challenged by the results of a randomized controlled trial of adjunctive nutritional support.[268] Partial parenteral nutrition plus an ad libitum oral diet proved as effective in inducing clinical remission as either elemental liquid diets administered by nasogastric tube or total parenteral nutrition and complete bowel rest among patients hospitalized because of continuing activity of their disease despite high-dose steroid therapy.[268]

Age and Disease Duration. Several small trials of enteral nutrition in children with extremely high success rates have been reported,[269] but caution is always required in drawing firm conclusions from very small studies.[270] The Canadian Pediatric Collaborative Trial of enteral nutrition versus corticosteroids[165] employed an oligopeptide-containing liquid diet very similar in composition to that used among adults in the ECCDS.[260] These two trials included, respectively, 78 children and 107 adults. The differences in patient populations and outcomes are summarized in Table 41.1-9. It seems likely that the higher remission rate overall with enteral nutrition in the pediatric study (75%) versus the adult study (53%) reflects differences in the nature of the patients randomized rather than an inherent difference in the responsiveness of childhood Crohn disease. Indeed, the subgroup of children with disease in relapse and of longer duration had a rate of clinical response to enteral nutrition very similar to that of adult patients. Alternatively, it could be argued that new-onset disease is more responsive to enteral nutrition, an observation that has also been made with infliximab therapy.[271]

Enteral nutrition does seem to be more feasible, if not inherently more efficacious, in pediatric populations. The formula can be infused nocturnally via a nasogastric tube in the home setting and will not interfere with normal activities. With the support of experienced nurses and physicians, enteral nutrition is, in general, well accepted by young patients. There is enough evidence of its short-term efficacy in active disease to support presentation as an alternate primary treatment to all young patients, particularly with predominantly small intestinal disease, for whom corticosteroids are being considered.

Maintenance of Remission. One of the limitations of liquid diet therapy has been the observed tendency for symptoms to recur promptly following its cessation. In most studies, 60 to 70% of patients experience a relapse within 12 months of stopping enteral nutrition and resuming a normal diet.[266] Chronic intermittent bowel rest with nocturnal infusion of an elemental diet 1 month of 4 has been recommended as a means of sustaining remission.[272] The beneficial effects on disease activity and growth of such cyclic enteral nutrition were confirmed in a recent randomized controlled trial versus alternate-day prednisone.[273] Phase 2 of the Canadian Pediatric Crohn Disease Study examined the effects of alternate-day administration of 0.3 mg/kg oral prednisone on the rates of clinical relapse and growth in comparison with cycles of exclusive enteral nutrition. During an 18-month period of follow-up, the difference between the percentage of patients remaining in continuous remission with alternate-day prednisone (47%) and with cyclic enteral nutrition (67%) was not statistically significant, but linear growth was significantly better among patients randomized to receive the nutritional therapy.[273] Continuation of nocturnal nasogastric feeding four to five times weekly as a supplement to an unrestricted ad libitum daytime diet was also associated with prolonged disease quiescence and improved growth in a historical cohort study.[159] In the long term, allowing normal food at times when family and friends are eating is particularly important in achieving compliance.[159]

Another "nutritional" strategy for maintaining remission has involved the use of fish oil supplements. A placebo-controlled study employing enteric-coated fish-oil capsules designed for ileal release demonstrated a substantial reduction in clinical relapse rate among patients with Crohn disease in clinical but not biochemical remission at baseline.[274] Eicosapentaenoic acid (fish oil) competes with arachidonic acid, thereby reducing its metabolism to leukotriene B_4, an amplifier of intestinal inflammation, by the 5-lipoxygenase pathway.

TABLE 41.1-9 ENTERAL NUTRITION AS PRIMARY TREATMENT OF ACTIVE CROHN DISEASE: COMPARISON OF TWO MULTICENTER ADULT AND PEDIATRIC CONTROLLED TRIALS

STUDY	RESPONSE	BASELINE CDAI	COLON ONLY INVOLVED
European Cooperative Crohn Disease Study IV[261] (*n* = 107)	53% to EN 85% to CS	323 (± 12 SEM) 316 (± 11 SEM)	22%
Canadian Pediatric Crohn Disease Study[165] (*n* = 78)	75% to EN 89% to CS	260 (242–278)† 309 (282–335)†	None*
Canadian Pediatric Crohn Disease Study subgroup with disease in relapse[165] (n = 21)	50% to EN 85% to CS	269 (233–304)† 292 (251–333)†	None*

CDAI = Crohn Disease Activity Index; CS = corticosteroids; EN = enteral nutrition; SEM = standard error of mean.
*Crohn disease confined to the colon was an exclusion criterion.
†Values in parentheses represent 95% confidence intervals.

Total Parenteral Nutrition

Greenberg has summarized studies of total parenteral nutrition (TPN) as primary treatment of active Crohn disease.[275] In contrast to studies of enteral nutrition in active disease, there are numerous retrospective reports but few prospective randomized controlled trials of TPN. From retrospective series among Crohn disease patients, one can expect an in-hospital remission rate of 64% after 14 to 21 days of treatment, with patients with isolated colonic Crohn disease responding less often than those with disease involving the small intestine alone or small intestine plus colon.[275] Two small prospective controlled trials suggest that TPN combined with bowel rest is of no primary therapeutic efficacy in the management of patients with acute Crohn colitis, although it will improve their nutritional status.[275] Only two randomized studies have compared TPN with exclusive enteral nutrition in the treatment of active disease; remission rates with either modality were comparable.[276,277] There is no evidence to suggest that TPN is superior to enteral nutrition in the treatment of acute inflammation.

Surgical Treatment

Optimal management of young patients with IBD often includes appropriate and timely referral for intestinal resection, which is increasingly performed laparoscopically.[278]

Indications for Intestinal Resection. The most common reasons for surgery include intractable symptoms despite medical therapy, intestinal complications including obstruction, intra-abdominal abscess, enterovesicular fistula, and, less frequently, free perforation or intractable hemorrhage. Many children have experienced growth impairment by the time resection is considered, an indication of the failure of medical treatment to adequately control intestinal inflammation.

Outcome. "To cut is not to cure."[279] Crohn disease is a chronic panenteric inflammatory process that cannot be eradicated by current medical therapy or by resection of gross disease. Patients who undergo ileal resection typically develop recurrent disease just proximal to the ileocolonic anastomosis, whereas the site of recurrence can be on either or both sides of the anastomosis following segmental colonic resection. Macroscopic lesions have been found in the neoterminal ileum of 72% of patients routinely colonoscoped 1 year following intestinal resection and ileocolic anastomosis.[279] However, the possibility of a significant asymptomatic interval, during which normal growth and pubertal development can resume, makes such surgery an attractive therapeutic option for young patients, despite the likelihood of eventual disease recrudescence. A substantial improvement in height velocity can be anticipated postoperatively in previously growth-impaired adolescents provided that the surgery is performed prior to or during early puberty.[280,281] The amount of catch-up growth achieved will depend on the duration of the clinical remission.

Several studies among adult patients have documented the cumulative rates of recurrence of symptomatic disease. The incidence of clinical recurrence averages about 10% per year postoperatively. Similarly, based on the return of symptoms with radiologic evidence of disease, the median postoperative recurrence-free interval was 5.1 years in a series of 82 children and adolescents undergoing a first resection.[280]

Factors Influencing Outcome. Risk factors for postoperative symptomatic recurrence have been examined in many studies of large cohorts of adult patients, but few reliable "prognostic factors" have been consistently identified.[280,282,283] The length of recurrent ileal disease appears comparable to the length of ileum inflamed preoperatively.[284] The rates of recurrence are lower after surgical resection with ileostomy than after resection with ileocolonic anastomosis.[285] The outcome after colectomy and end-ileostomy for isolated Crohn colitis is particularly good: 15% cumulative probability of symptomatic recurrence after 20 years versus 64% in patients with ileocolitis as their initial presentation in one typical study.[286] In two pediatric studies, anatomic distribution of disease was the most important factor influencing outcome.[280,281] Patients with extensive ileocolonic involvement experienced an excess of early recurrences (50% by 1 year) in comparison with children with preoperative disease in the terminal ileum with or without the right colon or in the more proximal small intestine (50% by 5 years).[280] Fistulizing disease and stenosing disease have been considered, respectively, poor and good prognostic factors for the length of postoperative remission in adult studies.[282,287,288] However, children undergoing resection because of stenosing or fistulizing complications (eg, bowel obstruction or intra-abdominal abscess) had delayed recrudescence of disease in comparison with those operated on simply for inflammatory symptoms refractory to medical therapy.[280] An early operative approach to localized disease and for complications of chronic inflammation is supported by these data.[138,280,281] The rapid return of symptoms after major resection in patients with extensive ileocolitis suggests that medical strategies should be maintained in this group.

Maintenance of disease quiescence via adjuvant pharmacologic treatment following surgery has proved as difficult as maintenance of medically induced remission. As discussed earlier in the chapter, meta-analysis of the now very large number of patients treated in a randomized fashion with oral 5-ASA in placebo-controlled trials no longer supports its routine use following resection of all gross disease.[194,195,197] Patients undergoing resection of isolated ileal disease may benefit.[196] Two studies have suggested a benefit to postoperative antibiotic administration in delaying endoscopic and clinical remission, but the number of patients on which this conclusion is currently based is small.[204,206] CIR budesonide administered postoperatively has not been helpful.[289] Data concerning 6-MP in the maintenance specifically of surgically induced clinical remission are very limited.[290] Smoking is consistently associated with higher recurrence rates, particularly in female patients, in all studies in which this variable has been examined.[291]

Management of Perianal Disease

At least until the advent of infliximab, the first line of medical therapy for perianal fistulae has been metronidazole. Eighty-three percent of adult patients with a variety of chronic perianal and rectovaginal fistulae and unhealed perineal wounds responded to 20 mg/kg/d over 2 to 4 months.[198] Subsequent follow-up for as long as 36 months indicated that although perianal disease seldom relapsed on full-dose therapy, a reduction in dose or cessation of therapy was often associated with exacerbation. Metronidazole could be successfully discontinued in only 28% of patients.[199] The place of other antibiotics in the management of perianal disease is less substantiated, but ciprofloxacin appears to offer benefit as sole or adjunctive therapy. Benefits from azathioprine or 6-MP, methotrexate, and cyclosporine have also been observed. Incision and drainage are indicated for abscesses. Other surgical treatments include fistulotomy for simple or low fistulae, fistulotomy with seton insertion for complex or high fistulae, and intestinal diversion for highly destructive lesions. As previously discussed, infliximab infused at baseline, 2 weeks, and 6 weeks proved highly successful in achieving a reduction in drainage and clinical closure of perianal fistulae.[242] Prior to infliximab, examination under anesthesia or MRI is required in order that any abscesses be identified and properly drained, usually with a seton.[292] As for intestinal inflammatory disease, regularly repeated infusions may be required to sustain clinical response.[244] MRI examinations can be used to detect persistence of fistulae despite the apparent clinical closure.

CLINICAL COURSE AND PROGNOSIS

Disease Severity

Crohn disease is heterogeneous in nature and varying in severity. Its protean nature precludes universally applicable statements about clinical course or prognosis. As depicted in Figure 41.1-7, the spectra of disease patterns among consecutively diagnosed prepubertal patients in Toronto in the past two decades were similar. In the 5-year follow-up, roughly one-third had mild symptoms only and another third more troublesome exacerbations but clear-cut remissions. The remaining third experience chronically active steroid-dependent or steroid-refractory disease, but half of these benefit significantly from resection and then experience a sustained remission. Thirty-six percent of the children diagnosed during the 1980s and the 1990s underwent intestinal resection by 5 years of follow-up.[116]

Disease Behavior

Recently, there have been attempts to characterize and categorize Crohn disease as "penetrating/fistulizing," "stenosing," or simply "inflammatory."[293] The fistulizing subgroup includes any patient with enteroenteric, enterovesicular, enterocutaneous, or perianal fistula or intra-abdominal abscess. The stenosing category includes patients with persistent abdominal pain and radiologic documentation of marked stenosis of a segment of small or large intestine. Although it has been argued that such behavior may be genetically determined, an analysis of the prevalence of each phenotype according to the duration of disease suggests that stricturing and fistulizing behaviors become progressively more common over time.[294] This is in contrast to major localization of disease, which is consistent over time[295] and appears to be genetically influenced.[8,41,54] Nevertheless, consideration of the disease behavior at a given time may guide therapy.

Overall Mortality and Cancer Risk

Death from Crohn disease is extremely rare in the pediatric population. The two disease-related deaths since 1980 among roughly 700 children and adolescents in Toronto occurred as a result of postoperative septic complications. In adulthood, there appears to be an increased mortality risk compared with age-matched controls (standardized mortality ratio 1.51).[295]

Persons with Crohn colitis may be at similar risk of developing carcinoma of the colon as those with ulcerative colitis. The absolute cumulative frequency of risk for development of colorectal cancer in extensive Crohn colitis was reported to be 8% after two decades of disease.[296] Accompanying severe perianal disease has been suggested as an additional risk factor. Colorectal carcinoma has been reported in a 21 year old diagnosed with Crohn disease at the age of 8 years.[297]

CARING FOR THE WHOLE CHILD

The need to address the psychosocial impact of Crohn disease on children and adolescents as well as on their fami-

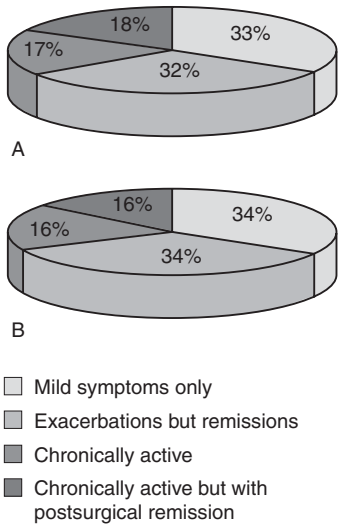

FIGURE 41.1-7 Clinical course of Crohn disease among consecutively diagnosed children at The Hospital for Sick Children, Toronto, Canada, during two decades. All children were prepubertal or in early puberty (Tanner stage 1 or 2) at the time of presentation. Patients were classified via retrospective chart review as having mild symptoms only, at least moderate excerbations but remissions, or chronically active disease (a portion of these achieving sustained remission following resection). *A*, 1980–1988 cohort (n = 100); follow-up 4.9 ± 1.8 years. *B*, 1990–1999 cohort (n = 163); follow-up: 4.7 ± 1.7 years.

lies is increasingly recognized.[298] The concept of health-related quality of life (HRQOL) has been defined as the functional effect of an illness and its treatment on a patient, as perceived by the patient.[298] HRQOL is determined not only by physical well-being but also by psychological state, degree of social support, effects of treatment, and complications.[298] Assessment of HRQOL provides a global measure of the patient's perceptions, illness experience, and functional status.[298] Increasingly, appraisal of the impact of treatments on HRQOL is being expected in clinical trials and in health policy making.

Several recent studies have explored the concerns of young patients with inflammatory bowel disease with quite consistent findings.[299,300] Although, in focus groups, children initially denied that Crohn disease interfered with their lives in any way, it became apparent that many were frustrated and angry about the physical symptoms and a lack of understanding of their illness by others.[300] North American and English children shared similar concerns about body image, having to miss out on things, uncertainty about exacerbations and future health, and unpleasant treatments.[299,301] A disease-specific instrument incorporating these patient-generated concerns has been developed to facilitate assessment of the overall impact of pediatric IBD.[299,302] Activity indices such as the Pediatric Crohn's Disease Activity Index[303] are designed to allow determination of the effects of treatment on the basic disease process, but they do not tell us how our patients are functioning day to day and how they feel about their chronic illness. Two adolescents may respond to the same physical symptoms with different outlooks and subsequent endeavors and achievements. Recognition of the disparity between the activity and severity of Crohn disease and emotional or functional disability may be facilitated by assessment of HRQOL.

When it is recognized that a child or adolescent needs help coping with his or her illness, it is equally important that there be effective interventions to restore emotional health and improve function. Although there are opinions and guidelines, strategies involving a multidisciplinary approach have not been subjected to scrutiny and appraisal, as have other therapies. Adolescents have a reluctance to participate in peer support groups, but whether "dyadic peer support," that is, matching with another patient of similar or somewhat older age, may be beneficial is beginning to be explored.

From the time of recognition of Crohn disease, it is important to create an atmosphere that permits both the child and parents to express their concerns about the physical state and the psychological aspects of the disease. As time goes by, an empathetic relationship between the medical team and the patients may enhance the likelihood of emotional expression. Support in coping with a chronic illness must be provided, but it is also important to understand and alleviate other stresses in the family environment, which may hinder coping with the illness. The overall impact of Crohn disease on a child is the result of the complex interplay among physical, psychological, and social factors. If depression is identified, this must be dealt with psychotherapeutically by a psychiatrist or psychologist. It is important to see the child alone to make psychological communication easier. Education is vital because well-informed patients and families may be more likely to develop active coping strategies.

FINAL COMMENTS: CROHN DISEASE IN 2004

The past several years have witnessed exciting progress in unraveling the etiopathogenesis of Crohn disease. The identification of the first gene conferring susceptibility is a landmark achievement in a complex disorder. The recognition of other genes determining susceptibility and influencing phenotypic expression is eagerly awaited.[304,305] Novel techniques allowing characterization of microbes inhabiting the gut hold promise that the microbial trigger(s) of unrestrained inflammation in susceptible hosts will ultimately be defined. The interactions between intestinal microbial flora and the signaling pathways involved in the innate and adaptive immune response are being continually elucidated. With better understanding of these pathways have come biologic agents, which already have had a major therapeutic impact on this often disabling disease.

Although "step-up" versus "top-down" therapy can be debated, optimal management entails identification of genetic or clinical predictors of outcomes and responsiveness to treatments so that recommendations can be individualized. Pediatric gastroenterologists have become aware of the need to consistently characterize the phenotype and, as it becomes possible, the genotype, thereby establishing a framework for multicenter evaluation of emerging therapies in what is clearly a heterogeneous chronic inflammatory disorder if not a spectrum of related but distinct "Crohn diseases."

2. Ulcerative Colitis

Alan M. Leichtner, MD
Leslie Higuchi, MD, MPH

Ulcerative colitis (UC) is a chronic inflammatory disease of the colonic and rectal mucosa of unknown etiology affecting children and adults. Although much of the available knowledge about this disease has been derived from studies of adult patients, in recent years, the number of investigations performed on pediatric patients has increased dramatically. The following discussion summarizes the key aspects of UC in children, emphasizing the unique aspects of the disease in childhood.

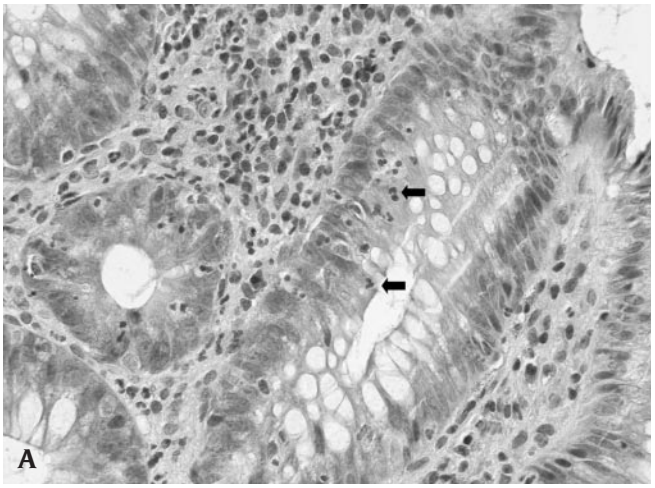
PATHOLOGY

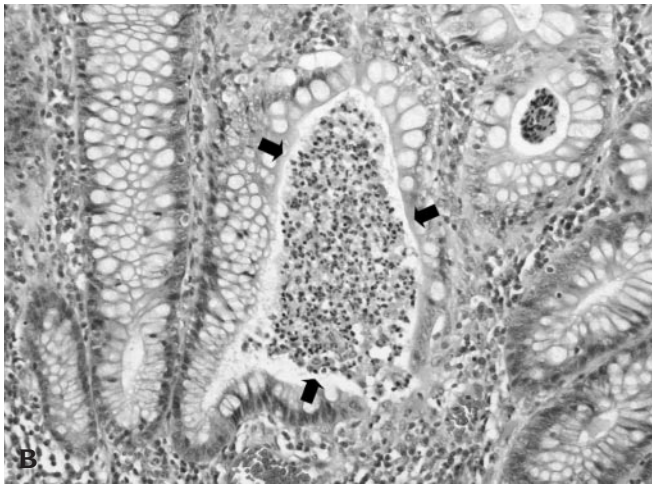
The first description of UC was in 1875 by Wilks and Moxon, who differentiated UC from infectious colitis.[1] In 1932, Crohn described regional enteritis, a transmural disease of the small intestine, as well as a type of transmural colitis, which was distinct from UC.[2,3] In 1960, formal criteria differentiating UC from Crohn colitis were established.[4] According to the classic definition, the inflammation in UC is limited to the colon and rectum. In untreated UC, the distal colon is most severely affected, and the rectum is virtually always involved. Inflammation is limited primarily to the mucosa, and involvement is continuous, extending from the rectum proximally and with varying degrees of ulceration, hemorrhage, edema, and regenerating epithelium.[5] In contrast to adult patients, who most commonly have disease confined to the left colon, only 15% of children have isolated rectal involvement or ulcerative proctitis, 20% have left-sided disease, and pancolitis is the most common pattern.[6] Although UC is limited to the colon, "backwash ileitis" owing to nonspecific inflammation of the terminal ileum may occur but is generally not associated with clinical small bowel disease. Grossly, the colonic mucosa appears erythematous, hemorrhagic, and roughened in active disease, whereas the inactive or quiescent phase is characterized by flattening of the mucosa and effacement of the normal haustral markings. In severely active colitis in which the mucosa has been destroyed, inflammation may extend into the submucosa and occasionally down to the muscularis. Such ulcers are typically broad and shallow rather than fissuring or knife-like, as would be more typical of Crohn disease (CD). Intervening areas of regenerating granulation tissue and residual mucosa may form islands of tissue called pseudopolyps. Thickening of the bowel wall and fibrosis are rare, although shortening of the colon and focal colonic strictures may occur in long-standing disease.

The histopathologic appearance of the mucosa in UC is characterized by continuous acute and chronic inflammation with diffuse mucosal infiltration by polymorphonuclear leukocytes and mononuclear cells.[5] The colonic epithelium shows the most characteristic changes. Cryptitis, crypt abscesses, mucin depletion, and surface erosion or ulceration typify the active inflammation, whereas chronic changes involve crypt architectural distortion with branching and atrophy, diminished numbers of goblet cells, and Paneth cell metaplasia in the left colon (Figure 41.2-1). Additional features of chronicity include villiform change of the mucosa and the appearance of basal plasma cells and lymphoid aggregates. In contrast to Crohn colitis, no granulomas or transmural inflammation and little fibrosis are present.

Recently, the classic pathologic description of UC has been subject to revision. It has become apparent that pharmacologic therapy may significantly alter the gross and histopathologic appearance of UC. Therapy may completely normalize the colonic mucosa histologically[7] or induce patchiness or discontinuity.[8] Given that these changes may mimic the appearance of CD in the colon and potentially lead to misdiagnosis, complete colonoscopy should be performed before treatment to maximize the ability to make a definitive diagnosis. Furthermore, children with new-onset disease may demonstrate unusual histologic features, such as absence or patchiness of features of chronicity and relative or absolute rectal sparing, even prior to the initiation of therapy.[9,10] Discontinuous disease has also been noted in adult patients who may demonstrate involvement of the appendix without surrounding cecal involvement.[11]

In contrast to the classic features of UC discussed above, CD tends to be characterized by focal involvement with skip lesions, transmural inflammation, and granulomas (Table 41.2-1). In an individual case, however, the histologic features may not clearly fall into either category, and the patient is said to have indeterminate colitis. Although there is no established formal definition of indeterminate colitis, in most cases, the diagnosis of indeterminate colitis is given when chronic colitis is present, but the clinician cannot reliably distinguish between CD and UC based on the available clinical, radiographic, endoscopic, and histologic data.[12–14] The prevalence of indeterminate colitis in adults and children with inflammatory bowel disease (IBD) is estimated to be 10 to 20%.[15,16] Approximately one-third to half of these patients will later be classified as UC or CD.[14,17]





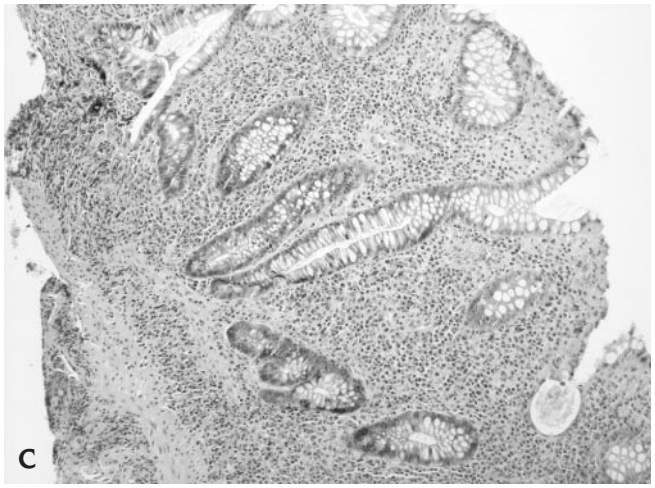


FIGURE 41.2-1 *A*, Active colitis with polymorphonuclear leukocytes invading the crypt epithelium resulting in cryptitis (hematoxylin and eosin; ×400 original magnification); *B*, Active colitis with a crypt abscess (hematoxylin and eosin; ×200 original magnification); *C,* Chronic colitis characterized by irregular glandular architecture with atrophic and branching crypts (hematoxylin and eosin; ×100 original magnification).

EPIDEMIOLOGY

The distribution of age at onset of UC is bimodal, with peaks occurring in the second and third decades and again in the fifth and sixth decades.[18] Between 15 and 40% of all patients with UC present before age 20 years.[19] The highest incidence in children is noted between the ages of 10 and 18 years. Although infants with UC have been reported, the disease is quite rare in individuals under 2 years of age.

The incidence and prevalence of UC vary considerably across different geographic areas. UC is common in North America and Northern Europe, particularly in the United Kingdom and Scandinavia, but is less prevalent in Southern and Central Europe and is seen quite infrequently in Asia, Africa, and South America.[19] Determination of meaningful estimates of incidence and prevalence is difficult because of variation in the definition of age limits for the pediatric population, inexact and nonstandardized criteria for diagnosis, and incomplete ascertainment of cases.[20] In the general population in Northern Europe and the United States, the incidence of UC has ranged from 3.9 to 7.3 cases per 100,000 people/year, with the prevalence ranging from 41.1 to 79.9 cases per 100,000 people.[21,22] The incidence of UC increased gradually in the pediatric population until 1978 but then became relatively stable worldwide. Current estimates for Northern Europe and the United States range between 1.5 and 4.0 cases per 100,000 children/year (Table 41.2-2).[16,22–26] The most recent surveys from Scotland and Sweden again suggest an increase in incidence in childhood UC over the last decade.[26,27]

Classically, the incidence of UC has been described as being highest in the white population. However, recent studies have demonstrated that blacks in the United States and the British Isles may have a comparable incidence and that the disease may actually occur more frequently in the Asian population in the British Isles.[27] UC is more common among Jewish than non-Jewish peoples, although disease rates in people of Jewish background also vary by geographic area.[28] Males and females are affected equally.

ETIOLOGY AND PATHOGENESIS

As with CD, the cause of UC remains unknown; however, a growing body of evidence suggests that both genetic and environmental factors play a role in pathogenesis (Table 41.2-3).[29] The most current theory proposes that disease results from an inappropriate and exaggerated immune response to normal constituents of the mucosal microflora.[30]

Evidence for an inherited predisposition to UC exists, although genetic factors may be less important than in

TABLE 41.2-1 COMPARISON OF PATHOLOGIC FEATURES OF ULCERATIVE COLITIS AND CROHN DISEASE

FEATURE	ULCERATIVE COLITIS	CROHN DISEASE
Gross/endoscopic		
Colonic involvement	Typically diffuse, continuous, extending proximally from rectum	Focal disease characterized by skip lesions
Rectal involvement	Almost always involved	Frequently spared
Ileal involvement	Nonspecific "backwash ileitis"	Typically involved with ulceration and nodularity
Ulceration	Broad and shallow	Early aphthous lesions, ulcers knife-like and fissuring, intervening areas of edema may give "cobblestone" appearance
Microscopic		
Depth of inflammation	Mucosal, except in severe disease	Typically transmural
Granulomas	Absent, except for occasional giant cell reaction to damaged crypts	Noncaseating granulomas commonly seen
Fibrosis	Unusual	Typical

patients with CD. Fifteen to 25% of patients with UC have other family members with IBD. Furthermore, the incidence is approximately 10 times greater when there is a positive family history.[31] The highest risk for a child developing UC occurs when an affected parent is Jewish, when both parents are affected, or when a sibling is affected. There appears to be a high concordance for the diagnosis of UC or CD among family members with IBD. In one study of families with two or more affected family members with IBD, among 83 families in which the proband had UC, 72 relatives had UC (81%; 72 of 89), and only 17 had CD (19%; 17 of 89).[32] Incidence studies of UC in twins reveal a pair concordance rate of 14 to 19% among monozygotic twins and a very low percent concordance rate of 0 to 5% among dizygotic twins.[33,34] This difference between monozygotic and dizygotic twins is much more striking in CD, with a pair concordance rate of 50% among monozygotic twins and 0 to 4% among dizygotic twins.[33,34] Although the concordance rates of disease are higher in monozygotic twins, the incomplete concordance suggests that nongenetic factors also contribute to the development of IBD.

Candidate gene studies suggest an association between human leukocyte antigen (HLA) class II genes and IBD, and this association is stronger in UC than in CD.[29] Two of the reported HLA associations with UC include the serologic subtype HLA-DR2 (particularly the deoxyribonucleic acid [DNA] genotype HLA-DRB1*1502 in the Japanese population) and the DNA genotype HLA-DRB1*0103 (especially with extensive UC).[29,35] Systematic genomic studies using linkage analysis report the presence of non-HLA susceptibility genes for UC located on chromosomes 3, 7, and 12.[36] The association of UC with Turner syndrome, a disorder with a clear genetic basis, also lends support for the importance of inherited factors in its pathogenesis.[37]

The incomplete concordance among monozygotic twins for UC suggests that nongenetic factors also contribute to the development of IBD. Multiple environmental factors also have been postulated to be important in the etiology of UC. Evidence of a birth cohort phenomenon suggests that early life exposure to environmental risk factors may influence the development of UC.[38,39] Koletzko and colleagues found that children with UC were three times more likely to experience a diarrheal illness during infancy than were unaffected siblings.[40] Glassman and colleagues reported an association between early cow's milk sensitivity and UC.[41] As is true for CD, the impact of breastfeeding on the development of UC remains controversial; some published studies suggest a protective effect,[42] whereas other studies show no effect.[40,43] Multiple studies report a lower risk of UC with appendectomy at a young age[44–46]; however, not all studies demonstrate this relationship.[47] In a population-based, case-control study, UC was inversely related to appendectomy only in those individuals who had surgery before 20 years of age.[45] Furthermore, the risk of UC was reduced only in patients who underwent appendectomy for inflammatory conditions (eg, appendicitis or mesenteric lymphadenitis) but not in patients who had the procedure for nonspecific abdominal

TABLE 41.2-2 STUDIES OF THE INCIDENCE OF ULCERATIVE COLITIS IN CHILDREN AND ADOLESCENTS

LEAD AUTHOR AND STUDY LOCATION	AGE RANGE	TIME PERIOD STUDIED	INCIDENCE (CASES/10^5 PERSONS/YR)
Calkins (1984),[22] Baltimore, Maryland	< 10 yr	1977–1979	M 0.34; F 0.36
	≥10 yr and ≤ 19 yr	1977–1979	M 2.25; F 1.32
Barton (1989),[23] Scotland	> 5 yr and ≤ 16 yr for UC	1968–1983	
		1968	1.9
		1983	1.6
Olafsdottir (1989),[24] Western Norway	≤ 15 yr	1984–1985	4.3

Lindberg (2000),[26] Stockholm, Sweden	≤ 15 yr	1984–1986	1.4
		1993–1995	3.2
Bentsen (2002),[16] Southeastern Norway	< 16 yr	1990–1993	2.1

UC = ulcerative colitis.

TABLE 41.2-3 ETIOLOGIC FACTORS IN THE PATHOGENESIS OF ULCERATIVE COLITIS

EVIDENCE FOR GENETIC PREDISPOSITION
Frequent positive family history (15–25%)
Higher rate of concordance in monozygotic twins than in dizygotic twins
Association with specific HLA class II genes
Association with other genetic disorders, eg, Turner syndrome
ENVIRONMENTAL FACTORS
Early childhood events, eg, diarrheal illness; may increase risk
Appendectomy at an early age; may decrease risk
Psychological stress; may cause exacerbations
Smoking tobacco; decreases risk
Drugs
Nonsteroidal anti-inflammatory drugs; may cause exacerbations
Oral contraceptives; conflicting data
Microbial factors; important in pathogenesis

pain.[45] These findings may suggest that the inflammatory condition that preceded the appendectomy, rather than the appendectomy itself, may be inversely related to the development of UC later in life.

Although the early theories that UC was a psychological disorder have been discounted, up to 40% of patients report psychological stress as a potential trigger of their disease.[48] Furthermore, stress has been demonstrated to be associated with relapse in animal models of colitis.[49] More research is required to assess the effect of stress on the immune system and the potential impact of stress on patients with UC.

The lower risk of UC among current smokers is one of the most consistent findings in multiple studies, although the potential mechanism of this association is still unknown. Current smokers have approximately half the risk of developing UC compared with nonsmokers.[50,51] Little information is available regarding the possible association of childhood exposure to passive smoking and the development of UC. One study demonstrated that passive smoke decreased the risk of developing UC in adulthood,[52] whereas another study demonstrated an association between passive smoke and the development of both childhood UC and CD.[53]

A number of published studies, mostly case reports and series, suggest that nonsteroidal anti-inflammatory drug (NSAID) use may precede the onset of IBD, lead to a reactivation of quiescent IBD, or exacerbate already active IBD in humans.[54–57] Cytoprotective prostaglandins exert predominantly anti-inflammatory effects in the setting of colonic inflammation, and it has been postulated that NSAIDs may worsen colitis by inhibiting the synthesis of these prostaglandins in the colon.[58] However, further study is needed to clarify any true association of NSAID therapy with the onset or exacerbation of UC, to identify those individuals at most risk, and to determine the safety profile of cyclooxygenase 2 inhibitors in comparison with standard NSAIDs in regard to potential colonic mucosa injury. Physicians may choose to advise their IBD patients to avoid NSAID medications until more information is available. However, some may argue that there is insufficient evidence to eliminate its use completely, especially among UC patients who may benefit from NSAID therapy, such as for arthritis.

The association between oral contraceptive use and UC remains controversial, with some studies suggesting an increased risk of UC and other studies showing no increased risk.[50,59]

The intestine is exposed to numerous luminal dietary antigens; thus, a potential relationship between dietary intake and the development of UC seems plausible. Ecologic and case-control studies have examined the association between certain foods and UC,[60,61] but, presently, there is no definitive link between diet and the development of UC. The collection of preillness dietary information and other methodologic issues of these retrospectively designed dietary studies hinder the interpretation of findings. For example, the ascertainment of recalled dietary intake after the onset of disease (retrospective design) may reflect changes in the diet secondary to the effects of the disease itself rather than the individual's dietary habits preceding the onset of disease.

Although no specific causative infectious agent has been identified, bacterial factors are likely to play a role in the initiation or perpetuation of intestinal inflammation by serving as antigens or costimulatory factors.[62] Several lines of evidence support the hypothesis that intestinal bacteria are involved in the development of UC in the genetically predisposed individual. Colitis in animals occurs in a number of different genetically altered rodents, including interleukin (IL)-2, IL-10, and T-cell receptor knockout mice and HLA-B27 transgenic rats.[63] Interestingly, most of these animal models do not develop colitis in germ-free environments, emphasizing the importance of bacteria in the development of intestinal inflammation in these colitis models. These findings suggest that multiple genes may contribute to the pathogenesis of IBD and that the interaction between genes and the environment is essential. Furthermore, modification of the intestinal flora with probiotic preparations or nonpathogenic *Escherichia coli* may help maintain remission of UC.[64–66] Increasing evidence suggests that probiotic preparations may be effective for preventive and maintenance therapy for pouchitis.[67,68] Of note, patients with UC who undergo colectomy and an ileal pouch-anal canal anastomosis (IPAA) experience pouchitis more commonly than patients with familial polyposis who undergo the same procedure.[69] The potential benefit of probiotic therapy and the higher incidence of pouchitis among patients with UC may further support the theory of an abnormal immune response to luminal bacteria in the genetically susceptible host, leading to the development of UC.

Ultimately, the damage to the large intestine that characterizes UC is the result of genetically determined dysfunction of the mucosal immune system. Inflammation occurs as a result of either excessive effector T-cell function or deficient regulatory T-cell function.[30] In UC, evidence suggests that an excessive T helper (Th)2-cell response occurs rather than the Th1-cell pattern typical of CD (Table 41.2-4). Th2 cells provide more efficient help in the activation of B cells and thus support a humoral immune response. The more frequent production of autoantibodies, such as antineutrophil cytoplasmic antibodies[70] and antitropomyosin antibodies,[71] in UC is thus consistent with an excessive Th2-cell

TABLE 41.2-4 CONTRASTING EFFECTOR T-CELL PATTERNS IN ULCERATIVE COLITIS AND CROHN DISEASE

	ULCERATIVE COLITIS TH2 RESPONSE	CROHN DISEASE TH1 RESPONSE
Cytokines	IL-5, IL-13	IFN-γ, IL-12, TNF-α
Autoantibodies	Frequent, eg, p-ANCA, antitropomyosin	Less frequent
Mucosal IgG subclass predominance	IgG1, IgG4	IgG2
Macrophage activation	Absent	Present

IFN = interferon; Ig = immunoglobulin; IL = interleukin; p-ANCA = perinuclear antineutrophil cytoplasmic antibodies; TNF = tumor necrosis factor.

response. Although IL-4 secretion is not increased in UC, the secretion of other cytokines characteristic of a Th2-cell response, namely IL-5 and IL-13, is elevated.[30] Furthermore, the immunoglobulin subclasses typically associated with a Th2 cell response, IgG1 and IgG4, are found in higher concentration in the serum of individuals with UC.[72]

Although there is mounting evidence that excessive effector T-cell function occurs in IBD, abnormal regulatory T-cell function may also be of critical importance in the pathogenesis of UC. Such abnormal regulation could lead to loss of normal oral tolerance to antigens of the mucosal microflora and result in persistent inflammation.[73] Abnormalities of antigen-presenting cells may also play a role in this abnormal response to the intestinal microflora.[30]

The epithelial cell barrier that limits or modifies exposure of the mucosal immune system to the microflora is a result of both passive or mechanical and active functions. Recent evidence suggests that epithelial cells can actively recognize luminal antigens through the expression of Toll-like receptors or other mechanisms. Thus, defects in either the passive or active epithelial barrier function might result in initiation or potentiation of mucosal inflammation by microbial antigens.[30]

Once the mucosal immune system is activated, cytokines and chemokines play important roles in the promotion and amplification of the inflammatory cascade. Levels of IL-8 are elevated in biopsy specimens and in rectal dialysates from patients with active UC.[74–76] IL-8 and other cytokines facilitate the recruitment and transmigration of neutrophils across mucosal surfaces.[77,78] In turn, these neutrophils produce leukotrienes and other mediators, which promote inflammation and contribute to tissue damage.

CLINICAL FEATURES

PRESENTATION

The cardinal symptoms of UC are diarrhea, rectal bleeding, and abdominal pain. However, several different patterns of presentation of UC are recognized, differing by the extent and severity of mucosal inflammation and the degree of systemic disturbance. Most commonly, UC presents with the insidious onset of diarrhea, later associated with hematochezia, but usually without systemic signs of fever, weight loss, or hypoalbuminemia.[79,80] In these patients, the physical examination is usually normal, with no abdominal tenderness.

Approximately 30% of cases have moderate signs of systemic illness and present with bloody diarrhea, cramps often associated with urgency to defecate, malaise, low-grade or intermittent fever, anorexia with weight loss, and mild anemia and hypoalbuminemia. Physical examination may reveal abdominal tenderness, and stool analysis shows varying amounts of blood and leukocytes.[79,80]

Severe colitis occurs in approximately 10% of patients and is characterized by five or more bloody stools per day, significant anemia, hypoalbuminemia, fever, tachycardia, and weight loss. The abdomen may be diffusely tender or distended. Children with this presentation are less likely to have a lasting response to medical therapy and may require early colectomy.[81] Adult and pediatric criteria for the diagnosis of severe or fulminant colitis are compared in Table 41.2-5.[81,82]

Isolated rectal involvement is unusual in children but can be recognized by the symptom complex of tenesmus, urgency, and the passage of formed or semiformed stool with blood and mucus.[83] Limited distal proctitis or proctosigmoiditis may extend to involve the more proximal colon with time in approximately one-third to half of cases.[84–87]

TABLE 41.2-5 CRITERIA FOR THE DIAGNOSIS OF SEVERE ULCERATIVE COLITIS

FEATURE	TRUELOVE AND WITTS[82]	WERLIN AND GRAND[81]*
Bloody stools	≥ 6 per day	≥ 5 per day
Fever	Mean evening temperature > 37.5°C or temperature ≥ 37.8°C at least 2 of 4 d	> 100°F during the first hospital day
Tachycardia	> 90 bpm	≥ 90 bpm
Anemia	Hgb ≤ 75% of normal value	Hct ≤ 30%

Erythrocyte sedimentation rate	> 30 mm/h	

Hct = hematocrit; Hgb = hemoglobulin.
*Patients must fulfill four of the five listed criteria or have toxic megacolon to be categorized as having severe colitis.

Although, by definition, UC is confined to the colon, children with UC may develop symptoms of gastroesophageal reflux or dyspepsia, with associated inflammation of the upper gastrointestinal tract.[88,89] In a controlled, blinded study of children with UC who underwent upper endoscopy, esophagitis was noted in 50%, gastritis in 69%, and duodenitis in 23% of patients.[88] In the same study, patients with CD were noted to have a higher incidence of inflammation in each of these areas. Moreover, granulomas of the upper gastrointestinal tract were seen in 40% of the patients with CD and duodenal cryptitis was noted in 26% of patients with CD but in none of the patients with UC. Focally enhanced gastritis, thought to be a specific feature of CD, has also been recognized in UC.[89] Despite the accumulating evidence of frequent upper gastrointestinal involvement in UC, more research is needed to determine whether this is a primary manifestation of UC or secondary to concomitant peptic disease.

Extraintestinal manifestations of disease may rarely be the presenting features and precede the gastrointestinal manifestations of UC. Although less commonly seen than in CD, the first sign of UC may be growth failure characterized by decreased linear growth velocity.[90,91] Children with UC may develop axial or perpheral arthritis, erythema nodosum, pyoderma gangrenosum, or primary sclerosing cholangitis prior to the recognition of colitis.[79]

Extraintestinal Manifestations

Approximately 25 to 35% of patients with IBD develop extraintestinal symptoms (Table 41.2-6).[92,93] Extraintestinal manifestations of IBD may occur before, during, or after the development of gastrointestinal symptoms and may even appear after surgical removal of diseased bowel.[93–97] Furthermore, the clinical activity of the extraintestinal manifestations may or may not correlate with the activity of intestinal inflammation.

Arthropathy is a frequent extraintestinal manifestation of UC. It occurs in approximately 20 to 25% of patients and occasionally may be the presenting manifestation of UC. Two major forms have been recognized: a peripheral arthropathy and an axial arthropathy.

The peripheral arthritis of IBD usually presents as an asymmetric, nondeforming, migratory polyarthritis of one or more large joints (knees, ankles, hips, wrists, or elbows). Exacerbations of peripheral joint disease seem to parallel increased activity of bowel disease in UC or CD.[98] Orchard and colleagues, in a study of 976 adults with UC, suggested that there may be two subtypes of peripheral arthropathy: a pauciarticular form with fewer than five swollen joints and a polyarticular form with more than five joints. Of these two subtypes, the pauciarticular arthropathy is more likely to correlate with exacerbations of bowel disease.[99] Treatment of the mucosal inflammation associated with UC generally results in improvement of the peripheral arthropathy; however, judicious use of NSAIDs or other anti-inflammatory agents may be required. In addition to its value in the treatment of colonic inflammation, sulfasalazine may have a direct effect on the arthritis.

Axial arthropathies, ankylosing spondylitis or sacroiliitis, occur in 1 to 4% of patients and are associated with HLA-B27 positivity in the majority of cases.[92–94,100] Ankylosing spondylitis associated with IBD runs a course independent of the activity of bowel disease and may progress to permanent deformity, despite colectomy.[93,94,100] Patients with UC also frequently develop enthesopathy characterized by inflammation at the site of attachment of tendons and ligaments to bone.

Pyoderma gangrenosum and erythema nodosum are the two major skin manifestations associated with UC and CD. Pyoderma gangrenosum occurs in less than 1 to 5% of patients with UC (although it is more commonly seen in UC than in CD)[92,95] and often is associated with active disease and extensive colonic involvement.[95,101] The classic pyoderma gangrenosum lesion often begins as a discrete pustule with surrounding erythema and then extends peripherally to develop into an ulceration with a well-defined border and a deep erythematous to violaceous

color.[102] The lesions of pyoderma gangrenosum tend to be multiple and localize below the knees and often develop at sites of trauma and previous surgical sites, including scars and ileostomy stomas.[101–103] Approximately 40% of patients with UC and pyoderma gangrenosum also develop joint symptoms.[95] Treatment of pyoderma gangrenosum involves intralesional or systemic therapy, and remission is difficult to achieve. Erythema nodosum occurs more frequently with CD (27%) in comparison with UC (4%) and usually coincides with increased bowel disease activity.[92,95,100] Erythema nodosum lesions appear as tender, warm, red nodules or raised plaques and usually localize to the extensor surfaces of the lower extremities, particularly over the shins.[104] Both pyoderma gangrenosum and erythema nodosum can precede the development of bowel symptoms, and pyoderma gangrenosum can occur even after bowel resection.[95] Other skin manifestations are unusual and include Sweet syndrome (acute febrile neutrophilic dermatosis) and, rarely, oral lesions.[105]

Ophthalmologic abnormalities are described in approximately 1 to 3% of children with IBD.[93] Episcleritis and uveitis are the more common ocular disorders reported.[106] Episcleritis usually presents with hyperemia of the sclera and conjunctiva, with or without pain and without loss of vision, and is treated with topical corticosteroids.[93,105] Uveitis is typically characterized by acute or subacute pain of the eye with visual blurring, photophobia, and headache and is diagnosed with a slit-lamp examination.[105] However, uveitis associated with IBD in children may be asymptomatic; thus, the incidence of associated eye findings may be underestimated in the literature.[107] Because of the potential risk of developing blindness, uveitis should be treated promptly with topical or systemic steroids.[105] Ocular inflammation appears to develop more commonly in patients with other extraintestinal manifestations, including arthritis, and may be associated with genes in the HLA region.[97,107] In addition, corticosteroid use increases the risk of increased intraocular pressure and the development of posterior subcapsular cataracts.[108,109] Given the potential eye complications, children with IBD should be monitored carefully at regular intervals, especially when receiving systemic corticosteroid therapy.

Hepatic abnormalities in children with UC have been well described. Although these are typically identified after the UC diagnosis, they may also precede the gastrointestinal symptoms.[110] Transient elevations of alanine aminotransferase occur in 12% of children with UC and appear to be related to medications or disease activity.[110] Persistent alanine aminotransferase elevations suggest the presence of primary sclerosing cholangitis or autoimmune chronic active hepatitis. Among children with UC, approximately 3.5% develop sclerosing cholangitis and less than 1% develop chronic active hepatitis.[110] The diagnosis of primary sclerosing cholangitis may be suspected based on symptoms of chronic fatigue, anorexia, pruritus, or jaundice, although many children may be asymptomatic.[111] γ-Glutamyl transpeptidase and alkaline phosphatase levels are typically elevated.[96] The diagnosis of primary sclerosing cholangitis is best established through a combination of cholangiography and liver biopsy.[111] Medical treatment has little impact on disease course, although ursodeoxycholic acid may be of some benefit.[112] There is a paucity of literature addressing the long-term outcome of children with primary sclerosing cholangitis specifically associated with UC.[110] In children with primary sclerosing cholangitis (with or without IBD), later age at presentation, splenomegaly, and prolonged prothrombin time at presentation were associated with poor outcome, defined as death or required listing for transplant.[96] Fatty changes of the liver observed on liver biopsies of patients with UC or CD may be secondary to malnutrition, protein losses, anemia, and corticosteroid use.[113] An increased risk of cholelithiasis has been reported in individuals with UC but is more commonly observed in CD.[114]

Thromboembolic disease, including cerebrovascular involvement, deep vein thrombosis, and pulmonary emboli, can lead to significant morbidity for individuals with IBD.[115–117] Multiple coagulation abnormalities are observed in IBD, including thrombocytosis; elevated levels of fibrinogen, factor V, and factor VII; and depressed levels of antithrombin III and factor V Leiden.[105,116] Controversy still remains as to whether the thromboembolic complications are directly related to the altered hemostatic states observed in UC and CD and may involve a more complex multifactorial cascade involving gene-gene and gene-environment interactions.[118] Rarely, other hematologic abnormalities associated with UC occur, including immune thrombocytopenic purpura[119] and autoimmune hemolytic anemia.[120]

Low bone mineral density occurs in children with UC but less often than in children with CD.[121] As with CD, corticosteroid use increases the risk of osteopenia. Chronic recurrent multifocal osteomyelitis, a rare disorder characterized by aseptic inflammation of the long bones and clavicles, was recently found to be associated with both UC and CD.[122] Other extraintestinal manifestations of UC include nephrolithiasis,[92,123] pancreatitis (related or unrelated to medications),[124,125] and pulmonary and cardiac involvement.[93]

Complications

A number of serious complications may occur in the course of UC. Whereas some of these, such as toxic megacolon, perforation of the colon, and massive hemorrhage, may occur with a severe exacerbation at any point of time, strictures and colon cancer typically happen in the setting of long-standing disease.

Toxic megacolon is a life-threatening complication of UC characterized by total or segmental nonobstructive dilatation of the colon of at least 6 cm in transverse diameter (as defined in adults) associated with systemic toxicity.[126–128] Although reported to occur in up to 5% of UC patients over their lifetime, it is relatively rarely encountered in our pediatric experience, and the overall incidence seems to be decreasing secondary to earlier recognition and improved management of severe colitis.[128] In contrast to typical UC, in which the inflammatory changes are limited to the mucosa, in toxic megacolon, the severe inflammation extends into the deeper layers of the colonic wall.[129]

The pathogenesis of toxic megacolon is probably multifactorial.[128] The extension of inflammation to the muscularis mucosa and myenteric plexus leads to paralysis of colonic smooth muscle, hypokalemia and hypomagnesemia further impair neuromuscular function, and low oncotic pressure owing to hypoproteinemia results in edema. Nitric oxide, an inhibitor of smooth muscle tone, may also play a role.[130] Disrupted mucosal integrity may allow entry of bacteria to submucosal tissues, leading to necrosis and peritonitis. Absorptive function of the mucosa is also impaired, resulting in increased luminal fluid volume and electrolyte losses.[131]

Risk factors for toxic megacolon include drugs that impair motility, such as anticholinergic agents, narcotic agents prescribed for analgesia or antidiarrheal effects, and antidepressants with anticholinergic effects.[129,132,133] Diagnostic procedures involving distention of the colon, such as colonoscopy and barium enema, may impair blood flow and increase mucosal uptake of bacterial products.[128] Metabolic abnormalities, such as hypokalemia, hypomagnesemia, or hypoproteinemia, may compromise colonic epithelial integrity and motor function. The early discontinuation or rapid tapering of steroids or 5-aminosalicylic acid (5-ASA) agents has been associated with the subsequent development of toxic megacolon.[128,129]

Toxic dilatation of the colon is accompanied by fever, abdominal distention, and tenderness, with or without peritoneal signs. In addition, tachycardia, hypokalemia, hypomagnesemia, hypoalbuminemia, dehydration, hypotension, and mental status changes can develop with progressive disease.[126,128] Leukocytosis with a predominance of immature neutrophils or anemia may be present. It is important to consider that clinical signs, particularly fever and tenderness, may be masked by high-dose steroid treatment. Therefore, a high index of suspicion is prudent regarding any change in clinical appearance, including attention to reduction in stool frequency, which may reflect colonic dysmotility rather than clinical improvement. Abdominal radiography reveals colonic dilatation, most frequently involving the transverse colon, sometimes accompanied by inflammatory changes including absent or markedly edematous haustral pattern (Figure 41.2-2).[134] Because the transverse colon is the most anterior portion of the colon, air will tend to accumulate in this segment of the colon in the supine position; however, with repositioning of the patient, the colonic air will redistribute, filling other segments of the bowel.[135]

The patient with toxic megacolon is at risk of colonic perforation, gram-negative sepsis, and massive hemorrhage.[126] Once the disorder is recognized, optimal management mandates prompt surgical consultation and should include stool bacterial culture with assay for *Clostridium difficile* toxin and treatment with broad-spectrum antibiotics and high-dose steroids. Effective monitoring requires serial physical examination and periodic (every 8 to 12 hours) supine and upright radiographs to assess colonic caliber and exclude the presence of intra-abdominal free air indicative of perforation. A nasogastric tube or, if necessary, passage of a long tube into the distal intestine may decompress the colon and minimize further fluid accumulation. Fluid and electrolyte homeostasis should be restored with intravenous normal saline, albumin, and blood. If not previously indicated, parenteral alimentation should begin in anticipation of a prolonged period of restricted enteral intake. Because most distention occurs in the anteriorly located transverse colon, positioning the patient prone, with or without a rectal tube, may facilitate colonic decompression. Patients who fail to respond to these aggressive medical measures and have persistence of toxic dilatation for longer than 48 hours, perforation, or ongoing hemorrhage may require emergency colectomy.

Massive hemorrhage in patients with UC may occur with or without toxic megacolon. Such hemorrhage is managed with blood transfusions and aggressive treatment for the underlying UC and may require urgent colectomy.[136] Colonic perforation may also occur with or without accompanying toxic colonic dilatation and requires urgent colectomy.[137] Intra-abdominal and hepatic abscesses occur less commonly than in CD, except after perforation or colectomy.

In long-standing UC, a colonic stricture may occur. Although in adults this may be due to carcinoma, in the pediatric age group, benign postinflammatory fibrotic strictures are most likely. These strictures usually occur in the rectum and sigmoid, are due to smooth muscle hypertrophy, and are thought to be potentially reversible.[138–140]

Individuals with long-standing UC are at a markedly increased risk of developing colorectal cancer.[141–143] This

FIGURE 41.2-2 Massive dilatation of the transverse colon in a patient with fulminant ulcerative colitis developing abdominal distention. Courtesy of Carlo Buonomo and the Radiology Teaching Collection, Children's Hospital, Boston.

risk increases with longer duration of disease and more extensive colonic involvement.[144,145] In patients with less than 8 to 10 years of disease, the risk is minimal but thereafter increases by 0.5 to 1.0% per year.[146] Early age at onset has not been consistently demonstrated to be an independent risk factor.[147] The risk of colorectal cancer is minimal in patients with proctitis or proctosigmoiditis, intermediate in patients with left-sided colitis, and highest in patients with pancolitis.[147] In a population-based cohort study in Sweden, Ekbom and colleagues reported standardized incidence ratios for colorectal cancer of 1.7 for ulcerative proctitis, 2.8 for left-sided colitis, and 14.8 for pancolitis.[142] Other risk factors for colorectal cancer in patients with UC include concurrent primary sclerosing cholangitis,[148–150] a family history of colorectal cancer,[151] and the occurrence of backwash ileitis.[152] In contrast, some retrospective studies suggest that 5-ASA agents may provide a protective effect in the development of colorectal cancer in patients with UC,[153,154] but other studies do not support these findings.[155] Recently, ursodeoxycholic acid has been demonstrated to be effective as a chemopreventive agent in patients with UC and primary sclerosing cholangitis.[156,157] The role of pharmacologic therapy and vitamin supplements, such as folate, in the development of colorectal cancer in patients with UC remains controversial, and further prospective studies are needed.[158]

Colonoscopic screening programs are designed to detect patients with low- or high-grade dysplasia prior to the development of cancer and to detect cancer as early as possible. However, there are no randomized controlled trials examining the effectiveness of surveillance colonoscopy for dysplasia and colorectal cancer in patients with UC, and screening may even miss cancer.[159,160] Furthermore, there is significant interobserver variation among pathologists in the determination of the presence and grade of dysplasia.[161,162] Current practice includes surveillance colonoscopy every 1 to 2 years beginning at 8 years after the diagnosis of disease for pancolitis and 15 years in those with left-sided colitis.[160] However, it may be prudent to perform the initial surveillance colonoscopy beginning at 8 to 10 years after diagnosis on all patients with UC to reassess the true extent of disease.[160] Biopsies are performed in four quadrants at 10 cm intervals from the cecum to the descending colon and then at 5 cm intervals beginning in the sigmoid colon. The American College of Gastroenterology recommends colectomy for cancer and high-grade dysplasia and dysplasia-associated lesion or mass, both of which have a high risk of associated malignancy, and low-grade dysplasia, despite the fact that some patients with low-grade dysplasia may not progress.[163] It is not clear whether surveillance practice should differ for patients with younger-onset UC, and there are no published formal recommendations to guide surveillance colonoscopy in children.[159]

DIAGNOSIS

Differential Diagnosis

The diagnosis of UC is established by the information gathered from a detailed history, physical examination, and a combination of laboratory, radiologic, and endoscopic studies. The goal of the evaluation of the child with suspected colitis is to exclude other etiologies such as an infectious process and to distinguish UC from CD. Physical examination should include assessment of height, weight, and body mass index; abdominal distention, tenderness, or mass; extraintestinal manifestations (eg, aphthous stomatitis, pyoderma gangrenosum, uveitis, or arthritis); fecal blood on rectal examination; and perianal abnormalities (eg, fistulae, fissures, or tags). Colonic inflammation is typically accompanied by bloody diarrhea with abdominal cramping. Rectal bleeding may be caused by a number of other disorders in children, including polyps, vascular abnormalities, Meckel diverticulae, intestinal duplications, surgical disorders such as intussusception and other causes of bowel ischemia, or anal disease, such as hemorrhoids or anal fissures. The bleeding from Meckel diverticulum is usually painless, copious, and without fecal leukocytes. Polyps also usually cause painless bleeding, which is often low grade and chronic but may be massive. Fissures may be secondary to constipation or trauma or may be among the perianal manifestations of CD, particularly if inflammation is prominent.

The differential diagnosis of colitis depends on the age of the child at the time of evaluation. In infancy, necrotizing enterocolitis, Hirschsprung enterocolitis, and allergic colitis must be considered. In contrast, in the older child and adolescent, enteric infection and IBD are the most common diagnoses. Infection with *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *Aeromonas*, certain strains of *E. coli*, and *Entamoeba histolytica* may resemble UC and should be excluded. Although *C. difficile* usually causes diarrhea without accompanying rectal bleeding, pseudomembranous colitis may develop. Vascular injury and consequent ischemic colitis may occur in children with Henoch-Schönlein purpura and hemolytic uremic syndrome. In the latter disorder, the characteristic intravascular hemolysis and renal injury characteristic of hemolytic uremic syndrome may not be present initially. A complete list of the causes of colitis is provided in Table 41.2-7.

In addition to details of the clinical presentation, the history should include a family history, recent antibiotic therapy, infectious exposures, growth and sexual development, and the presence of extraintestinal manifestations of UC. Findings on physical examination may help to distinguish UC from CD; for example, pronounced growth failure or a perianal abscess strongly suggests the diagnosis of CD. A severely ill child with UC may have tachycardia, orthostatic hypotension, fever, or dehydration. Such findings in the presence of abdominal distention and a concerning abdominal examination may herald a fulminant presentation of UC with increased risk of developing toxic megacolon.

Laboratory Assessment

Initial laboratory evaluation should include blood tests, stool for occult blood and stool cultures, and a urinalysis. A complete blood cell count with differential may reveal a leukocytosis with or without left shift, microcytic anemia, and thrombocytosis. Thrombocytosis, hypoalbuminemia, and

elevated erythrocyte sedimentation rate or C-reactive protein may indicate increased disease activity.[164–166] Unlike the erythocyte sedimentation rate, the assay for C-reactive protein is not affected by the hematocrit or other serum proteins and thus may be a superior marker for intestinal inflammation. The presence of anemia with low mean corpuscular volume, wide red blood cell distribution width, and low iron levels may indicate an iron-deficient anemia secondary to ongoing fecal blood losses or malabsorption of iron. However, even children with significant mucosal inflammation may have normal laboratory test results. In a study of children with UC or Crohn colitis, 13 of 36 patients with UC (36%) had normal blood test results, including 7 of 28 UC patients with macroscopic findings on colonoscopy and 12 of 31 UC patients with histologic moderate or severe chronic inflammation.[166] Although insensitive, a positive assay for fecal leukocytes by Wright stain or methylene blue preparation may suggest colitis. More recently, assays of white blood cell proteins, such as calprotectin or lactoferrin, have been proposed as more reliable indicators of colonic inflammation.[167–169] Stool cultures should be performed to detect enteric infections. It is important to note, however, that a significant percentage of patients with bacterial colitis will have negative cultures. In sexually active patients, rectal cultures for gonorrhea should be considered. *C. difficile* is detected more frequently in patients with UC than in the general population. Assay for both *C. difficile* toxins should be obtained in all patients, regardless of prior antibiotic treatment.[170–172]

Several unique serum antibodies have been proposed as tools for use in screening symptomatic children for IBD and discriminating UC from CD.[173,174] Perinuclear antineutrophil cytoplasmic antibodies (p-ANCAs) are seen in 60 to 80% of subjects with UC compared with 10 to 27% of those with CD.[173,175,176] In contrast, anti–*Saccharomyces cerevisiae* antibodies (ASCAs) are commonly found in individuals with CD but are rarely seen in UC. In a study of 173 children, assay of ASCAs yielded a sensitivity of 55% and a specificity of 95% for CD, and assay of ANCAs had a sensitivity of 57% and a specificity of 92% for UC.[173] Using modified cutoff values to optimize the sensitivity of the ASCA and ANCA assays in a study of 128 pediatric patients undergoing evaluation for IBD, Dubinsky and colleagues noted an increase in sensitivity for detecting IBD from 69 to 81%, but this was accompanied by an increase in false-positive rates among the children without IBD.[174] Therefore, these tests should not be considered a substitute for the traditional evaluation of a child for UC. Furthermore, because a significant fraction of children with CD may have positive assays for p-ANCAs, serologic studies may not reliably discriminate between CD and UC. In particular, p-ANCAs tend to test positive in the serum of patients with CD who exhibit UC features.[173,177] Additional evidence will be required before the routine use of serologic testing can be endorsed in the child with suspected UC.

RADIOLOGY

Plain abdominal radiographs, both upright and supine, are typically used to detect complications of UC, such as colonic dilatation, obstruction owing to stricture, and pneumoperitoneum from perforation. The extent of disease may occasionally be ascertained by noting the distribution of abnormal haustral patterns as outlined by air.[178–180] These films form a baseline for later comparisons. With the increasing application of endoscopic procedures, the barium enema has been assigned a very limited role in the evaluation of children with UC. A barium enema should never be performed in patients with acute, active colitis because of the risk of precipitating toxic dilatation. Single-contrast barium enema is rarely performed except in young children but may help in assessing the character and extent of colonic disease. In mild to moderate colitis without dilatation, an air-contrast barium enema may reveal enough detail to detect mucosal granularity, ulcerations, and nodular haustral folds. Even without air contrast, a barium enema may reveal the chronic changes of foreshortening, loss of haustra, pseudopolyps, and strictures. An upper gastrointestinal series with small bowel follow-through should be performed to assess for any evidence of abnormality of the terminal ileum or a more proximal gastrointestinal tract and the presence of fistulae, which would suggest CD. The only exception is the finding of UC-associated "backwash ileitis," which should be distinguished from terminal ileal disease of CD. With backwash ileitis, the ileum appears patulous and inflamed, involvement is limited to the distal ileal segment, and pancolitis is present; there should be no evidence of extensive ulcerations or stricturing, as seen with CD.[140] A late film during the upper gastrointestinal series to study the right colon (anterograde colonogram) may uncover colonic involvement.[181] This technique is safer than a barium enema, although lack of colonic distention may make interpretation difficult. Computed tomography is not typically performed in the initial assessment for UC but may demonstrate diffuse bowel wall thickening, marked rectal wall thickening, and perirectal fibrofatty pro-

liferation.[140] In moderately to severely ill patients with bowel dilatation, extensive bleeding, persistent fever, or abdominal mass, computed tomography may identify an intra-abdominal abscess. Recently, Doppler ultrasonography[182,183] and leukocyte-labeled scintigraphy[184] have been proposed as accurate means of assessing the extent and activity of UC; however, more study is needed before routine application of these studies can be recommended.

Endoscopic Assessment

Flexible sigmoidoscopic or colonoscopic inspection of the colon and ileum, in conjunction with mucosal biopsies, provides the most sensitive and specific evaluation of intestinal inflammation. Although in older children and adults, sigmoidoscopy can be performed with more limited sedation and preparation of the colon, these advantages do not apply to young children; therefore, full colonoscopy with examination of the terminal ileum at diagnosis may be preferable. To establish the extent of disease involvement by colonoscopy, we recommend biopsies from the terminal ileum and each segment of the colon even if there are no macroscopic findings at a particular level of the colon. However, colonoscopy is contraindicated in severe colitis because of the risks of perforation and hemorrhage and the induction of toxic megacolon. In patients with severe disease, a limited proctosigmoidoscopy often suffices to establish the diagnosis. Excessive bowel distention with air insufflation should be avoided, and the examination should be halted on encountering areas of severe inflammation.

In UC, typical findings seen by the endoscopist include a diffuse, continuous involvement of the mucosa starting at the rectum and extending more proximally into the colon. In children with UC, however, rectal sparing has occasionally been noted.[9,10] Also, previous topical therapy may also result in the appearance of distal sparing. The colonic mucosa often appears edematous, erythematous, and friable, with loss of vascular pattern, minute surface erosions, and ulcerations. Larger, deeper ulcerations with associated exudate may develop in more severe disease. With long-standing UC, pseudopolyps may be present. In contrast, in CD, colonoscopy may reveal focal ulcerations (aphthous lesions) with intervening areas of normal-appearing mucosa (skip lesions). In severe or chronic CD, linear ulcerations, nodularity (cobblestoning), and strictures or stenoses may be present. In general, the ulcerations in CD are deeper and focal versus the diffuse, superficial ulcerations typical of UC.[185–187]

Although inflammation of the upper gastrointestinal tract has been reported primarily in children with CD, such inflammation can also be seen in UC.[88,89,188,189] Nevertheless, the pattern of inflammation (eg, presence of granulomas characteristic of CD) may differentiate the two entities. Therefore, some centers recommend initial upper endoscopy in addition to colonoscopy in all patients with suspected IBD.

THERAPY

Overview

UC is a chronic disease requiring careful monitoring, patient education, and expert management by a team consisting of the primary clinician, gastroenterologist, nurse, nutritionist, social worker, and psychiatrist or psychologist. An alliance with a pediatric surgeon familiar with IBD is essential for management of potential complications. Because the success of management depends on the degree to which the patient and family understand and participate in the treatment, they must be educated about the disease and incorporated as members of the team, often a major challenge for the physician. Support groups and organizations such as the Crohn's and Colitis Foundation of America are indispensable not only in disseminating information but also in providing a community to counter the isolation that often attends the diagnosis of a chronic disease.

The effective management of UC in children demands special considerations. Poor compliance with recommendations for medical therapy is a major reason for treatment failure, especially in the pediatric age group. Younger children may not be able to swallow tablets or capsules or refuse medications on the basis of taste. Extemporaneous suspensions and the administration of capsule contents or crushed tablets in applesauce or foods of similar consistency are possible options for these patients. Older children and adolescents are unlikely to be compliant with medication programs that require multiple daily doses of medication; accordingly, regimens should be streamlined. In the choice of medication, the pediatric gastroenterologist must also consider the unique aspects of the pediatric patient, such as growth, pubertal development, and psychosocial adjustment to disease, and the potential adverse effects of certain drugs. For example, corticosteroids, which may inhibit growth and cause cosmetic problems, can cause devastating problems for the teenage child. Monitoring children during therapy presents challenges as well. The physician must balance the need to perform follow-up blood tests and radiologic and endoscopic procedures against the trauma that these tests may cause for certain children.

The goals of medical therapy of UC in children are the induction of remission with control of symptoms, the prevention of relapse, the avoidance of complications, and the provision of optimal quality of life. With the advent of more effective agents, mucosal healing has been proposed as a goal of therapy, but this approach remains controversial and is often impractical. The choice of therapy depends on the severity of the inflammation and the distribution of inflammation in the colon. The following discussion reviews the utility of the various individual agents used in the management of UC (Table 41.2-8) and offers an approach to therapy based on disease severity and distribution.

Pharmacologic Agents

Aminosalicylates are the principal therapeutic agents for treatment of mild to moderate UC in childhood. Both the initially discovered agent sulfasalazine and newer formulations containing 5-aminosalicylate have proven efficacious in the induction of remission in mild to moderate disease and in the subsequent maintenance of remission.

A combination of 5-aminosalicylate and sulfapyridine linked by an azo bond, sulfasalazine is split by colonic flora into its two constituents. The 5-aminosalicylate is poorly

TABLE 41.2-8 COMMONLY PRESCRIBED MEDICATIONS FOR ULCERATIVE COLITIS

MEDICATION	DOSAGE	MAJOR SIDE EFFECTS
SULFASALAZINE	40–75 mg/kg/d PO, divided bid or tid; adult dose: 4–6 g/d, divided bid or tid	Nausea, headaches, diarrhea, photosensitivity, hypersensitivity reaction, pancreatitis, azoospermia, hemolytic anemia, neutropenia
MESALAMINE		
Oral formulation	30–75 mg/kg/d PO divided bid to qid (depending on preparation); adult dose: 2.4–4.8 g/d divided bid to qid	Nausea, headaches, diarrhea, pancreatitis, nephritis, pericarditis, pleuritis
Enema formulation	2–4 g PR q 12–24 h	
Suppository formulation	500 mg PR q 12–24 h	
CORTICOSTEROIDS		
Intravenous or oral formulation	1–2 mg/kg/d of prednisone or equivalent, IV or PO, divided q 12–24 h (maximum 60 mg/d)	Cushing syndrome, growth suppression, immunosuppression, hypertension, hyperglycemia, increased appetite, osteoporosis, aseptic necrosis (hip), cataracts
Enema formulation	50–100 mg of hydrocortisone PR qhs	
Suppository formulation	25 mg of hydrocortisone acetate PR qhs	
Foam formulation	One application PR qhs	
6-MERCAPTOPURINE	1.0–2.0 mg/kg/d PO qd	Nausea, emesis, immunosuppression, hepatotoxicity, pancreatitis, myelosuppresion
AZATHIOPRINE	1.5–2.5 mg/kg/d PO qd	Nausea, emesis, immunosuppression, hepatotoxicity, pancreatitis, myelosuppression
CYCLOSPORINE	Induction regimen for fulminant colitis: initial dose: 4–6 mg/kg/d IV continuous or divided bid; maintenance oral dose varies according to oral preparation	Nephrotoxicity, hypertension, headache, hirsutism, immunosuppression, nausea, emesis, diarrhea, tremor, hypomagnesemia, hyperkalemia, hepatotoxicity, seizures, gingival hyperplasia

absorbed from the colon and is considered to be the active anti-inflammatory moiety.[190] The proposed mechanisms of action of 5-aminosalicylate include inhibition of the synthesis of the leukotriene B_4, a potent chemotactic agent, from arachidonic acid and the scavenging of reactive oxygen metabolites.[191,192] The sulfapyridine is absorbed and excreted in the urine and is responsible for many of the common dose-related and transient side effects of headache, malaise, nausea, vomiting, anorexia, heartburn, epigastric distress, and diarrhea.[193] In addition, a number of rare and potentially severe hypersensitivity reactions, including skin eruptions, fever, leukopenia, agranulocytosis, aplastic anemia, pancreatitis, systemic lupus erythematosis, and pulmonary dysfunction, may occur. Sulfasalazine interferes with folic acid absorption and may cause megaloblastic anemia if a folate supplement is not administered. About 80% of adult men develop reversible abnormalities of sperm, which can compromise fertility.[191] Parodoxically, cases of exacerbation of colitis have been reported and probably represent salicylate hypersensitivity.[194] Children at risk for glucose-6-phosphatase deficiency should be screened prior to sulfasalazine treatment. Given the potential for intolerance, the dosage of sulfasalazine is gradually increased over 1 week from 10 mg/kg daily to 40 to 50 mg/kg, up to a maximum of 75 mg/kg in two to four divided doses. Symptoms and blood counts should be monitored closely. Because sulfasalazine impairs folate absorption, 1 mg daily folate supplements are usually provided.

Newer agents that use alternative systems have been created to deliver 5-aminosalicylate (mesalamine) to the colon without sulfapyridine.[195] Asacol and Pentasa contain 5-aminosalicylate in a delayed-release coating to prevent proximal absorption of the drug and ensure delivery to the small intestine and colon. Two azo-bonded compounds, which, like sulfasalazine, are cleaved in the colon, are available: olsalazine, which contains two 5-aminosalicylate moieties, and balsalazide, which contains a 5-aminosalicylate molecule bonded to 4-aminobenzolyl-β-alanine. All of these agents have been demonstrated to be effective in the treatment of acute UC and in the maintenance of remission in adults. Although some studies suggest an advantage of azo-bond ASA agents (ie, balsalazide) in comparison with delayed-release ASA agents (ie, mesalamine), the overall data suggest equivalence between the different oral aminosalicylates when comparable amounts of the ASA are released at the site of disease activity.[196] Anecdotal evidence for efficacy of oral aminosalicylates in children with UC exists, but the only controlled trial failed to demonstrate a therapeutic effect comparable to that of sulfasalazine.[197] In this multicenter, randomized, double-blind study, the efficacy and safety of olsalazine (30 mg/kg/d; maximum 2 g/d) were compared with those of sulfasalazine (60 mg/kg/d; maximum 6 g/d) in the treatment of mild to moderate UC. The findings demonstrated clinical remission after 3 months in 79% of the sulfasalazine-treated children in comparison with 39% of the olsalazine-treated children. The authors suggested the low dosage of olsalazine as a possible explanation for the difference in efficacy between sulfasalazine and olsalazine. Only 10 to 15% of patients receiving 5-aminosalicylate compounds in clinical trials experienced side effects, including nausea, vomiting, headache, abdominal pain, diarrhea, rash, and hair loss.[198] Occasionally, severe side effects, such as pancreatitis, pericarditis, nephritis, pneumonitis, and an exacerbation of colitis, may occur.

Olsalazine use is associated with a significantly higher risk of diarrhea. Oligospermia and folate deficiency associated with sulfasalazine use do not occur with the newer 5-aminosalicylate compounds.

The choice of an appropriate oral aminosalicylate for use in children must consider ease of administration. Children who cannot swallow tablets may be able to accept extemporaneous suspensions of sulfasalazine or the content of capsules, in the form of powder or beads, when mixed in applesauce or other foods of similar consistency. Cost should also be considered.

Topical aminosalicylates are effective in the treatment of proctitis, proctosigmoiditis, or left-sided UC.[199–201] To be effective, topical therapy must reach the most proximal extent of the disease activity. Mesalamine suppositories spread to the upper rectum, and enemas and foams can reach the splenic flexure or into the distal transverse colon.[191,202] Mesalamine enemas or suppositories are effective as first-line therapy and maintenance therapy for mild to moderately active left-sided UC or proctitis, respectively.[196] Rectal mesalamine may be superior to oral mesalamine in the treatment of active ulcerative proctitis.[203] Mesalamine enemas may be superior to rectal corticosteroids[204] and are also effective in treating distal colitis that is unresponsive to oral aminosalicylates or corticosteroids.[191,202] Combination therapy with oral and topical mesalamine is more effective than one agent alone in the treatment of mild to moderate distal colitis.[205] Topical agents may rarely be associated with side effects.

Corticosteroids are effective in the induction of remission in children with moderate to severe UC. In this context, steroids do not seem to adversely affect surgical outcome if surgery becomes necessary. Treatment is begun with a relatively high dosage of prednisone or methylprednisolone (1 to 2 mg/kg/d, up to a maximum of 40 to 60 mg) in two doses and sustained until disease is controlled, usually within 2 weeks, and then maintained in a single daily dose for another 2 to 4 weeks. Subsequently, with the adjunctive use of a 5-aminosalicylate, the dose is tapered gradually by 5 mg decrements weekly to a dose approximating the child's endogenous production of corticosteroid (approximately 5 mg of prednisone/m^2 surface area) and is then gradually withdrawn over an additional 2 to 4 weeks. If exacerbation of disease activity prevents complete withdrawal of steroids, chronic alternate-day steroid therapy may be necessary. In an uncontrolled study of 20 children with active UC, 85% of the children achieved clinical remission with combination therapy of corticosteroids (oral prednisolone for pancolitis or topical prednisolone for distal colitis) and mesalamine (20–40 mg/kg/d).[206] Reassessment with colonoscopy at 8 weeks demonstrated complete endoscopic remission in 40% and full histologic remission in only 15%, suggesting that clinical remission may not correlate with endoscopic or histologic remission. Potential short-term complications of steroid therapy in patients with UC include increased appetite, weight gain, fluid retention, mood swings, hyperglycemia, hypertension, insomnia, acne, and facial swelling (moon facies). Complications of long-term steroid therapy (usually of greater than 3 months) include growth retardation, osteopenia with compression fractures, aseptic necrosis of the hip, and cataracts.[207] Effects of steroid therapy on growth may be complex because disease activity itself may cause growth retardation. Some patients resume normal growth velocity only after steroid suppression. Other patients whose disease remains in remission may show catch-up growth velocity only after steroid withdrawal.[80,208] Currently available oral preparations of rapidly metabolized steroids, such as budesonide, which may have decreased systemic toxicity, have not yet been proven to effectively treat patients with pancolitis.[209]

Topical corticosteroid therapy may be sensible when disease is limited to the distal colon and rectum. Corticosteroid suppositories, foam, or enemas can be used as first-line induction therapy in patients with mild or moderately active ulcerative proctitis or left-sided UC[196] or may be used in an attempt to reduce the dose of systemic steroids necessary to control disease. Rectal administration of hydrocortisone or prednisolone permits more direct delivery of steroids to distal UC sites; however, as with oral steroid therapy, prolonged treatment with topical steroids may induce systemic steroid side effects, including adrenal suppression.[199,202] Budesonide in an enema preparation may induce remission in distal colitis with fewer systemic steroid side effects.[210] In a randomized, double-blind, placebo-controlled trial, budesonide enema therapy (2.0 mg or 8.0 mg/enema, once per evening) effectively induced remission, with significant improvement in sigmoidoscopy and histopathology scores, compared with placebo in adults with active distal UC or proctitis.[210]

Immunosuppressive agents are being administered increasingly as adjuncts to steroid therapy. 6-Mercaptopurine (6-MP) and azathioprine, which is converted to 6-MP in the liver, are appropriate agents in cases of UC refractory to or chronically dependent on steroid therapy. These immunomodulatory agents can reduce disease activity and allow the withdrawal of steroid therapy in children with steroid-dependent UC; however, the time to clinical response is usually 4 to 8 weeks.[211,212] In a small open-label trial of children with CD or UC, six of nine patients with UC reduced their steroid therapy by at least 75% with azathioprine therapy.[211] In another series of 16 children with severe, steroid-dependent or steroid-refractory UC, 6-MP or azathioprine therapy allowed the discontinuation of steroid therapy in 75%, and 67% remained without steroid therapy at 3 to 65 months.[212] Given their steroid-sparing effects and reasonable tolerance by children with IBD, 6-MP and azathioprine offer an alternative maintenance treatment of IBD in children. In a study of 95 children with either CD or UC, only 18% required discontinuation of the medication; the majority of side effects responded to dose reduction or improved spontaneously.[213] Side effects reported include aminotransferase elevations and hepatitis, pancreatitis, bone marrow depression, hypersensitivity reactions, and recurrent infections.[213,214] Therefore, frequent monitoring for complications with complete blood counts and liver function tests is advised, especially at the initiation of therapy. Furthermore, because evaluation for thiopurine

methyltransferase genetic polymorphism can identify those children at higher risk for drug toxicity,[215] genetic analysis or a functional measure of enzyme activity should be performed on all patients prior to beginning treatment. For a child with normal drug metabolism, the starting dose of 6-MP is 1 to 1.5 mg/kg/d as a single dose and of azathioprine is 1.5 to 2 mg/kg/d. Children with intermediate levels of enzyme should be given lower doses, and homozygotes with very low levels should not receive the medication. Some clinicians have used 6-MP metabolite levels to monitor for compliance and potential toxicity and to permit safe dose adjustment in nonresponding patients.[216]

Given the high relapse rate with withdrawal of 6-MP in adults with UC,[217] the majority of children requiring azathioprine or 6-MP to suppress disease activity most likely will require long-term maintenance therapy with these agents. There are no studies in children addressing this issue to date. At the present time, evidence does not suggest any definitive increased risk of malignancy secondary to long-term use of azathioprine in adults.[218] However, one article has identified a slightly increased risk of Epstein-Barr virus–associated lymphoma in a large cohort of patients treated with long-term 6-MP or azathioprine.[219]

Methotrexate has been recommended as an alternative for patients intolerant of 6-MP but appears to be less effective for the treatment of UC than for CD.[220] Although open-label trials in adults with UC suggested a benefit of methotrexate in the induction of remission,[221,222] a double-blind, randomized trial failed to show any advantage of methotrexate in the induction or maintenance of remission in adults with chronic active UC in comparison with placebo.[223] Although methotrexate can be useful in treating children with CD intolerant to 6-MP, there are currently no published studies describing its efficacy in children with UC.[224] Studies evaluating the effectiveness of mycophenolate mofetil, another immunodulatory agent, for UC show mixed results and may suggest increased side effects compared with other immunomodulatory agents, such as azathioprine.[225–227]

For adult patients with severe colitis unresponsive to intravenous corticosteroid therapy, cyclosporine has been demonstrated to be very effective, and, in contrast to most other immunosuppressive agents, a response occurs within a mean of 7 days.[228] However, such intensive immunosuppression should not be started if surgery is believed to be imminent, such as in a septic patient, a patient with toxic megacolon, or a patient with a suspected perforation. In children with steroid-refractory UC, intravenous or oral cyclosporine therapy has also successfully induced remission.[229–231] In a study of 14 children treated with oral cyclosporine therapy for severe active colitis unresponsive to high-dose intravenous steroids, 80% achieved clinical remission within 2 to 9 days; however, the majority of children who initially responded to cyclosporine eventually required colectomy within 1 year.[231] The exact dosage of cyclosporine varies in different protocols, depending on whether intravenous or oral medication is used.[228,230,231] In addition to the potential complications of immunosuppression, cyclosporine commonly produces renal toxicity, hypertension, tremors, paresthesias, and hypertrichosis. Children on cyclosporine or tacrolimus should receive prophylaxis for *Pneumocystis carinii* and have careful monitoring of electrolytes, blood glucose, renal function, blood pressure, and neurologic status. A recent review outlines specific recommendations on the initiation and monitoring of cyclosporine therapy in children with IBD.[232] A related agent, tacrolimus can also induce remission when administered orally to children with severe active colitis.[233] However, the majority of the children who responded to either agent relapsed or underwent colectomy within 1 year.[231,233] Therefore, cyclosporine and tacrolimus may be most useful in delaying emergent colectomy at a time when the child's health status is most compromised and may allow time to improve the child's health and emotional status in preparation for future "elective" colectomy.[231] If either cyclosporine or tacrolimus is used as induction therapy, the aim should be to transition patients to a less toxic maintenance medication, such as 6-MP, over a 3- to 6-month period.[234]

In open, uncontrolled trials, therapy with infliximab (chimeric monoclonal anti–tumor necrosis factor-α antibody) has resulted in clinical improvement in adults and children with UC.[235–237] In an open-label study of 9 children and adolescents with moderate to severe UC, 7 children (77%) responded based on a decrease in disease activity as measured by the Physician Global Assessment and corticosteroid therapy was discontinued in six children (66%).[237] A small, double-blind, placebo-controlled clinical trial of infliximab in 11 adults with severe, active, steroid-refractory UC suggested a clinical benefit for patients treated with one dose of infliximab (5 mg, 10 mg, or 20 mg/kg/dose) compared with those who received placebo.[238] In this study, 4 of 8 UC patients receiving infliximab improved compared with 0 of 3 receiving placebo. In a larger, randomized, double-blind, placebo-controlled study of 43 adults with moderately active, glucocorticoid-resistant UC, there was no significant difference in remission rate or sigmoidoscopic score between the group treated with infliximab (5 mg/kg/dose at week 0 and 2) and the placebo group.[239] Given the risk of infusion reactions, anti–nuclear antibody formation, and opportunistic infections and the unclear therapeutic benefit, the role of infliximab in the treatment of UC, especially in children, cannot be supported without further study.[240–242]

Despite the potential role of infectious agents in the pathogenesis of UC,[63] the use of antibiotic therapy in the treatment of UC remains controversial. There is a lack of consistent evidence of the effectiveness of antibiotics in the induction and maintenance of remission in UC.[243–246] Nevertheless, empiric broad-spectrum antibiotics often are administered in the setting of severe active UC,[81,247] especially if there is concern for toxic megacolon or other surgical complications.[128] Probiotics have shown some promise for the maintenance of remission in adults with UC.[64–66] In an open-label trial of the probiotic VSL #3, containing a mixture of bifidobacteria, lactobacilli, and *Streptococcus salivarius*, administered to adults with inactive UC, 75% of patients remained in remission during the

12-month study.[65] In two randomized, controlled, comparison trials, nonpathogenic *E. coli* strains and mesalamine maintained similar rates of remission in adults with quiescent UC.[64,66] There have been no formal studies on the effectiveness of probiotics in children with UC.

A number of other agents have been proposed for the treatment of UC, but insufficient evidence of efficacy or troublesome side effects have prevented them from becoming part of the standard therapeutic armamentarium. Given the decreased risk of UC in smokers, nicotine has been studied as a potential treatment. Despite limited evidence that transdermal or topical nicotine therapy may be beneficial in adults with active UC, the potential side effects make this an inappropriate therapy for children.[248,249] Several placebo-controlled studies suggest a benefit of adjunctive therapy with fish oil supplementation containing eicosapentaenoic acid, a potent inhibitor of leukotriene B_4 synthesis, in the treatment of active UC.[250–252] However, fish oil supplementation does not appear to show any benefit in maintenance therapy.[251,253] Furthermore, therapeutic dosing requires that a large number of capsules be taken daily, and the fishy odor and diarrhea associated with therapy limit tolerance. Randomized, controlled trials in adults with active distal UC suggest that therapy with topical short-chain fatty acid preparations results in clinical improvement, but there is no statistically significant advantage in comparison with placebo.[254,255] In several open-label trials, adults with steroid-resistant UC showed a clinical response to heparin therapy[256–258]; however, a controlled trial did not show any advantage of heparin treatment for moderate to severe UC compared with corticosteroid therapy.[259] In an open-label pilot study, daclizumab (humanized anti-IL-2R antibody [CD 25]) resulted in clinical and endoscopic improvement in adults with refractory UC[260]; further study is needed to determine the effectiveness of this novel therapy.

Approach to Medical Therapy

The first step in the medical therapy of UC is the induction of remission (Table 41.2-9). In the child with mild to moderate pancolitis or left-sided UC, with no or only minimal systemic signs, oral aminosalicylates are usually the first line of therapy. Moderate to severe disease usually requires oral corticosteroids for the induction of remission. Restriction of residue in the diet has been anecdotally reported to reduce symptoms during a flare of disease.[261] Severe or fulminant colitis, as defined by more than five to six bloody bowel movements per day, fever, tachycardia, anemia, and hypoalbuminemia, requires hospitalization and intravenous corticosteroids. Intravenous fluids for rehydration and correction of electrolyte imbalances should be administered, with transfusion of packed red blood cells and albumin if indicated. Central venous access for parenteral alimentation is advisable for patients who are unable to tolerate enteral nutrition. Empiric broad-spectrum antibiotic coverage should be considered, especially if there is a suspicion of a toxic megacolon or another surgical complication. Early surgical consultation is recommended. Failure of the patient with fulminant colitis to respond to 7 to 14 days of intravenous steroid therapy should prompt consideration of cyclosporine or tacrolimus therapy or colectomy.

For the cooperative child with mild to moderate proctitis or proctosigmoiditis, topical aminosalicylate suppositories or enemas are appropriate first-line therapy. Topical steroids in the form of suppositories, foam, or enemas are an alternative for nonresponsive disease. Children who fail to respond to topical therapy may need systemic therapy as outlined above for more extensive disease.

The second phase of therapy is the maintenance of remission. Generally, aminosalicylates are the first choice for maintenance therapy. For children with frequent relapses requiring corticosteroid therapy or dependence on steroids, the addition of maintenance treatment with 6-MP or azathioprine should be considered. Remission of proctitis or proctosigmoiditis may be maintained by alternate-day or twice-weekly topical therapy, although oral aminosalicylates are generally preferred by children.

Nutritional Therapy

The provision of adequate nutrients is essential for optimal healing of UC.[262,263] Children with UC usually develop nutritional issues as a result of poor oral intake secondary to symptoms rather than malabsorption or increased metabolic demands; thus, promotion of good nutritional intake is an essential part of therapy.[264] The goals of nutritional therapy are to establish metabolic homeostasis by correcting nutrient deficits and replacing ongoing losses, to provide sufficient

TABLE 41.2-9 RECOMMENDED APPROACH TO MEDICAL THERAPY OF ULCERATIVE COLITIS

DISEASE EXTENT AND SEVERITY	INDUCTION PHASE*	MAINTENANCE PHASE*
Extensive colitis		
Mild to moderate	Oral aminosalicylates	Oral aminosalicylates
Moderate to severe	Oral corticosteroids	1. Oral aminosalicylates 2. 6-MP or azathioprine
Distal colitis	1. Topical aminosalicylates 2. Topical corticosteroids 3. Oral aminosalicylates or corticosteroids	1. Intermittent topical aminosalicylates or corticosteroids 2. Oral aminosalicylates
Fulminant colitis	1. Intravenous corticosteroids 2. Cyclosporine or tacrolimus or colectomy	Oral aminosalicylates and 6-MP or azathioprine

6-MP = 6-mercaptopurine.
*When multiple alternatives are listed, these should be prescribed in the order presented.

energy and protein for positive nitrogen balance or net protein synthesis, and to promote catch-up growth toward premorbid percentiles. Enteral nutrition is preferred to total parenteral nutrition when possible. Continuous nocturnal nasogastric infusions of enteral formula may be necessary in those who cannot voluntarily increase their intake. In contrast to CD, enteral nutrition is not an effective primary therapy for active UC.[196,232] Studies suggest no advantage of total nutritional support and bowel rest in addition to conventional medical therapy in the treatment of UC.[265,266] However, bowel rest and total parenteral nutrition are clearly indicated in patients with severe colitis and possible surgical complications. Furthermore, correction of nutrient deficiencies and maintenance of adequate nutritional status are critical in preparing the patient for surgery.[262]

Surgery

Although medical therapy remains the first-line treatment for UC, colectomy may be required for patients with severe or medically refractory disease or to prevent colon cancer. Because the inflammation in UC is limited to the colon, colonic resection will most often result in resolution of symptoms. However, because colectomy is not without potential long-term complications, such as the development of pouchitis in patients who undergo ileoanal anastomosis,[267] resection of the colon should not be promoted as a "cure" of UC.

Timely surgical intervention in the appropriate setting may avoid complications of UC. Standard indications for colectomy in a patient with UC include fulminant colitis or a complication of colitis, such as massive hemorrhage, perforation, stricture, or toxic megacolon; failure of medical therapy; steroid dependency; and the presence of colonic dysplasia.[268] Retardation of growth and sexual maturation, despite optimal medical therapy and nutritional supplementation, may also prompt consideration of surgery because prepubertal children may experience catch-up growth after colectomy. In one series, 11 of 18 children increased their median height velocity from 3.85 cm/yr preoperatively to 7.35 cm/yr postoperatively.[269] Improvement in medical therapy, however, has led to a decline in the frequency of colectomy. At one center, a retrospective review of children and adolescents with UC revealed a decrease in the frequency of colectomy from 48.9% from 1955 through 1964 to 26.2% from 1965 through 1974.[6]

There are no early predictors to help determine who will proceed to colectomy; however, children with more severe disease at presentation are more likely to undergo colectomy. Hyams and colleagues, in a retrospective review, reported that the 5-year colectomy rate in patients with mild disease at presentation was 8% compared with 26% in patients with moderate to severe disease at presentation.[270] In another retrospective review of 73 children with UC between the ages of 1 and 18 years, the combination of steroid dependency and pancolitis was associated with an increased need for colectomy.[271]

Except in the setting of emergent colectomy, a complete evaluation should be performed to ensure that there is no evidence of CD prior to colectomy. Prior endoscopies and pathology reports should be carefully reviewed, and if not done recently, an upper gastrointestinal series with small bowel follow-through, colonoscopy, and endoscopy should be performed. If there is evidence suggesting the possibility of CD, the patient and family need to be informed of the potential for postoperative recurrence and the relative contraindications of ileoanal pull-through procedures in patients with CD.

The current standard surgical option for UC is colectomy with IPAA.[268] This procedure removes the entire colon and the rectal mucosa, avoids permanent ileostomy, and preserves anorectal function. If the rectal mucosa is in good condition, many centers use the two-stage operative approach. During the first stage, a subtotal colectomy of the cecum to proximal rectum, the removal of the distal rectal and proximal anal mucosa, and the formation of the ileal pouch are performed. In this initial stage, a diverting loop ileostomy is performed to allow the pouch to heal. The second stage involves closure of the loop ileostomy with restoration of fecal flow to the pouch. The creation of a distal ileal reservoir, usually in a "J" or "S" configuration, helps improve continence postoperatively, and elimination of a complete rectal dissection preserves the anorectal sphincter apparatus and parasympathetic innervation to the bladder and genitalia. Surgeons at some centers also complete the IPAA in one stage, without the loop ileostomy.[272] Some authors believe that the omission of the diverting ileostomy may increase the risk of anastomotic leaks and prolong recovery,[273] and the need to retain the anal transition zone may result in persistent mucosal inflammation and the potential for malignant transformation. Thus, candidate patients for the one-stage IPAA should be selected carefully.[274]

If the patient presents for emergent surgical intervention, such as with fulminant colitis, a three-stage operative approach may be used. At the time of acute presentation, a subtotal colectomy is performed with formation of a rectal stump with the remaining unresected rectum and ileostomy. After the first operation, the rectal mucosa is treated with topical therapy to induce mucosal healing. At the second operation, the distal rectal and proximal anal mucosa is removed, and the ileal pouch is created. The ileostomy is reversed at the third operation.

The potential complications of IPAA include small bowel obstruction, pelvic sepsis, anastomotic leak, fecal incontinence, pouchitis, strictures, or fistulae.[268,274,275] The development of fistulae raises the suspicion of CD. In one series of children aged 9 to 16 years who underwent proctocolectomy with IPAA, late complications (bowel obstruction, pouch fistula) occurred in 11 of 29 (38%) and pouchitis developed in 9 of 29 (31%) of the children with UC.[276] Median follow-up was 4 years (range 6 months to 9 years). In this same study, daytime continence was noted in 100% and nighttime continence in 93%. The median frequency of bowel movements was 4 per 24 hours, and 7% of patients had nighttime bowel movements.

Pouchitis, or inflammation of the newly created ileal reservoir, is the most significant chronic complication in UC patients undergoing IPAA. In adult series, approxi-

mately 40% of patients will have a single episode of pouchitis, 15% will have recurrent pouchitis, and 5% will develop chronic pouchitis.[277] Symptoms of pouchitis include diarrhea, rectal bleeding, abdominal cramping, urgency and incontinence of stool, malaise, and fever.[277] Patients with UC who undergo IPAA have pouchitis more commonly than patients with familial polyposis who undergo the same procedure,[69] suggesting that this complication is related to an underlying defect characterizing UC. Pouchitis may occur more frequently in children and adults with extraintestinal manifestations of UC,[278] especially primary sclerosing cholangitis.[279,280] Laboratory studies may demonstrate anemia and an elevated erythrocyte sedimentation rate. The definitive diagnosis is established by flexible sigmoidoscopy of the pouch with biopsies.

Broad-spectrum antibiotics are usually the first-line treatment for pouchitis.[278,281] Metronidazole is the most commonly used antibiotic, but alternative therapies include ciprofloxacin, amoxicillin-clavulanic acid, erythromycin, and tetracycline.[277,278] If there is no improvement with antibiotics, other options include mesalamine enemas and steroid enemas or oral therapy with mesalamine, sulfasalazine, or steroids.[277,282,283] Other therapies that may occasionally be effective include cyclosporine enemas, short-chain fatty acid enemas, butyrate suppositories, and glutamine suppositories.[277,284–286] Probiotic therapy may prevent the onset of acute pouchitis after ileostomy closure and effectively maintain remission of chronic pouchitis.[67,68] A double-blind, placebo-controlled study evaluated the efficacy of a probiotic preparation, VSL#3 (containing a mixture of bifidobacteria, lactobacilli, and *S. salivarius*), compared with placebo in maintenance of remission of chronic pouchitis in 40 patients in clinical and endoscopic remission. Three patients (15%) in the VSL#3 group had relapses within the 9-month follow-up period compared with 20 (100%) in the placebo group.[67] In another double-blind, placebo-controlled study performed by the same authors in 40 patients, VSL#3, administered immediately after ileostomy closure for 1 year, effectively reduced the onset of acute pouchitis in the VSL#3 group (10%) in comparison with the placebo group (40%).[68]

Several studies suggest that there is a low risk of dysplasia in the ileal pouch,[287,288] which may be associated with chronic pouchitis.[289] Furthermore, the development of adenocarcinoma has been reported in the ileal pouch.[290] At present, the long-term risk of development of dysplasia is not yet known, and definite recommendations for endoscopic screening of the pouch are not available.

PROGNOSIS

Most children with UC have the potential for a full, active life with good general health. Ten percent of patients experience only their presenting episode of colitis. Twenty percent of patients have intermittent symptoms, 50% have chronic disease, and the remaining 20% have chronically active, incapacitating disease.[291] Limited distal UC diagnosed in adults and children can extend further to involve more proximal colon with time.[84–87] Disease involvement eventually will extend beyond the rectosigmoid in approximately 29% of children and adolescents with ulcerative proctitis and 58% with proctosigmoiditis.[84,86] The extension of disease may necessitate a change in medical therapy to control disease activity and may have implications for an increased risk of colorectal cancer in the future.[143] In addition, the physician should always be alert for signs of the upper gastrointestinal, perianal, or ileal pouch involvement that may unmask CD.

Advances in medical therapy have dramatically altered the prognosis for medical management of UC, with fewer patients requiring surgery to control the disease and more patients avoiding the long-term complications of steroids. The majority of patients are able to resume full activities, including school and athletics. In general, UC has no specific effect on fertility and poses no risk to the fetus, although an increased risk of preterm births has been reported in some studies.[292–294] In contrast, women with UC who undergo proctocolectomy with IPAA may experience reduced fertility.[294] If UC is active at the time of conception, the course of disease activity may be worse during the pregnancy.[295]

In the treatment of children and adolescents with UC, it is essential to care for not only the physical components of the disease but also the psychosocial aspects, including quality of life and coping abilities of the child and family. Previous studies report an increased risk of psychiatric and behavioral issues in children with IBD, including depression, anxiety, and low self-esteem.[296–299] Burke and colleagues reported that children are at increased risk for depression as early as the time of diagnosis.[298] Adolescents with IBD may experience a delay in autonomy, which may affect their ability to gain independence from caregivers.[300,301] MacPhee and colleagues reported that in contrast to the typical adolescent, adolescents with IBD tend to seek emotional support from family members rather than from peers and maintain extended family in their social support networks.[300] They also found that these affected adolescents often depend on their parents' coping skills rather than their own coping strategies to deal with stressors. In fact, the adolescents' quality of life health scores correlated with the parental coping styles rather than adolescent coping styles. Studies have reported a lack of correlation between severity of illness and psychiatric and behavioral issues in children and adolescents with IBD.[298,302] Interestingly, stressful life events and a lack of family cohesion may be more predictive of adolescent depression in new-onset IBD,[298] and affected adolescents' health-related quality of life scores appear to correlate more with satisfaction and degree of closeness with their social supports, such as parents, than with disease severity.[300]

In contrast to previous studies, Gold and colleagues reported normal psychosocial adjustment among their population of children and adolescents with IBD and speculated that the professional supports provided by their clinic may have been instrumental in these findings.[303] The findings of these studies emphasize the need for further study of the risks of psychiatric and behavioral issues and affected quality of life among children with IBD. More recently, two

patient-generated, disease-specific, health-related quality of life questionnaires for children with IBD have been validated, the IMPACT and IMPACT-II questionnaires.[299,304] Hopefully, these instruments, along with more generalized health-related quality of life questionnaires, will provide vital information to improve the care of children with IBD.

Despite the successes of medical management, currently there is no true "cure." The medications used to control the disease have potential morbidity, and the risk of colonic carcinoma is significant and cumulative, warranting careful surveillance even in those children without relapses of disease activity. Confronting a chronic disease, with frequent medical visits and frustrating relapses, the prospects of surgery in childhood and adolescence, and the need to cope with such issues, is a tremendous emotional burden for the patient and family, requiring ongoing psychosocial support. Physicians need to be able to recognize the warning signs of depression and other psychiatric and behavioral problems and offer appropriate psychiatric and psychological support if necessary. Colectomy may result in resolution of symptoms and almost eliminate the risk of colorectal carcinoma but presents its own risks of potential morbidity, discomfort, and mortality. All of these medical, surgical, and psychosocial factors must be considered and reconciled by the patient, family, and medical team in the long-term management of children with UC.

CONCLUSION

UC in children results from the complex interplay of genetic and environmental factors. Diagnosis and management of this chronic disease remain challenging, particularly in view of the unique requirements of pediatric patients who must complete their physical and emotional development. Colectomy with ileoanal anastomosis provides long-term relief of symptoms for most patients failing medical therapy, but others develop pouchitis, which may itself become a chronic IBD. For these patients, the true "cure" must await further study of the genetic basis of UC and its pathogenesis.

3. Undetermined Colitis and Other Inflammatory Diseases

Barbara S. Kirschner, MD

This chapter describes four inflammatory disorders that are distinguishable from the chronic inflammatory bowel diseases, ulcerative colitis, Crohn disease, and indeterminate colitis (see Chapter 41.1, "Crohn Disease," and Chapter 41.2, "Ulcerative Colitis"): eosinophilic gastroenteropathy (EG), hemolytic uremic syndrome (HUS), Henoch-Schönlein purpura (HSP), and Behçet syndrome (BS).

EOSINOPHILIC GASTROENTEROPATHY

EG is a chronic, relapsing disorder in which eosinophils constitute the predominant cell type in the inflammatory infiltrate of the gastrointestinal (GI) tract. The entity was described first by Kaijser in 1937.[1] Subsequently, patterns of clinical presentation were correlated with the extent of the eosinophilic infiltration (diffuse vs circumscribed) by Ureles and colleagues[2] and the depth of the eosinophilic reaction (mucosal, muscular, and serosal) by Klein and colleagues.[3]

In some cases in which specific foods clearly precipitate symptoms, this condition may be difficult to distinguish from the allergic gastroenteropathy described by Waldman and colleagues.[4] However, at least 50% of patients with EG have no personal or family history of atopy, and often dietary restriction does not cause resolution of symptoms.[5–7] Furthermore, allergic gastroenteropathy is characterized by mucosal injury in infants (partial or subtotal villous atrophy) rather than tissue eosinophilia.[8–11] In older children, those with symptoms of recurrent abdominal pain and positive elimination-challenge tests to foods were more likely to show endoscopic findings of esophagitis, gastric erosions, and lymphonodular or erosive duodenitis than villous atrophy or tissue eosinophilia.[12]

Isolated eosinophilic infiltration involving only the esophageal mucosa may occur, often mimicking the symptoms of reflux esophagitis. Multiple concentric esophageal furrows or rings may been seen on endoscopy.[13] Esophageal pH probe studies are normal, and eosinophils remain in the esophageal mucosa despite treatment with antireflux medications.[14–17]

Epidemiology

EG is rare, with a peak incidence in the second and third decades. Katz and colleagues described 12 children with GI symptoms and blood and tissue eosinophilia.[5] These patients could be divided into two groups: those with milk-sensitive enteropathy and those with EG. The first group, infants with allergic histories, who developed GI symptoms at about 5 months of age and improved with milk elimination, had immunoglobulin (Ig)G milk antibodies but not raised total IgE or IgE milk antibodies. The second group was older, averaging 4 years of age, with chronic symptoms, including growth failure, that did not respond to dietary manipulation. These children had signs of systemic allergy (asthma, rhinitis, urticaria) and elevated serum total IgE and IgE milk-specific antibodies. Intermittent use of corticosteroids was necessary to control the disease in the latter group.

Eosinophilic infiltration of the mucosa is associated with abdominal pain, vomiting, peripheral edema resulting from protein-losing enteropathy in severe cases, and hematochezia when the colon is diseased.[3–6] Several reports of EG in children have observed that the small bowel, especially the jejunum, is the most commonly involved site.[6,18] In children, inflammation of the submucosa and muscularis may be prominent, particularly in the antral region, and frequently causes obstructive symptoms. Serosal infiltration is the least common form and may be accompanied by eosinophilic ascites.[18,19] Formula or food intolerance, especially to cow's milk protein, soy protein, or beef, may be associated with eosinophilic infiltration of the mucosa. Even breast milk colitis may be associated with increased eosinophils in rectal biopsies.[20,21] Infectious agents such as *Giardia lamblia*, the roundworm *Eustoma rotundaturn*, cytomegalovirus, dog hookworm, and *Anisakis* (acquired following the ingestion of some species of raw fish) have been implicated as possible agents that trigger an eosinophilic response. Oral medications, such as gold, have been observed to cause EG.[22,23] Two cases of EG following liver transplant were reported by Dhawan and colleagues.[24] In each case, protracted intestinal symptoms developed several weeks post-transplant, and mucosal biopsies showed intense eosinophilic infiltration. Clinical improvement was achieved with corticosteroid therapy.[24]

Pathogenesis

The etiologic basis of EG is unknown. The prevalence of allergic histories varies widely in different series, from nil to greater than 70%.[4,6,7,14] Total IgE is elevated in some patients and normal in others. Serum IgE levels demonstrate variable responses to food challenge, suggesting that both IgE-mediated and IgE-independent mechanisms may be important in different patients with EG.

Although food sensitivity may play a role in some patients, the inciting factor is undetermined in most. Instillation into the jejunum of foods thought to provoke symptoms in specific patients has caused tissue eosinophilia in some[3,25] but not in others.[3,5] Spergel and colleagues identified 26 patients with eosinophilic esophagitis who underwent skin-prick testing and patch testing to identify potential food antigens.[26] Milk and egg were the most common positive foods with skin-prick testing and wheat with patch testing. In these patients, symptoms resolved or improved, as did esophageal eosinophil counts, when these foods were avoided. In contrast, dietary restriction of specific foods identified by history and skin tests did not alleviate symptoms in the majority of children with eosinophilic esophagitis reported by Teitelbaum and colleagues.[7]

Eosinophil recruitment and activation are induced mainly by three cytokines: interleukin (IL)-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), and IL-5. Desreumaux and colleagues detected IL-3, GM-CSF, and IL-5 in the duodenal and colonic biopsies of 9 of 10 patients with EG but 0 of 10 controls.[27] They suggested that the presence of these cytokines in the mucosa may perpetuate eosinophilic infiltration via autocrine or paracrine actions.

Teitelbaum and colleagues studied the immunopathologic features of eosinophilic esophagitis in 11 children before and after treatment with fluticasone proprionate.[7] Greater numbers of mucosal CD3 and CD8 lymphocytes and CD1a dendritic antigen-presenting cells were seen in children with eosinophilic esophagitis versus normal controls. They postulated that the latter cells may stimulate T-cell proliferation and the production of eosinophil chemokines, such as eotaxin. Once activated, the eosinophils may release cytokines, leukotrienes, and granule proteins (such as major basic protein), which are not only cytotoxic but also may stimulate other cells, leading to smooth muscle contraction and dysphagia, as well as the production of tumor necrosis factor (TNF)-α and IL-8.

Clinical Manifestations

Gastrointestinal Symptoms. The most common GI symptoms of EG are vomiting (50%), abdominal pain (40%), and growth failure (35–100%).[6,7,14] Gastroduodenal or small bowel edema and cellular infiltration of the submucosa and muscularis may cause obstructive symptoms. Infiltration in the muscle layer of the esophagus may cause dysphagia when a mass effect is present. When the appendiceal wall is diffusely infiltrated with eosinophils, symptoms resemble those of acute appendicitis. Rare GI complications include ileal perforation and colonic stricture.[17] Diarrhea may be associated with rectal bleeding (23%), especially in infants.[5,6,19,28] Friesen and colleagues described 11 children with "dyspepsia" or upper abdominal pain that occurred at night or with eating.[29] Systemic symptoms included fatigue, headache, dizziness, and joint pain in two-thirds of the patients. Gastric and duodenal mucosal histology was compatible with EG. Ascites containing large numbers of eosinophils accompanies serosal inflammation. Circumscribed polypoid lesions with heavy eosinophilic inflammation in the antrum or small intestine can cause obstructive symptoms (which may mimic pyloric stenosis in infants) or intussusception.[18,30]

Eosinophilic esophagitis usually presents with vomiting, pain, and dysphagia, symptoms that mimic reflux esophagitis. Recent studies have suggested that a personal history of atopy (food allergy, reactive airway disease, allergic rhinitis or conjunctivitis, or atopic dermatitis) can be identified in the majority of patients with eosinophilic esophagitis. Eosinophilic esophagitis can be differentiated from reflux esophagitis by the presence of a normal barium esophagram, 24-hour pH probe study, density of eosinophils within the esophageal mucoal biopsy, and lack of response to acid-reducing therapies.[7,14–17]

Peripheral Edema. Edema of the extremities and periorbital regions may develop in children with EG and hypoproteinemia. Hypoalbuminemia, present in 33 to 100% of children, results from protein-losing enteropathy.[4–6]

Laboratory Findings. Peripheral blood eosinophilia occurs in 70 to 100% of children with EG.[5,6,19] Increased bone marrow precursors may be observed in the absence of increased circulating eosinophils. Elevated serum food-specific IgE antibodies occur in some patients, although their specificity and meaning are uncertain. Iron deficiency is common, especially in children with enteric blood loss.[4,6,8] Intestinal absorptive function as assessed by D-xylose excretion and fecal fat determinations in a few pediatric patients have been normal.[4] As mentioned above, esophageal pH probe studies are normal in eosinophilic esophagitis but abnormal in patients with reflux esophagitis.

Diagnosis

The diagnosis of EG is strongly suggested when the characteristic symptoms are accompanied by blood eosinophilia. Further supportive evidence may come from a careful dietary history that elicits a temporal relationship between ingestion of specific foods and the onset of symptoms.

Total serum protein, albumin and circulating IgE levels, and specific food-related IgE antibodies may be abnormal in some patients but are often not found, even in cases of documented reactions to specific foods, especially cow's milk protein.

Radiographic studies may demonstrate narrowing and nodularity of the antrum and/or duodenum or thickened mucosal folds in the small bowel. Intestinal dilatation and flocculation of barium occur in some cases.

Endoscopic examination of the esophagus may show granularity with furrows or rings involving varying extents of mucosa, including that proximal to the distal esophagus.[13,14] Biopsies from children with eosinophilic esophagitis show increased eosinophilic density compared with healthy controls and those with reflux esophagitis, although the criteria differ among published studies from more than 5 versus less than 5 eosinophils per high-power field (HPF) to more than 15 versus less than 15 eosinophils per HPF.[7,14,16] The stomach and duodenum may show nodular-

ity, erythema, friability, erosions, and ulceration in affected areas. Kokkonen and colleagues observed that children with recurrent abdominal pain who demonstrate lymphonodular hyperplasia involving at least 50% of the duodenal bulb are more likely to have tissue eosinophilia and food-induced symptoms than children without duodenal lymphonodular hyperplasia.[31] Gastric biopsies may demonstrate EG more consistently than intestinal biopsies because the intensity of the latter infiltrate varies even within the same individual.[5] Decreased vascular pattern, friability, and erosions have also been observed in EG involving the colon.[6,28]

Proof of diagnosis depends on finding excessive eosinophils in biopsy or resected tissue specimens, assuming that other causes of eosinophilic infiltrates, such as lymphoma, Crohn disease, parasitism, vasculitis (especially polyarteritis nodosa), chronic granulomatous disease, and the hypereosinophilic disorder Job syndrome, have been excluded. Hoefer and colleagues noted that lymphadenopathy and inflammation of the omentum and mesentery may be present in EG, but isolated ileal involvement and "fat wrapping" (characteristic of Crohn disease) are absent.[18] Most patients with EG have more than 10 eosinophils per HPF in the antral or duodenal mucosa.[32] Allergic proctocolitis in infants usually shows focal eosinophilic infiltration ranging from 15 to 60 eosinophils per HPF.[28,33] In the study of 35 infants with allergic colitis described by Machida and colleagues, tissue eosinophil concentrations were more than 20 per HPF compared with 8.6 per HPF in control infants.[34] Macroscopic changes in the infants with colitis varied from patchy erythema with loss of vascular pattern to frank ulceration; prominent lymphonodular hyperplasia was seen in 10 of these infants.[34]

Management

When specific foods provoke the characteristic symptoms, dietary elimination and use of an elemental diet may resolve GI symptoms, associated blood, and tissue eosinophilia and improve growth in children with EG and eosinophilic esophagitis.[4,5,15,17,26,35,36] The elemental formulas Neocate or Neocate-1-Plus (Scientific Hospital Supplies Ltd, Liverpool, UK) were given to 10 patients with eosinophilic esophagitis, aged 10 months to 12 years, for a minimum of 6 weeks. [35,36] Complete resolution of symptoms occurred in 8 of 10 patients, along with a significant reduction in intraepithelial eosinophils. In a second larger study of 51 children with eosinophilic esophagitis, an elemental diet for 4 weeks led to clinical improvement within a mean of 8.5 days and a reduction in esophageal eosinophils from 33.7 to 1.0 per HPF.[15] When symptoms persist, corticosteroids (1.0 to 2.0 mg/kg/d)[7,16,37] and possibly oral disodium cromoglycate (50 to 200 mg 4 times daily)[6,38] control symptoms in most children. Low-dose (5 to 10 mg) or alternate-day corticosteroids are needed in some cases for long-term control.

More recently, the use of swallowed fluticasone propionate, administered via an inhaler without a spacer, has been used in children with eosinophilic esophagitis.[7,39] Initially, doses of 220 µg/puff 4 puffs twice daily for 6 weeks were studied.[38] Subsequently, lower doses (2 to 4 years old, 44 µg/puff; 5 to 10 years, 110 µg/puff; 11 years and older, 220 µg/puff) twice daily for 8 weeks resolved symptoms and significantly reduced eosinophil density in mucosal biopsies.[7] A rapid clinical response was observed within 1 week. Two patients of 13 fluticasone-treated children developed *Candida* esophagitis, which responded to fluconazole.[7]

Ketotifen, an H_1 antihistamine that stabilizes mast cells, may also benefit children with EG.[40] Melamed and others described six children, with a mean age 16.9 years, whose prolonged abdominal pain, elevated circulating IgE levels, and mucosal eosinophilic infiltrates normalized after receiving 2 to 4 mg daily for 4 to 6 months.[40]

Limited results have been described using montelukast (Singulair), a leukotriene antagonist, in eight pediatric patients "unresponsive to standard therapies" with eosinophilic gastroenteropathy involving the esophagus (four patients), duodenum (two patients), or colon (two patients).[41] The patients ranged in age from 2 to 17 years and received 5 to 10 mg daily. Symptoms resolved in all within 2 to 4 weeks.

Occasionally, bowel resection or gastroenterostomy has been performed for gastric outlet or small bowel obstruction caused by EG,[3,6,18,38] but most of these complications were reported prior to the use of corticosteroid therapy.

HEMOLYTIC UREMIC SYNDROME

HUS, first described by Gasser and colleagues in 1955,[42] is defined as the development of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency in a previously healthy person. Now several forms of this syndrome, varying in their etiology, age at diagnosis, and prognosis, are recognized.[43–46] A prodrome of GI symptoms averaging 3 to 16 days precedes the development of the HUS in 90 to 100% of children.[47–49] Atypical or incomplete forms of HUS include *Escherichia coli* O157:H7 diarrhea with hemolytic anemia and thrombocytopenia but without renal injury, as well as HUS associated with invasive pneumococcal disease rather than diarrhea[50,51]

Epidemiology

Characteristically, HUS occurs in children less than 5 years of age.[47–49] It is endemic in Argentina, southern Africa, and the western United States, and epidemics have occurred in many other parts of the world. Between 1971 and 1980, Tarr and Hickman observed a fourfold increase in incidence in King County, Washington, from 0.63 to 2.81 cases per 100,000 children younger than 15 years.[49]

An epidemic form occurring in the summer, associated with the abrupt onset of diarrhea,[47,49] has a good prognosis, with an expected mortality under 6%.[49] A sporadic form in older children has neither seasonal influence nor obvious prodrome and has a higher mortality.[46] Siblings who develop HUS during infancy more than 1 year apart are thought to have an autosomal recessive trait that predisposes them to HUS and a mortality rate of 68%.[43–45]

Most cases of HUS in the Pacific Northwest (58%) are preceded by enteric infection with Shiga toxin–producing *E. coli* (STEC) O157:H7.[52] This *E. coli* serotype has a dis-

tinct cell membrane adhesion molecule, intimin, which attaches to follicle-associated epithelium of ileal Peyer patches.[53] Over a 2-year period, the organism was isolated from the stools of nine patients with HUS in British Columbia's Children's Hospital, an incidence far in excess of the incidence in all stools submitted for routine diagnosis (1.9%).[54] In a national prospective study of postdiarrheal HUS in the United States, 80% of patients had serum samples positive for *E. coli* O157 lipopolysaccharide antibody titers.[55] This O157:H7 serotype was originally described as a cause of hemorrhagic colitis.[56] Subsequently, isolated cases of HUS were reported following outbreaks of gastroenteritis (both bloody and nonbloody) with *E. coli* O157:H7.[52,57] Among children presenting with STEC diarrhea, HUS developed in 18% of children with *E. coli* O157:H7 but none of those with the non-O157:H7 serotype.[58] Isolates of this serotype produce a toxin cytotoxic for Vero and HeLa cells in tissue culture (verocytotoxin).[54] Dissemination of *E. coli* O157:H7 has been reported to occur through contaminated food (such as undercooked hamburger, unpasteurized milk and yogurt, unpasteurized apple cider, and vegetables, such as raw alfalfa and radish sprouts, grown in a garden fertilized with cow manure), contaminated municipal water supplies, and person-to-person spread in a day-care center.[47,52,59] More recently, reports of HUS have followed trips to dairy farms (where 13% of the calves were colonized with *E. coli* O157:H7) and petting zoos (where O157 was isolated from goats and sheep).[60,61] Thus, *E. coli* O157:H7 appears to cause a spectrum of disease, including diarrhea, hemorrhagic colitis, and HUS. The factors that determine which disease entity develops in an individual child are unknown, but geographic and genetic influences have been suggested.

Non-O157:H7 STEC strains appear to account for a larger number of cases of HUS in children in Europe than in the United States. Of 394 children studied in Germany and Austria, O26 was detected in 15% and O111 in 43%.[62] These authors emphasized the rising importance of non-O157:H7 serotypes in HUS. Similar findings were noted in an Australian population of 98 children with HUS.[63] Serotype O111:H- was the most common isolate, and none had O157:H7. Enteric infections with various non–*E. coli* organisms, including *Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*, and enteroviruses, have been associated with the development of HUS.[47,64]

HUS has been associated with invasive *Streptococcus pneumoniae* infections in the absence of diarrheal disease.[65] Seven children, mean age 16 months, developed HUS after *S. pneumoniae* pneumonia (five patients) or meningitis (two patients). These children represented 23% of all HUS cases seen in Atlanta, Georgia, between 1994 and 1996. In contrast to diarrhea-associated HUS, which occurred between June and August, the *S. pneumoniae* HUS cases were seen year round. All seven patients required dialysis, compared with 48% of the diarrhea-associated HUS. The findings were not consistent with pneumococcal septic shock and disseminated intravascular coagulation because D-dimers and prothrombin time were not elevated and fibrinogen was not decreased. The authors reiterated the position of the Academy of Pediatrics that vancomycin be included in the therapy of suspected or proven invasive *S. pneumoniae* infections. A more recent study comparing invasive pneumococcal HUS with diarrhea-associated HUS noted that the former patients were younger (22.1 vs 49 months), were more likely to require dialysis (75% vs 59%), had longer duration of hospitalization (32.2 vs 16.1 days), and needed more platelet transfusions (83% vs 47%) and red blood cell transfusions (7.8 vs 2.0).[66]

HUS has also been reported following renal transplant. Although most cases were associated with cyclosporine therapy, it has been suggested that tacrolimus may cause exacerbations of HUS in patients previously treated with cyclosporine.[67]

Pathogenesis

The central lesion in HUS is vascular endothelial damage. Endothelial cells show swelling and separate from the basement membrane with widening of the subendothelial space.[68] Glomerular involvement occurs in the classic form in young children, whereas arteriolar lesions with intimal and subintimal edema, proliferation, and necrosis are more common in older children.[46,68]

The precipitating cause of this vascular injury is probably the release of Shiga-like toxins (SLT-1, SLT-2, and SLT-2 variants), also called verotoxins, which damage the microvasculature of the intestinal wall, leading to hemorrhagic and ulcerative lesions.[47,56] The B subunits of the SLTs bind to high-affinity glycolipid (GB_3) cell-surface receptors on target organs and are internalized by endocytosis.[47] The verotoxins produced by *E. coli* O157:H7 thus cause endothelial damage and gain entrance to the circulation, leading to severe cell injury or death.[52,54,56,57] Lipopolysaccharide can also damage endothelial cells and promote thrombosis. Shiga-like toxin also induces TNF production in the kidney but not in other tissues. Alternatively, perturbations in endothelial prostacyclin metabolism are postulated to be important in sporadic HUS.[68] Prostacyclin (PGI_2), a potent inhibitor of platelet aggregation, is normally produced in endothelial cells, and studies have suggested that PGI_2 deficiency, the presence of an inhibitor of PGI_2 production, or rapid degradation of PGI_2 may be important in patients with HUS.[68] Proulx and colleagues observed increased circulating pro- and anti-inflammatory cytokines (IL-6, IL-8, IL-10, and IL-1Ra) in children who developed HUS in contrast to normal controls and children with non–verotoxin-associated hemorrhagic colitis.[69] IL-8, an activator of white blood cells, may explain the leukocytosis seen in HUS.[47]

The vascular injury induces microangiopathic hemolytic anemia, thrombocytopenia, and local deposits of fibrin microthrombi. Ischemic changes result in focal or generalized renal cortical necrosis and damage to other organs (colon, liver, myocardium, brain, pancreas, and adrenal glands).[47,68,70]

Genetic Aspects

Recent studies have identified a subset of patients with atypical HUS who have mutations in the gene coding for the sol-

uble complement regulator factor H gene (*FH1*).[71] In a German series of 111 patients with atypical HUS, 14% had *FH1* mutations.[72] The mutant proteins cause reduced binding of the central component C3b/C3d to heparin and endothelial cells, leading to progression of endothelial cell and microvascular damage.[73] Other mutations of the human complement regulator membrane cofactor protein were found in three families with multiple affected individuals with HUS.[74] The mutations were also associated with reduced C3b binding and diminished ability to prevent complement activation.

Clinical Manifestations

Gastrointestinal. Gastrointestinal lesions occur in 90 to 100% of children with HUS. In 70 to 80%, bloody diarrhea precedes the recognition of HUS by 3 to 16 days[47–49]; other children have a prodrome of abdominal pain, nonbloody diarrhea, and/or vomiting. Resolution of the GI symptoms usually begins before the onset of renal insufficiency, with hematochezia clearing first, followed by improvement in the diarrhea and abdominal pain. However, the colitis may persist for as long as 2 months.[47] Rectal prolapse has been described in up to 10% of patients with colitis.[47] Occasionally, patients have thrombosis of vessels in the muscularis and serosa, resulting in necrosis and perforation of the colon.[75]

The endoscopic appearance of the bowel is characterized by hyperemia, edema, and petechiae, sometimes in association with ulceration.[75,76] Berman reported that the gross appearance was indistinguishable from that of chronic nonspecific ulcerative colitis, but rectal biopsies in these children showed only edema and submucosal hemorrhage with scant inflammation.[76] In a series of eight patients who underwent colectomy for HUS, the findings were limited to the transverse and left colon in seven, with only one patient showing involvement of the right colon.[77]

Barium enema examinations may demonstrate focal or diffuse bowel wall edema, thumbprinting, filling defects, mucosal irregularity, fine marginal spiculations, colonic spasm, or colonic dilatation (Figure 41.3-1).[75,76] Initially, the findings may mimic chronic inflammatory bowel disease until the full syndrome becomes apparent.

Hemolytic Anemia. Microangiopathic hemolytic anemia with fragmented erythrocytes occurs in all children with HUS. It usually develops suddenly within 1 to 2 days, resulting in a mean hemoglobin concentration of 6.1 g/d.[48] Several mechanisms are responsible for the anemia, including mechanical stress owing to microvascular disease, oxidative injury to red blood cells, and direct Shiga-like toxin injury.[47] Transfusions are required in 64% of children.[48]

Thrombocytopenia. Thrombocytopenia (platelet count under 150,000/mm^3) occurs in 92% of children with HUS owing to platelet trapping within organs. As mentioned above, platelet aggregation defects may occur in the presence of normal platelet counts. Other tests of coagulation status, including prothrombin time and partial thromboplastin time, are normal.[47,48,68]

Renal Insufficiency. Although all children with HUS are azotemic (mean peak blood urea nitrogen of 95 mg/dL), the severity of the renal impairment is variable. Oliguria (less than 15 mL urine per kilogram body weight per day) and anuria (less than 25 mL urine per day) each occur in 32% of affected children.[48] In approximately 50% of cases, the anuria lasts for up to 3 days, but oliguria may persist for weeks. One-third of children have no documented oliguria. Hypertension, which is mild, begins early in the course of the illness in most patients,[47] is usually labile, and is easily controlled. However, some children may require peritoneal dialysis. The time for creatinine clearance to return to normal averages 3.7 months and corresponds to the duration of the preceding oliguria. Chronic renal insufficiency persists in approximately 9.5% of children.[48]

Neurologic Disease. Central nervous system (CNS) manifestations of HUS (changes in consciousness and abnormal movements, tone, and posture) are found in one-third of children with HUS.[47] The frequency of seizures has decreased with careful attention to fluid and electrolyte balance and implementation of dialysis. Serious CNS complications, such as cerebral edema or stroke, which are reported in up to 5% of children, may be fatal.[47]

FIGURE 41.3-1 Barium enema in a 6-year-old child with hemolytic uremic syndrome. Extensive spasm and narrowing of the descending colon (*arrow*) are illustrated during the period of bloody diarrhea. Gastrointestinal symptoms resolved 1 week later but were followed by the onset of acute renal failure.

Liver Disease. Elevations of hepatic enzymes (2- to 20-fold above normal) for serum glutamic-oxaloacetic transaminase, serum glutamic-pyruvic transaminase, γ-glutamyl transpeptidase, alkaline phosphatase, and 5′ nucleotidase have been observed in most patients in whom these tests were done.[75,78] This transient hepatocellular injury may be caused by focal hepatic hypoxia. Similarly, elevated serum amylase and lipase levels are observed in about 20% of patients, as well as hyperglycemia in 4 to 15%.[47]

Diagnosis

HUS in childhood usually occurs in a previously healthy child who develops diarrhea (generally bloody) and abdominal pain followed by the acute onset of hemolytic anemia, thrombocytopenia, and renal insufficiency. Initially, the GI manifestations may be mimicked by intussusception, enteric infection, or inflammatory bowel disease (especially ulcerative colitis), which can be excluded by appropriate radiologic, microbiologic, and histologic studies. Stool specimens should be obtained for enteric pathogens, including *E. coli* O157:H7. This serotype metabolizes sorbitol slowly; therefore, *E. coli* strains with this characteristic can be sent to specialized laboratories for confirmation. However, the yield is low if specimens are sent after the first week of diarrhrea.[47] The deoxyribonucleic acid (DNA) probes for genes associated with toxin production and polymerase chain reaction methods are being evaluated.[47] Typical hematologic and renal findings are discussed above.

Treatment

Severe GI symptoms require hospitalization and intravenous fluids during the prodromal period prior to the development of HUS. Because *E. coli* O157:H7 is sensitive to ampicillin and amoxicillin, some authors suggest treating all cases with one of these antibiotics.[54] Butler and colleagues observed that the administration of ampicillin to children with ampicillin-resistant strains of *Shigella dysenteriae* 1 was associated with a greater incidence of HUS than occurred in non–antibiotic-treated children infected with the same organism.[79] They also postulated that the risk of HUS might be reduced if children were treated early with appropriate antibiotics. Tarr and colleagues cautioned against the empiric use of antibiotics for *E. coli* O157:H7 colitis until the risks and benefits have been analyzed by controlled clinical trials.[80] These authors expressed concern that the incidence of HUS might be increased through proliferation of *E. coli* O157:H7 or the release of cytotoxins through bacterial lysis or "sublethal damage." In a prospective study of 71 children under 10 years of age with *E. coli* O157:H7 diarrhea, Wong and colleagues observed that antibiotic treatment conferred a relative risk of 14.3 when compared with children who had not received antibiotic therapy.[81] It should be noted that a meta-analysis of nine studies of whether antibiotic use increased the risk of HUS did not detect greater risk.[82] Rarely, surgical intervention may be necessitated by bowel necrosis.[75]

Primary attention should be directed toward management of fluid and electrolyte balance, renal insufficiency, hypertension, seizures, and hemolytic anemia. Siegler recommends that after correcting for necessary previous losses, fluids should be limited to ongoing loss (insensible water loss plus urine and GI output).[47] Sodium should be withheld from children with edema and hyponatremia. Similarly, potassium should not be given unless levels fall into the low normal range. Nutrition is important in these catabolic, hypoalbuminemic patients. For children with ongoing diarrhea or vomiting, transpyloric feeds or total parenteral nutrition (TPN) may be required. Peritoneal dialysis is employed as necessary in infants and preschool-age children except if there is severe colitis or abdominal tenderness.[5,47,48,83] There is no direct evidence that anticoagulant therapy is beneficial.[45,84]

For children with severe anemia (hematocrit < 15%) or those symptomatic from anemia, packed red blood cell transfusions (10 mL/kg) can be given. Those with *Pneumococcus*-related HUS should receive blood products free of T-antigen antibody.[47] Siegler cautions against the use of platelet infusions, except for severe bleeding or those requiring invasive vascular procedures (such as TPN line placement) or surgery because exogenous platelets may provide further substrate for aggregation and microthrombus formation.[47] Plasma transfusions, plasmapheresis, or exchange transfusion has been reported to improve the anemia, thrombocytopenia, and renal insufficiency in some children with HUS and may be considered in patients demonstrating a poor response to supportive therapy.[83–85] Intravenous gammaglobulin administered to nine children did not demonstrate benefit on the duration of hemorrhagic colitis, anuria, or hospitalization when compared with nine children with HUS who did not receive this form of therapy.[86] Prostacyclin levels that were low prior to plasma therapy become normal following the plasmapheresis.[87] The possible future role of antitoxin directed against the verotoxin remains to be investigated.[46]

Hypertension usually responds to short-acting calcium channel blockers (such as nifedipine or nicardipine). Siegler recommends using either nifedipine at 0.25 to 0.5 mg/kg/dose as needed every 2 to 6 hours or nicardipine 0.5 to 1.0 mg/kg/dose every 6 to 8 hours as needed. Nicardipine can also be administered as a constant intravenous infusion of 1.0 μg/kg/min.[47] The use of dialysis has been responsible for the reduced mortality in HUS. Siegler recommends that dialysis be instituted for severe uncontrollable hyperkalemia, fluid overload associated with pulmonary edema, or severe uremic symptoms such as encephalopathy.[47] Other indications are a blood urea nitrogen over 150 mg/dL, a need for TPN when adequate fluid intake cannot be tolerated, and severe CNS dysfunction.

Future potential therapeutic approaches include oral administration of the GB_3 receptor, intravenous antibodies to Shiga-like toxins or lipopolysaccharide, and inhibitors of TNF production and platelet aggregation.[47]

HENOCH-SCHÖNLEIN PURPURA

HSP, a multisystem vasculitic disorder, primarily affects children under 7 years of age. Schönlein described an asso-

ciation of arthritis with purpura in 1837.[88] The clinical syndrome, subsequently extended to include abdominal pain and GI bleeding by Henoch in 1874,[89] is characterized by urticarial or purpuric skin lesions, colicky abdominal pain, sometimes with hematochezia, and arthralgias or arthritis and hematuria, which may be accompanied by proteinuria. Symptoms persist for an average of 3.9 weeks, although recurrences are common, occurring in 40% of patients.[90]

Epidemiology

In a review of 131 children with HSP, more than 75% were less than 7 years of age.[90] Seasonal variation was noted, with one-third of cases occurring during the spring. An upper respiratory infection or fever occurred 1 to 3 weeks before symptoms of HUS in 90% of children. A cluster of 20 cases was identified in Connecticut, of whom 10 were from Hartford County,[91] but no etiologic agent was identified. Although the disorder has been known as anaphylactoid purpura, family and personal allergic histories are not more frequent than expected for a comparable age group.[90] Genetic susceptibility is suggested by an analysis of *DRB1* polymorphisms; increased frequencies of *DRB1**01 and *DRB1**11 with decreased *DRB1**07 are observed in patients with HSP compared with controls.[92,93]

Pathogenesis

Factors that contribute to the development of HSP have been further elucidated since the last publication of this chapter. Clinical observations suggest that infectious agents (including β-hemolytic streptococci, *Bartonella henselae*, varicella and other viruses, and *Mycoplasma*) or medications (including penicillins, ciprofloxacin, acetylsalicylic acid, vancomycin, levodopa, cocaine, acetylcholinesterase inhibitors, carbamazepine, and streptokinase) may trigger an immune response, leading to IgA1 immune complex (IgA1C) deposition in blood vessel walls in susceptible hosts.[90,91,94–96] IgA1C is normally cleared by the asialoglycoprotein receptor of hepatocytes, which binds the oligosaccharide chains of the IgA1 Fc fragment.[96] High levels of IgA1C are found in the circulation of patients with HSP nephritis. Abnormally glycosylated IgA1 aggregates, which may be less well cleared by hepatocytes, have been identified in patients with HSP nephritis but not those without renal involvement.[96,97] Activation of the alternate complement pathway may generate chemotactic factors and polymorphonuclear infiltration. Antineutrophilic cytoplasmic antibodies are detected in 10% of patients.[98]

Serum TNF levels are higher during the acute phase of HSP than during remission and in those with renal involvement in contrast to those with normal renal function. Immunohistochemical staining of skin lesions reveals intracellular TNF in the nucleated epidermal layer, with lesser amounts of IL-1 and IL-6 staining, suggesting that these cytokines may contribute to the inflammation in HSP.[99]

Microscopic findings show perivascular infiltrates of polymorphonuclear leukocytes, lymphocytes, and occasional histiocytes around small blood vessels in the skin and GI tract, as well as IgA deposits in capillary walls and the dermal-epidermal junction. Mucosal IgA deposition can be seen in the biopsies of the duodenum in the absence of vasculitis.[100] Intimal proliferation and thrombosis have been described in cerebral vessels in children with seizures. Vasculitis results in edema and hemorrhage in various organs, including the intestine, pancreas, gallbladder, lung, myocardium, testis, and cerebral cortex.[90,101–103] In glomeruli, there are diffuse polymorphonuclear infiltrates or hyalinization with thickening of the basement membrane of Bowman capsule.

Clinical Manifestations

Skin Involvement. Skin lesions occur in 97 to 100% of children with HSP.[90] Usually, there is an urticarial eruption on the extensor surfaces of the legs, buttocks, and arms, which changes to red, nonblanching macules. Children under 2 years of age may present with scalp, facial, or extremity edema, whereas older children often show petechiae, especially on the lower extremities. Edema of the lower extremities, which is more common in children less than 3 years of age, is often seen in combination with facial or scalp swelling. Prominent purpuric lesions involving the face and ears were recently described in 6 infants less than 1 year of age.[104]

Gastrointestinal Involvement. GI symptoms occur in 65 to 90% of children.[90,105,106] Colicky abdominal pain, often associated with vomiting, results from submucosal edema and hemorrhage. Abdominal pain develops within 8 days of the rash in 75% of pediatric patients, although intervals as long as 150 days between GI symptoms and skin findings have been observed.[105] Hypoproteinemia may develop secondary to protein-losing enteropathy. Obvious GI bleeding (melena or hematochezia) occurs in 25% of children and hematemesis in approximately 10%. Children with abdominal pain frequently show tenderness to direct palpation (75%), but rebound tenderness is uncommon (9%).[105] Stools are guaiac positive in 50% of children. Rare intestinal complications include intussusception (2–3%), perforation, pancreatitis, and cholecystitis.[90,101–103] When intussusception develops, it is seen in children 5 to 7 years of age; early surgical intervention markedly reduces mortality.[90,106,107] Intussusception in HSP usually originates in the ileum (90%) or jejunium (7%), and approximately 58% of cases are confined to the small bowel.[108] In contrast, most idiopathic intussusceptions are ileocolonic. In one series of children who underwent exploratory laparotomy, excessive amounts of peritoneal fluid were observed. Rarely, small bowel obstruction may develop from entero-entero fistulae or late-onset stricture formation.[109,110]

Endoscopic examination may demonstrate coalescing purpuric lesions, especially in the descending duodenum, gastritis, or punctate erythematous and ulcerative changes in the colon.[100,109,111] Tomomasa and colleagues described endoscopic findings in nine children with HSP.[111] No esophageal abnormalities were observed. Gastric changes in two children consisted of diffuse mucosal edema, patchy erythema, and multiple erosions. Diffuse severe erythema with erosions was noted in the duodenal bulb (two patients) and

the second portion of the duodenum (three children). Rectosigmoid examination in six children demonstrated shallow ulcers in two, but studies were normal in the other four. Endoscopic biopsies revealed polymorphonuclear infiltrates in the lamina propria, predominantly around blood vessels.

Radiologic studies of the small bowel and colon show thumbprinting (Figure 41.3-2), representing submucosal edema and hemorrhage, spasm, ulceration, and pseudotumor,[101] usually in the jejunum and ileum (Figure 41.3-3), but the colon may be affected. Similar findings may be seen in lymphoproliferative disorders, other hemorrhagic conditions (hemophilia, leukemia), scleroderma, and Crohn disease.[101]

In a series of 139 pediatric patients, remission occurred within 4 weeks in 84 patients, 5 to 8 weeks in 19 children, and 9 to 53 weeks in 18 children.[112] Thus, symptoms of extrarenal HSP often last more than 1 month. The authors also noted that renal involvement was more common in children whose extrarenal symptoms lasted for 6 weeks versus 3 weeks for those not developing renal disease. Relapses of GI symptoms have been reported 7 years after the initial episode.[102]

Joint Involvement. Arthritis and arthralgias, usually oligoarticular and nonmigratory, occur in 65% of children with HSP. Ankles and knees are involved more than the upper extremities.

Renal Manifestations. Hematuria (gross or microscopic) occurring in approximately 40% of all children with HSP[90] is reported in 70% of children with GI disease.[106] Two-thirds of children with hematuria also develop proteinuria. Muller and colleagues reported that measuring urinary tubular marker proteins (*N*-acetyl-β-D-glucosaminidase and α_1-microglobulin) correlated with the extent of early and late renal involvement and suggested that their use may be helpful in identifying those who will develop HSP nephritis.[113] Renal lesions are more frequent in older children than in those less than 2 years of age and usually follow skin and GI involvement.[90] Serious complications include hypertension (sometimes leading to hypertensive encephalopathy) and renal failure. Glomerular lesions include glomerular proliferation, hyalinization, and IgA deposits in the mesangium. Autopsy studies of the kidneys demonstrate endothelial thickening, thrombosis, and medial necrosis of small renal arteries. In Europe, HSP accounts for 15% of children receiving dialysis for renal failure.[114]

Hepatobiliary Involvement. Chao and colleagues described hepatobiliary involvement in 20 of 225 children with HSP.[115] Symptoms included right upper qudrant pain (80%), nausea (45%), lethargy (20%), and vomiting (15%). Laboratory tests revealed elevated alanine transaminase in 15 of 20 patients (75%) and elevated γ-glutamyl transpeptidase in 6 of 20 patients (30%). Abdominal ultra-

FIGURE 41.3-2 Upper gastrointestinal series demonstrating focally thickened folds and thumbprinting due to submucosal edema in the proximal jejunum in a 14-year-old girl with recurrent episodes of colicky abdominal pain. Four weeks later she developed typical skin lesions of Henoch-Schönlein purpura on the lower extremities.

FIGURE 41.3-3 Upper gastrointestinal and small bowel follow-through demonstrating extensive thickening of mucosal folds in the descending duodenum and entire jejunum in a 10-year-old boy with recurrent vomiting and scattered macular erythematous lesions on the buttocks and lower extremities due to Henoch-Schönlein purpura.

sonography demonstrated hepatomegaly in 75% and gallbladder wall thickening in 25% of this group. The findings subsided within 3 to 7 days after steroid therapy. Viola and colleagues described a child with ischemic necrosis of the bile ducts (which they attributed to HSP vasculitis of the peribiliary vessels), which resulted in biliary cirrhosis and liver transplant.[116]

Scrotal Involvement. Vasculitis of the scrotum may result in findings and symptoms that must be differentiated from torson of the spermatic cord.[117] In one study, 22 of 93 children (24%) with HSP showed signs of scrotal involvement. Of the 22 patients, 8 had surgical exploration and none had testicular torsion. The authors recommended the use of high-resolution Doppler ultrasonography to identify those patients in whom surgical intervention could be avoided.

Other Presentations of HSP Vasculitis. Case reports describing children with HSP have included rare presentations, including ataxia owing to brainstem vasculitis, loss of vision from retinal artery occlusion, pulmonary hemorrhage, and hypertension without other signs of renal disease.

Diagnosis

The diagnosis of HSP rests on the presence of characteristic clinical features with supporting laboratory, endoscopic, and radiologic studies as indicated. Peripheral blood counts show leukocytosis (10,000 to 20,000/mm^3) with left shift in half of the children. Erythrocyte sedimentation is elevated (greater than 20 mm/h) in 75% of children.[118] Urinalyses may not demonstrate hematuria or proteinuria until several weeks after the initial presentation. The presence of microscopic blood should be checked in stool specimens. High-frequency ultrasonography may be helpful in equivocal cases, as when abdominal pain develops prior to skin or renal involvement.[119,120] Findings of HSP include thickened bowel wall (3–11 mm), which may be diffuse or focal, free peritoneal fluid, impaired peristalsis of affected loops, and bowel dilatation. Serial examinations during the course of the disease can determine whether the lesions are extending or resolving and whether there is re-expansion of the small bowel lumen and reappearance of peristalsis. Complications such as intussusception and perforation can be detected by this method.[119,120]

Endoscopic evaluation may be indicated to exclude other conditions if the diagnosis is unclear.

Histologic examination of skin biopsies from recent lesions demonstrate leukoclastic vasculitis, often with IgA1 (but not IgA2) deposits. IgA1 deposits may not be present in necrotic or old lesions.[121]

Physicians should be aware that activation of coagulation secondary to endothelial damage may result in D-dimer concentrations more than 10 times the upper limit of normal.[122] However, in none of the 15 children were the platelet count, prothrombin time, thrombin time, protein S and C, or antithrombin 3 levels abnormal. The authors caution against interpreting the abnormal D-dimers as indicating disseminated intravascular coagulation in patients with HSP.

Management

Therapeutic intervention for HSP is usually directed at specific complications, such as severe abdominal pain, hypertension, renal insufficiency, and GI or cerebral hemorrhage. The efficacy of other recommended medical approaches has not been studied in controlled clinical trials.

Gastrointestinal Disease. Children with severe abdominal pain should be admitted to the hospital because of the potential risk of intussusception, hemorrhage, or perforation. Supportive care with intravenous fluids and nasogastric suction is helpful in comforting severely symptomatic children. Corticosteroids used for GI manifestations of HSP are controversial. Allen and colleagues suggest that abdominal pain resolves in the majority of children after steroid therapy and that tapering this medication in some patients leads to clinical relapse, which improves with reinstitution of steroids.[90] Rosenblum and Winter retrospectively compared the hospital course of 48 children with HSP, 58% of whom were treated with prednisone (1–2 mg/kg/d) and 42% of whom did not receive corticosteroids.[105] Abdominal pain resolved within 24 hours in 44% of the steroid-treated group but in only 14% of the nonsteroid-treated group. At 48 hours, resolution was 65% in the steroid group and 45% in the other group, although this difference was not statistically significant. By 72 hours after admission, resolution of pain was similar in both groups (75%). The report concluded that corticosteroid administration may hasten resolution of abdominal pain but that controlled trials should be undertaken.

Whether intravenous gammaglobulin is beneficial in persistent steroid-dependent HSP has not been reported. Jordan suggested that glomerulonephritis may have been precipitated in one patient by this therapy.[123] Relapse is frequent in HSP, with 40% of children developing symptoms as late as 7 years after the initial episode.[90,102] In one child with severe cerebral and retinal vasculitis, intravenous pulse methylprednisolone was not effective, but plasmaphoresis led to prompt resolution of symptoms.[124]

Surgical treatment is required rarely for massive gastric hemorrhage, intussusception, obstruction, intestinal perforation, or cholecystitis.[90,102,125] Careful and repeated physical examinations are necessary to identify early signs of these complications.

Renal Disease. Management of the renal complications of HSP will not be discussed, but, clearly, blood pressure and renal output must be carefully monitored. Urine samples should be analyzed regularly for hematuria and proteinuria. Antihypertensive medications, fluid restriction, and dialysis may be necessary.[126] Recently, the combined use of corticosteroids and azathioprine was reported to reduce the progression to chronic HSP nephritis when compared with historical controls.[127] Intravenous pulse methylprednisolone or oral prednisone followed by oral

cyclophosphamide reduces proteinuria and may lessen the development of renal insufficiency.[128]

BEHÇET SYNDROME

BS is a multisystem vasculitic disorder reported first in 1937.[129] The original description included aphthous stomatitis, genital ulcers, and uveitis. Because there are no pathologic or laboratory findings that definitively establish the diagnosis, several clinical criteria have been proposed.[130,131] Although the disease affects predominantly young adults in Japan, the Mediterranean region, and the Middle East, pediatric cases have been described.[132–143] Genetic predisposition is suggested by the observation that the class I human leukocyte antigen (HLA) HLA-B51 is positive in 62.8% of patients with BS compared with 24.6% of healthy controls.[144] A positive family history is also higher in HLA-B51–positive patients (83%) versus HLA-B51–negative patients (58%). Immunologic processes are thought to be causally related to the vasculitis; thus, current forms of therapy use immunomodulatory medications. The clinical presentation of BS may closely resemble that of Crohn disease, but the presence of genital ulcers, very severe oral ulceration, and neurologic complications aids in differentiating the two conditions.[134,145]

Epidemiologic Aspects

The prevalence of BS varies greatly among different countries. It is most common in Japan (10 per 100,000) compared with England (0.6 per 100,000) and the United States (0.3 per 100,000).[131] The incidence appears to have increased between 1958 and 1977 in Japan. Presentation prior to the onset of puberty is unusual.[146] In one series of 297 patients, only 34 had symptoms prior to 19 years of age, with the youngest being 13 years old.[146] Ammann and colleagues described six children whose onset of symptoms of BS began at 2 months to 11 years of age.[133] Although the majority of adult patients are male (70%), half of the pediatric patients are female.[133,134]

Familial cases are uncommon, but isolated instances involving parents with affected children have been described.[147] A transient form of BS may occur in neonates born to mothers with the disease.[135]

Pathogenesis

The cause of BS is unknown, but genetic and immunologic factors probably contribute to the development of this disorder. Peripheral blood mononuclear cells show a significantly higher number of IL-2–producing $CD4^+$ cells (T helper 1 response) than do controls.[148]

The primary histopathologic lesion consists of vasculitis that affects predominantly small vessels. Initially, there is endothelial proliferation and infiltration with mononuclear cells, which is followed by a polymorphonuclear response. The same vascular lesion may occur in large veins and cause thrombophlebitis, as well as in large arteries, leading to gangrene or aneurysm formation. Studies have shown deposition of C3 and C9 in blood vessel walls and circulating immune complexes in patients with BS. In the newborn form, transient circulating IgG immune complexes and reduced total hemolytic complement were detected, suggesting transplacental passage of immune complexes or autoantibodies.[135] Some authors reported that serum IL-8 more reliably reflects disease activity than the erythrocyte sedimentation rate or C-reactive protein level.[149] However, this was not confirmed in a different center.[150]

Lehner and colleagues observed that specific HLA haplotypes are associated with some forms of BS.[151] When compared with controls, HLA-B5 occurs more frequently in patients with ocular involvement, HLA-B27 is increased in those with arthritic symptoms, and HLA-B12 correlates with mucocutaneous signs. The allele *B**5101 is found in 80% of patients with BS compared with 26% in controls.[152] Additional associations with *B**5101 were the development of BS at a younger age and the presence of erythema nodosum. However, there is no association between homozygosity for HLA-B51 and the severity of the course of BS.[144]

Recently, genetic linkage analysis in a Turkish population has suggested that chromosome 6p may be a second susceptibility locus for BS.[153] In addition, six patients with trisomy 8 have been described with BS and myelodysplastic syndrome.[154]

Clinical Manifestations

Several classifications have been proposed to define the diagnostic criteria for BS.[129,130] These consider the major manifestations (buccal ulceration, genital ulceration, uveitis, and skin lesions) and its less frequent signs (GI lesions, thrombophlebitis, arthritis, CNS lesions, and family history).

Major Manifestations. ***Oral Ulcers.*** Painful recurrent oral ulcers are the most common feature of this disease. They persist for 7 to 14 days, subside spontaneously, and recur several days to months later. Because this finding may occur in up to 10% of the normal population, additional manifestations are necessary to establish the diagnosis of the disease.

Genital Ulcers. Ulcerations on the genitalia are reported in 93 to 98% of patients with BS.[134,155] However, the rates are lower in children at first presentation (32%).[139] Their gross appearance and clinical course are similar to those of the oral ulcers and occur equally in male and female children.

Skin Lesions. The cutaneous manifestations of the disease are varied and include folliculitis, erythema nodosum, acne, vesicles, pustules, and other nonspecific lesions.[155] The formation of a sterile pustule at the site of needle trauma (behçetian reaction) occurs in approximately 40% of pediatric patients.[139]

Ocular Involvement. The signs of ocular disease are iritis with hypopyon and posterior uveitis. Visual impairment is usually bilateral and may result in optic nerve atrophy, glaucoma, and cataracts. This manifestation is much less common in Western countries than in Japan and Turkey, where it is a major cause of blindness. Between 21 and 47% of pediatric patients have ocular involvement.[134,139]

Minor Manifestations. ***Gastrointestinal Disease.*** The frequency of GI involvement in patients with BS varies widely in different series and perhaps in different regions. Yazici and colleagues reported that no patient had GI signs of BS in their review of 297 patients from Turkey.[146] Japanese authors have observed intestinal symptoms in at least 15% of patients with BS.[156] The frequency is higher in Japanese children with BS, with 58% having GI disease.[140] The most frequent complaints are colicky abdominal pain and nonbloody diarrhea, but vomiting, flatulence, and constipation may occur. Perianal ulceration may occur with or without concurrent genital ulceration.[142] Rare cases of esophageal involvement have been reported. GI involvement has been demonstrated by technetium 99m leukocyte scintigraphy and follow-up by ileocolonoscopy in children with BS without GI symptoms.[143] Radiologic examinations demonstrate thickened mucosal folds, pseudopolyps, deformity of bowel loops, ulcerations, and fistulae.[112] Ulcerations are localized or diffuse, with the majority (76%) occurring in the ileocecal region.[124] Extension of the ulcers to the serosal surface may result in perforation. Recurrence is often at the site of anastomosis, and 44% of surgically treated cases require reoperation.[124] Postoperative azathioprine results in a lower reoperation rate: 7% versus 25% at 2 years and 25% versus 47% at 5 years.[157]

The typical colonoscopic findings in BS are ileocecal location (96%), solitary ulcer (67%), size greater than 1.0 cm (76%) with a mean size of 2.9 cm, and deep ulcers (80%; 62% with discreet margins).[158] The differentiation of BS from chronic nonspecific ulcerative colitis and especially Crohn disease depends on the character of the intestinal endoscopic and radiologic findings and the associated extraintestinal manifestations. The correct extraintestinal diagnosis may be obscured by the presence of BS and ulcerative colitis or Crohn disease in the same family.[145] Baba and colleagues noted that the ileocecal location and the depth of the ulcers in BS distinguish this disease from chronic ulcerative colitis.[156] In comparison with Crohn disease, there was less inflammation in the area surrounding the ulcer, and granulomas were not seen.[156,159] Fistula formation has been reported in BS.[134,155] The recurrent genital ulcers and CNS signs seen in BS are rarely found in ulcerative colitis or Crohn disease.[145]

In contrast to children with Crohn disease, growth based on the mean height standard deviation score at the time of diagnosis is usually normal in BS: 0.38 ± 1.08 at 1 year and 0.35 at 2 years after diagnosis.[142] Body mass index is reported to be normal in children with BS. Kim and colleagues analyzed the response to medical therapy and need for surgical intervention based on the colonoscopic appearance of ulcers in 50 patients with BS.[160] The most common were volcano-type ulcers (50%), followed by aphthous ulcers (28%) and geographic ulcers (22%). Complete remission following medical therapy was better for geographic ulcers (73%) and aphthous ulcers (64%) than for the volcano type (24%). Remissions were achieved after surgical intervention in 52% of patients with volcano-type ulcers. However, recurrence rates were also higher for the volcano-type ulcers (47%) than the geographic and aphthous ulcer types (11% and 9%, respectively).

Vascular Disease. The vasculitic process described above can affect both arterial and venous systems. Small vessel disease accounts for many systemic signs, but large vessel involvement may result in severe complications. Recurrent superficial thrombophlebitis, vena cava thrombosis, and arterial occlusions leading to infarction and hemorrhage from rupture of aneurysmal dilatations have been reported. Increases in the Q–T interval, ventricular arrhythmias, and sudden death were described in 1997.[161]

Arthritis. Chronic nonmigratory seronegative pauciarticular arthritis affecting the knees, ankles, hips, elbows, and wrists occurs in up to 50% of patients with BS. The course tends to be nondestructive, with rare radiologic evidence of bone erosion, although synovial thickening and effusion may occur.[155]

Neurologic Manifestations. Headaches are reported in 37% of children with BS.[139] More severe neurologic involvement is reported in 1 to 20% of patients with BS. Episodes may be transient or progressive and include pyramidal signs, organic confusional states leading to dementia, meningoencephalitis, cranial nerve palsies, dural thrombosis, pseudotumor cerebri, seizures, and quadriparesis.[119] There may be mild pleocytosis with or without an elevation of protein in the cerebrospinal fluid. Low-dose methotrexate (7.5–12.5 mg per week) appears to have a beneficial effect in reducing cerebrospinal fluid IL-6 levels and dementia.[162]

Diagnosis

The diagnosis depends on the presence of characteristic clinical findings.[131] The criteria of Mason and Barnes, described in 1969, include three major and two minor criteria (described under "Clinical Manifestations").[130] Subsequently, an International Study Group (ISG) recommended that the diagnosis should be based on the presence of three or more episodes of oral aphthous ulcers plus two of the following lesions: recurrent aphthous genital ulcers, uveitis or retinal vasculitis, cutaneous vasculitis, or cutaneous hyperactivity to needle prick (positive pathergy test).[131] The technique of performing the pathergy test affects the rate of positive response.[163] The positivity rate was statistically higher with nondisposable blunt needles than with disposable sharp needles. Recently, the specificity of the ISG classification compared 302 patients with BS and a control group of 438 patients with other conditions, including ulcerative colitis, Crohn disease, and familial Mediterranean fever.[164] Of those diagnosed with BS, 98% fulfilled the ISG criteria compared with 1% of the control group.

Fujikawa and Suemitsu described 31 pediatric patients with BS and observed that the diagnosis in children may be difficult because of the long interval between disease onset and the presence of sufficient symptoms to satisfy the diagnostic criteria of BS.[137] The prevalence of oral ulcers increased from 77% in the first 6 months to 100% during the course of the illness. Similarly, genital ulcers increased from 45 to 58%, uveitis from 10 to 29%, and skin lesions from 39 to 55%. Krause and colleagues noted that the interval between the first disease sign and the full disease

complex in children was 3.9 ± 3.5 years, thus emphasizing the difficulty in diagnosing BS in pediatric patients.[139]

Management

Therapeutic intervention for active disease must take into account the range and seriousness of complications as described by Yazici and colleagues.[146] Corticosteroid medications form the mainstay of treatment for BS.[165] Relief of symptoms occurs initially in most patients, but recurrences are common. Topical preparations are usually effective for genital ulcers, whereas oral or intravenous administration is required for uveitis, intestinal lesions, and neurologic manifestations. A prospective randomized 2-year trial of colchicine (1–2 mg/kg/d) versus placebo was conducted in adults with BS.[166] There was a reduction in genital ulcers, erythema nodosum, and arthritis in the colchicine group relative to the placebo group. Colchicine use in children was described in five patients (dose: 13.5 ± 8.1 μg/kg/d increasing to 26 ± 9.2 μg/kg/d), with a response in two patients but only a partial response in three others.[142]

Immunosuppressive agents such as colchicines, azathioprine, chlorambucil (combined with prednisone 1.0 mg/kg/d), thalidomide (1 mg/kg dose at varying intervals of once daily to once weekly), and cyclosporine (10 mg/kg/d) have been effective in patients with severe disease who did not respond to steroids or who could not tolerate a reduction in steroid dosage.[142,165,167–171]

Yazici and colleagues and Greenwood and colleagues observed that azathioprine (2.5 mg/kg/d) was beneficial in controlling the progression of eye disease, recurrent uveitis, arthritis, the frequency of genital ulceration, reducing steroid requirement, and preventing relapse.[167,168] This finding was confirmed by Hamuryudan and colleagues, who observed significantly less deterioration in visual acuity in patients receiving azathioprine versus placebo.[169] Two children with oral, genital, and intestinal ulcerations that did not improve with steroid therapy achieved long-term control following treatment with chlorambucil.[133] Short-term improvement in GI symptoms was observed in a child treated with colchicine.[134]

Thalidomide may induce remission in refractory patients, including one infant who initially responded to 10 mg/kg per day for 4 weeks and subsequently relapsed but responded to 5 mg/kg daily.[141,170] Kari and colleagues reported thalidomide use for a mean duration of 2.2 years (1.3–4.3 years) in 5 children with BS who had been unresponsive to corticosteroids.[142] The dose range was very broad, varying from 0.6 to 1.1 mg/kg/d to 2.4 to 3.7 mg/kg two to three times weekly. Three achieved complete remission and two partial remission. Neuropathy developed in two children, and in one, it was irreversible after 1.3 years of treatment with 1 mg/kg/d. In some cases beginning in childhood, symptoms resolve; however, a mortality of 3% has been reported and was related to large vessel involvement.[138]

There is evidence that a subpopulation of T cells (CD45RA+Vγ Vδ2+) in patients with BS produces high levels of TNF-α when stimulated with phorbol myristate and anti-CD3.[172] Thus, it is not surprising that infliximab has been used in a few patients who were either refractory to corticosteroids, colchicines, thalidomide or cyclosporine,[173] chronically active and steroid dependent,[174] or sight-threatening panuveitis.[175] In most cases, infliximab was administered in the usual dose of 5 mg/kg. Response may occur as early as 24 hours followed by corticosteroid tapering and remission by 2 weeks.[173,174] In the five patients reported with panuveitis, response was noted within 24 hours and complete remission within 7 days in all.[175]

4. *Surgical Aspects*

Jacob C. Langer, MD, FRCSC

Most children with inflammatory bowel disease (IBD) can be managed using a combination of nutritional and pharmacologic approaches. Initially, the goal of therapy is to bring about a remission of the disease, and subsequent therapy is designed to prevent recurrence. Although, historically, these measures have been successful in many patients, and the continual development of newer pharmacologic agents has improved the armamentarium of the pediatric gastroenterologist, there continue to be a number of situations in which surgery may be the most appropriate course of action. The surgeon may participate in the care of these children for a number of reasons, including resection of diseased tissue, repair of narrowed or perforated intestine, bypass or defunctioning of involved bowel, drainage of abscesses, and provision of access for enteral or parenteral nutrition.

Indications for surgical management of pediatric IBD are summarized in Table 41.4-1. Although infrequent, complications such as free perforation, toxic megacolon, and massive bleeding are indications for emergent surgical intervention. In the majority of cases, surgery is indicated only after nonoperative management has failed or when complications of medical management have occurred. This is particularly true in children with small bowel Crohn disease, who are at higher risk for recurrence and further loss of bowel length.

This chapter reviews the surgical management of Crohn disease and ulcerative colitis and highlights some of the special issues that these diseases pose in childhood.

TABLE 41.4-1 INDICATIONS FOR SURGICAL INTERVENTION IN THE MANAGEMENT OF INFLAMMATORY BOWEL DISEASE IN CHILDREN

FAILURE OF MEDICAL MANAGEMENT
Complications of steroid or other drug therapy
Persistent symptoms despite maximal medical therapy
COMPLICATIONS
Crohn disease
Perforation
Fistula formation
Excessive or uncontrolled bleeding
Fibrous stricture with intestinal obstruction
Ongoing sepsis
Growth failure
Ulcerative colitis
Excessive or uncontrolled bleeding
Toxic megacolon
Mucosal dysplasia or fear of colon cancer

PRINCIPLES OF PREOPERATIVE ASSESSMENT AND PREPARATION

Prior to considering surgery for a child with IBD, a number of steps must be taken, including confirmation of the diagnosis, staging of the disease, complete assessment of any complication that might lead to consideration of surgery, evaluation of the surgical risk, and optimization of the patient's condition to minimize that risk. It is also important to have a series of full and complete discussions with the child and family so that they understand the risks and potential benefits of surgery.

The extent of disease should be assessed prospectively using a combination of barium studies and endoscopy. In children with colitis, it is important to differentiate between ulcerative colitis and Crohn colitis because the surgical options differ between these two conditions. This determination is made on the basis of colonoscopic biopsies, the distribution of the disease in the colon, and the presence or absence of disease elsewhere in the gastrointestinal tract. Computed tomography, ultrasonography, and magnetic resonance imaging may also be very useful in evaluating the presence of inflammation or thickening and in identifying the presence and location of fistulae or abscesses.

The goal of preoperative preparation is to achieve normal nutritional status and to minimize the dose of steroids. These steps are very important because the risk of serious complications such as anastomotic leak and sepsis is increased in patients who are malnourished or on chronic high-dose corticosteroids.[1] This is usually accomplished by using bowel rest, nutritional support, and "steroid-sparing" medical therapy. Nutritional therapy with concomitant bowel rest can be accomplished using either parenteral or enteral routes. Parenteral nutrition, although effective, is associated with significant risks from metabolic derangements, trace element deficiencies, central line complications, and a much higher cost. For enteral nutrition, most physicians use elemental feeding through a nasogastric or gastrostomy tube. There is, however, no convincing evidence that elemental diets are better than the use of standard enteral formulas.[2] Preoperative nutritional therapy over a 4- to 6-week period is extremely effective, safe, and well tolerated.[3] The addition of immunosuppressive agents such as azathioprine, 6-mercaptopurine, cyclosporine, methotrexate, tacrolimus, or infliximab may also help to decrease or eliminate the use of steroids.

CROHN DISEASE

The surgical approach to the child with Crohn disease depends on the location of the disease and the indication for surgery.

Ileocecal Disease

Children with ileocecal disease may develop fixed fibrotic changes, local perforation and abscess formation, or fistulization to the colon, bladder, vagina, proximal small bowel, or skin. Children may also be considered for surgery if they experience recurrent symptoms whenever the steroids are tapered, and the disease is therefore controlled only on unacceptably high doses of steroids. The decision to recommend surgery in these children may be difficult and should be made collaboratively between the family, the gastroenterologist, and the surgeon. The decision must be based on the balance of the risk of long-term high-dose steroids and the surgical risks (including infection, anastomotic leak, adhesions, and recurrent disease). Once a decision has been made, the extent of disease must be confirmed, and other studies may be done as necessary. Examples may include computed tomography or magnetic resonance imaging to assess the possibility of local abscess or fistula formation and renal ultrasonography to look for hydronephrosis owing to ureteral compression.

The surgical goal is removal of the grossly involved bowel. Although, previously, many surgeons did frozen sections of the resection margins to ensure that all microscopic disease had been removed, this is no longer recommended because it does not result in a lower recurrence or complication rate[4] and increases the risk of short bowel syndrome. The anastomosis can be hand-sewn or stapled, and the factors known to increase the rate of anastomotic leak include malnutrition, previous perforation or contamination, and chronic high-dose steroid administration.[1] In patients who have intra-abdominal sepsis or in whom anastomotic healing is felt to be compromised, a temporary Brooke ileostomy or a proximal defunctioning loop ileostomy should be done.

Ileocolic resection has traditionally been performed using a midline or transverse lower abdominal incision. Recently, a number of authors have described a laparoscopy-assisted approach to this procedure that results in less pain, shorter hospitalization, and an improved cosmetic appearance (Figure 41.4-1).[5] The laparoscopic approach can be used successfully even in patients with previous intra-abdominal abscesses or fistulae. Laparoscopy may also be useful in some cases in which the diagnosis of Crohn disease may be in doubt.

A small group of patients may present with multiple areas of symptomatic small bowel disease, with or without ileocecal involvement. Indications for surgery are similar to those mentioned above, but multiple resections would result in excessive loss of bowel length. In patients with multiple, short areas of involvement, strictureplasty has been advocated (Figure 41.4-2). The results of this procedure in both adults and children have been encouraging, with no evidence of a higher rate of leak, infection, or recurrence.[6] Patients with ileocecal disease combined with obstructive proximal disease may require ileocolic resection and a combination of proximal resections and/or strictureplasties, and the specific operation must be individualized.

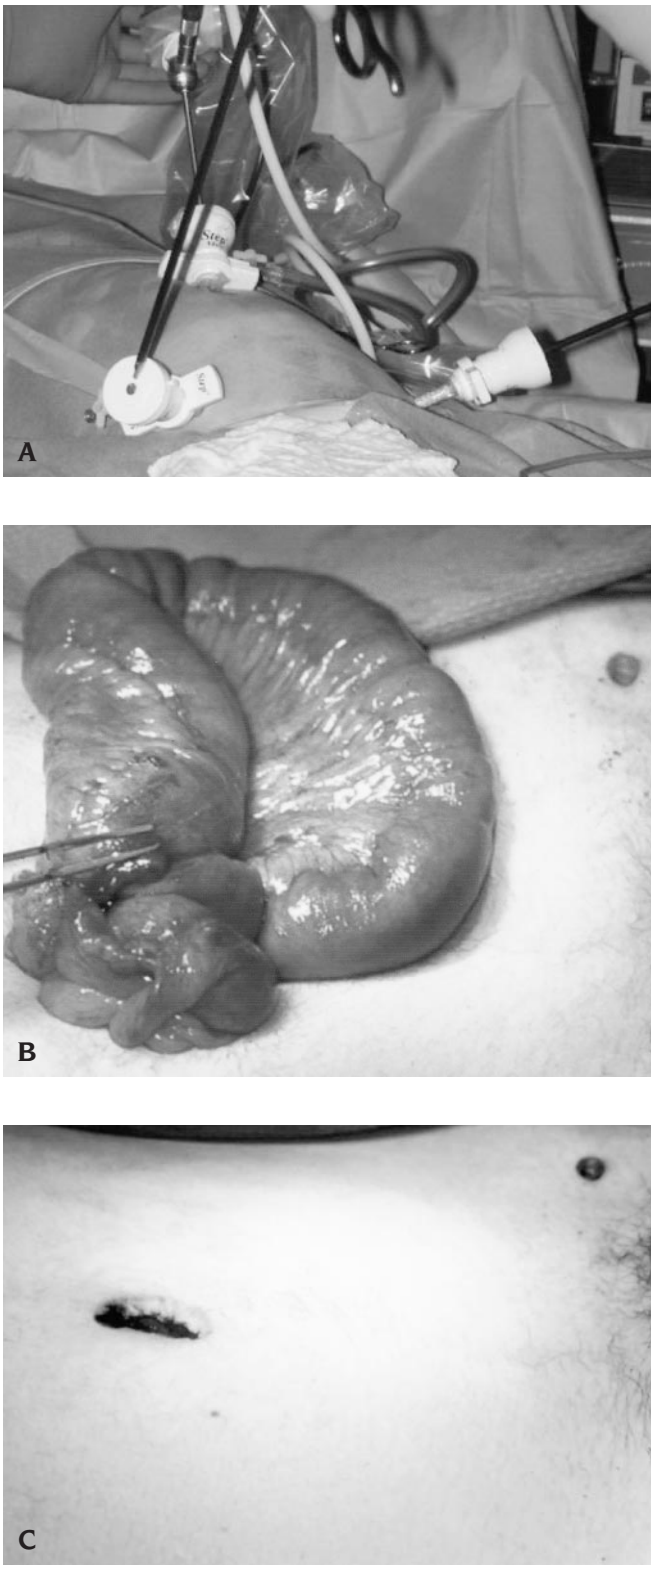

FIGURE 41.4-1 Laparoscopy-assisted ileocolic resection. The right colon and ileum are mobilized laparoscopically using several 3 to 5 mm ports (*A*), and the final resection and anastomosis are done through a small umbilical incision (*B*). The final result is shown (*C*).

FIGURE 41.4-2 Strictureplasty for multiple strictures in small bowel Crohn disease. The bowel is incised longitudinally across the stricture and then closed transversely. Strictureplasty should be performed on all strictures that cannot permit passage of a 10 cc Foley balloon.

The principles are to surgically treat only bowel that is thought to be causing symptoms, to do strictureplasties on short narrow areas, and to conserve small bowel length as much as possible. Like ileocolic resection, these procedures can usually be done using a laparoscopy-assisted approach.

Perianal Disease

Perianal disease can present a difficult management problem in children because anal fistulae are often deep and complex and surgical treatment may lead to permanent sphincter damage. The first-order treatment should consist of metronidazole and immunosuppressive agents, which may permit healing of the fistulae without the need for surgery. True perirectal abscesses require surgical drainage, but as conservative an approach as possible should be taken. The use of a defunctioning ileostomy for perianal disease is controversial, and it is likely that the same efficacy can be achieved through the use of elemental feeding or total parenteral nutrition with bowel rest. However, a stoma may provide better control of pain and perineal excoriation because it completely diverts the fecal stream. In extremely severe cases of perianal Crohn disease in which there has been extensive destruction of the anal sphincter, a total proctocolectomy with permanent ileostomy may be necessary.

Fistulizing Crohn Disease

Fistulae between the small bowel or colon and the skin, intestine, bladder, or vagina often can be treated medically using bowel rest, steroids, metronidazole, and immunosuppressive agents, although at least 50% of these will recur after therapy is discontinued. In cases in which medical management fails and the fistula is symptomatic, excision of the fistula with local resection of the involved bowel should be done.[7] In cases of fistulae to bladder or vagina, the defect in the normal structure can often be repaired without the need for resection. Some authors believe that fistulizing Crohn disease is an absolute indication for surgical intervention, although improving results with newer medical approaches, such as infliximab, may permit some patients to avoid surgery in this setting.[8]

Gastroduodenal Disease

Although relatively common, this form of Crohn disease can almost always be successfully managed using acid-reducing agents such as H_2 blockers or omeprazole, as well as standard medical therapy for Crohn disease. Surgery may be necessary for rare cases involving fistulae, strictures, or severe symptoms.[9]

Crohn Colitis

Crohn colitis often presents a complicated picture. Isolated colonic disease can usually be differentiated from ulcerative colitis by the presence of skip lesions or evidence of transmural involvement. Often both endoscopy and a barium enema are necessary because endoscopy provides mucosal detail and biopsy tissue, and the barium study permits assessment of distensibility (ie, fibrosis) and fistula formation. In cases in which only a small segment of colon is involved, local resection with primary anastomosis can be done. However, this approach is associated with a high incidence of recurrence or anastomotic complications (Figure 41.4-3).

Most patients have multiple areas of involvement, and at least a subtotal colectomy is necessary. The options for these children are a Brooke ileostomy, an ileorectal anastomosis, or a total proctocolectomy. Sphincter-saving pouch procedures and continent ileostomies are associated with a

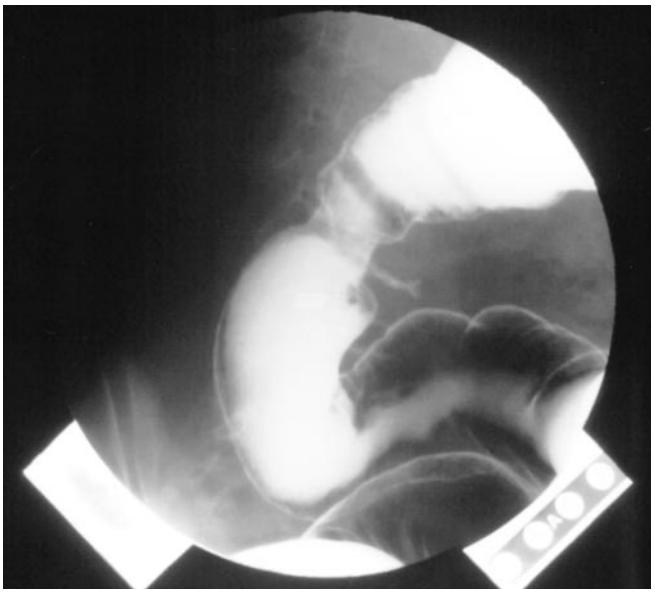

FIGURE 41.4-3 Child with a short segment of colonic disease, which was managed by local resection and anastomosis. The child then developed recurrent disease at the anastomosis with development of a recurrent stricture and fistula, requiring a more extensive resection.

prohibitive complication rate and are contraindicated in the presence of Crohn disease.[10] Although functional results in children are extremely good following subtotal colectomy with ileorectal anastomosis, at least 50% of these children will ultimately require a permanent ileostomy because of recurrent rectal disease.[11]

ULCERATIVE COLITIS

Emergency Management

For children with ulcerative colitis, emergent surgical intervention is carried out for life-threatening bleeding or toxic megacolon. The primary goal of surgery should be to remove the area that is bleeding or that is pathologically distended. Although a definitive procedure may be appealing, in the vast majority of emergency cases, a subtotal colectomy should be performed with ileostomy and either mucous fistula or Hartmann pouch. Some authors have recommended ileostomy with "blow hole" decompression for patients with toxic megacolon as an alternative to colectomy.[12]

Nonemergency Management

For most children with ulcerative colitis, surgery is considered because of symptoms that are resistant to medical management or because of complications (or the fear of complications) from pharmacologic therapy. Because ulcerative colitis is a mucosal disease, surgical removal of all colonic mucosa results in cure. Options for definitive surgery include total proctocolectomy with either Brooke or continent (Kock) ileostomy or colectomy with ileoanal anastomosis ("restorative" proctocolectomy) (Figure 41.4-4). Although the former alternatives were commonly used in the past, the

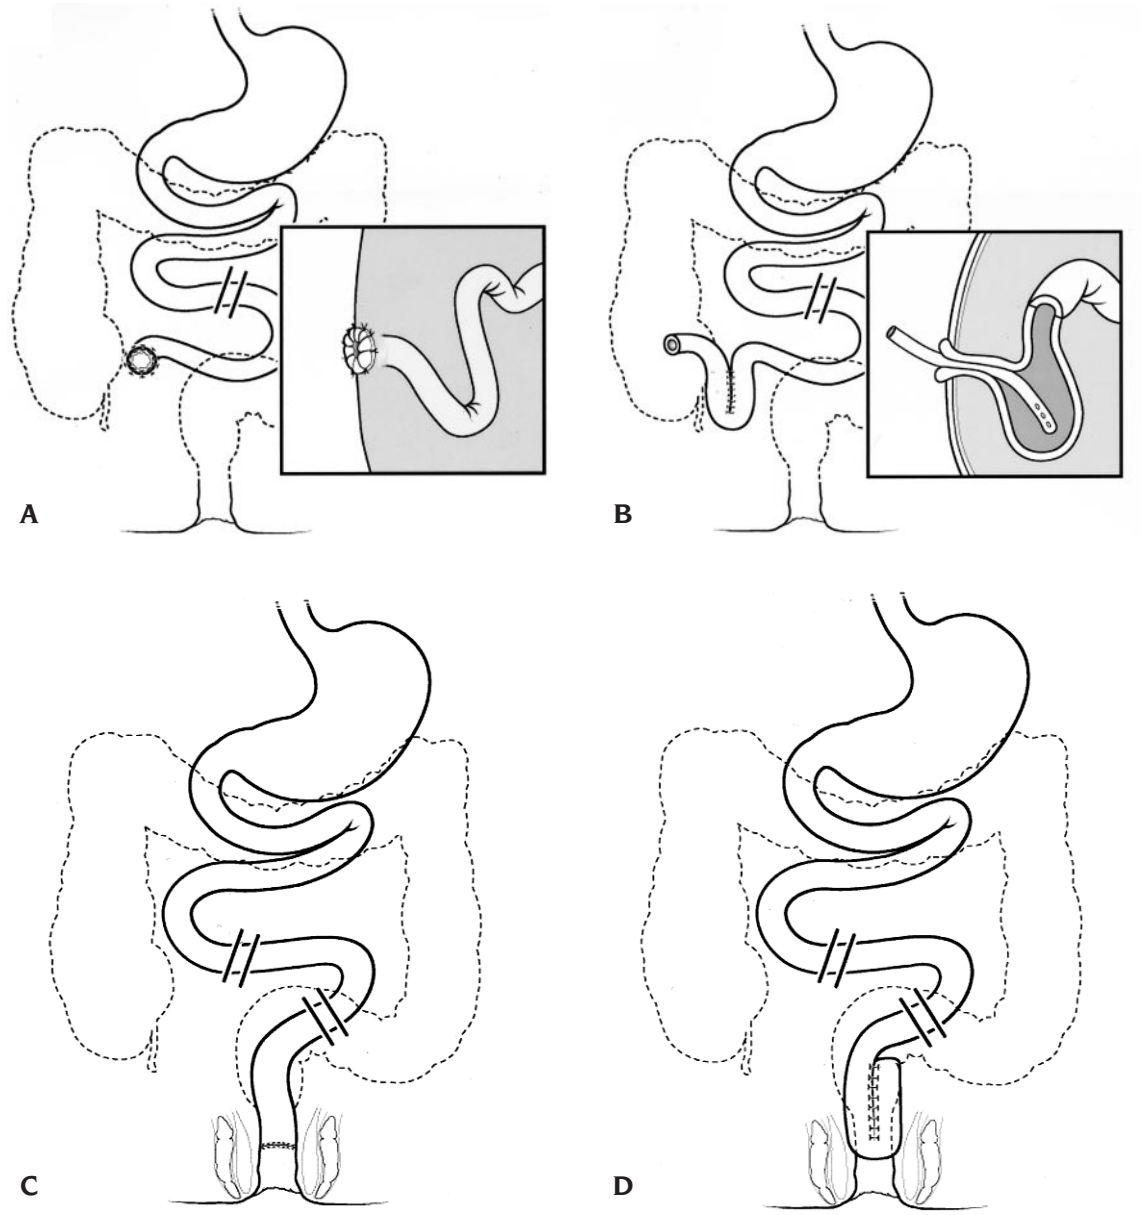

FIGURE 41.4-4 Options for reconstruction after colectomy for ulcerative colitis. A, Proctocolectomy and Brooke ileostomy; *B*, proctocolectomy with continent ileostomy (Kock pouch); *C*, subtotal colectomy with straight ileoanal anastomosis; *D*, subtotal colectomy with J pouch.

need for a permanent stoma and the high complication rate of the continent ileostomy[13] have made total proctocolectomy unappealing for most children, and by far the most common approach currently is subtotal (or "total abdominal") colectomy with restorative proctocolectomy.

A number of controversies exist as to the best approach to restorative proctocolectomy in children. In some cases, a subtotal colectomy may be performed as the primary procedure, with a reconstructive operation done in a second stage. Indications for this approach include an emergency situation, high preoperative steroid dose, poor nutrition, or concern that the diagnosis may be granulomatous colitis (Crohn disease) rather than ulcerative colitis. If the colectomy and reconstruction are to be done simultaneously, a proximal defunctioning ileostomy is usually, but not always, placed.[14,15] Controversy exists regarding a number of technical issues in restorative proctocolectomy, including straight ileoanal pull-through versus pouch formation, shape of the pouch (J, S, or W), or stapled versus handsewn anastomosis. Potential advantages of the straight pull-through include a simpler procedure, lower incidence of complications, absence of postoperative pouchitis (see below), and avoidance of a defunctioning ileostomy.[16] Potential advantages of a pouch include lower stool frequency and a decreased incidence of incontinence and perianal excoriation.[17] The use of a stapled anastomosis permits retention of a short length of transitional epithelium. This, theoretically, results in improved sensation with less incontinence, an advantage that is counterbalanced by the long-term risk of cancer and the need for periodic lifelong surveillance using proctoscopy. Thus far, comparative studies in children have failed to document a clear advantage to either approach.[18,19]

There is controversy around the appropriateness of restorative proctocolecomy in patients with "indeterminate" colitis. In general, it is best to start with a subtotal colectomy and ileostomy in these patients and wait for permanent sections on the resected colon. If, at that point, the diagnosis of ulcerative colitis is still not certain, a pouch procedure can be safely done,[19] but the patient and family must understand that the risks of pouchitits or the ultimate development of Crohn disease may be higher than are seen with clearly defined ulcerative colitis.

Both colectomy and formation of a J pouch have been described as laparoscopic or laparoscopy-assisted procedures (Figure 41.4-5). The advantages of this approach include less pain, shorter time to a full diet, and a better cosmetic result.[20] In addition, because laparoscopic surgery is thought to result in a lower incidence of adhesions,[21] it is hoped that laparoscopic surgery will decrease the relatively high incidence of postoperative small bowel obstruction seen in patients undergoing colectomy.

COMPLICATIONS AND POSTOPERATIVE MANAGEMENT

As with any abdominal procedure, patients undergoing surgery for IBD may develop wound infection, adhesions, stoma dysfunction, and ventral hernias. However, the more disturbing complications include anastomotic leak, recurrent Crohn disease, and pouchitis.

The major risk factors for the development of an anastomotic leak are administration of steroids and nutritional status. A leak can be diagnosed clinically by the presence of fever, local pain and tenderness, ileus, and fluid drainage. Radiographs may demonstrate increasing free intraperitoneal air. It is rarely necessary to do contrast studies soon after an anastomosis or pouch procedure to document a leak; in fact, such a study could potentially make matters worse. Abdominal computed tomography or ultrasonography may show free air or fluid accumulation. Treatment of documented leak usually consists of laparotomy or laparoscopy with defunctioning ileostomy. In selected cases in which there is a small leak that is not accompanied by systemic sepsis and that is well localized, management with bowel rest and antibiotics may be effective. Primary revision of the anastomosis or pouch, without proximal diversion, should never be attempted.

Crohn disease usually recurs in the region of an anastomosis and may occur weeks to many years following surgery. Early recurrence is highest in patients with active inflammation at the resection margins and patients with multiple anastomoses.[4] The risk of late recurrence is very high, especially in children, and approaches 90 to 100% in series with long-term follow-up.[22] A number of recent randomized trials in adults have demonstrated that chronic postoperative administration of 5-acetylsalicylic acid, metronidazole, or azathioprine results in decreased recurrence rates in patients with both Crohn colitis and ileitis.[23] Overall, patients can be given the "rule of thirds" with respect to outcome from surgery: roughly one-third will have a relatively prompt recurrence, one-third will have 5 to 10 years before their next recurrence, and one-third will go more than 10 years or indefinitely without recurrent disease.

Inflammation in the ileal pouch ("pouchitis") is a common complication following ileoanal pull-through for ulcerative colitis. It occurs in approximately 40% of patients, and the incidence is not influenced by the type of

FIGURE 41.4-5 Laparoscopic approach to subtotal colectomy and ileostomy. The dissection is done using four port sites (one of which will become the ileostomy site), and the colon is ultimately removed through the ileostomy site.

pouch or method of anastomosis.[24] The etiology of pouchitis is unknown. Interestingly, it is never seen in patients who have had restorative proctocolectomy for familial polyposis, suggesting that the same mechanism for inflammation in ulcerative colitis may cause pouchitis.[25] Inflammation is only rarely seen in patients undergoing straight ileoanal pull-through without a pouch, suggesting that stasis within the pouch may play a role. Pouchitis may be the first sign of unsuspected small bowel Crohn disease in patients who have been initially diagnosed as having ulcerative colitis or indeterminant colitis. Most patients have mild pouchitis, which can be successfully treated with metronidazole or ciprofloxacin. In approximately 15% of patients, more aggressive therapy with local steroids or 5-acetylsalicyclic acid may be necessary, and in approximately 5%, the pouchitis is severe enough that the pouch must be removed. Other complications, such as anastomotic stricture, perforation with pelvic sepsis or fistula formation, or poor pouch emptying, may also result in loss of the pouch.[26] Successful conversion to a continent ileostomy has been reported in some patients with a failed pelvic pouch.[27]

PSYCHOSOCIAL CONSIDERATIONS

IBD presents some unique psychosocial issues in children when compared with the same disease processes in adults. As with any chronic illness in childhood, the disease impacts not only on the child but on the entire family as well. It is crucial for the attending physician and surgeon to be aware of this and to involve the family in discussions and the decision-making process.

Most children with IBD are adolescents and are going through a normal process of developing independence from their parents and struggling with their self-image.[28] The disease may interfere with this process by imposing dependency on parents; creating self-image problems owing to cushingoid features, delay in onset of puberty; and stomas; and socially isolating the child because of frequent hospitalizations, chronic pain, and diarrhea. Withdrawal from steroid medication, which often occurs during the postoperative period, commonly causes depression, which must be expected and explained to the child and family so that the feelings are not misinterpreted. It is imperative for the health care team to be aware of and sensitive to these issues because the mental health of the child impacts so strongly on physical recuperation.

Finally, quality of life is an important factor in the decision to perform surgery and in the assessment of postoperative results. Several quality of life indexes have been described for use in adults with Crohn disease and ulcerative colitis, which may be useful for surgeons in clinical practice.[29,30] Quality of life issues have also been assessed in great detail for adults undergoing restorative proctocolectomy for ulcerative colitis.[31,32] However, as yet, there have been no specific attempts to measure quality of life in children and adolescents with IBD. Despite this, for many children with IBD, the decision to have an operation may revolve more around a quality of life issue than a medical one, and the surgeon must be patient and respectful while the child and family struggle to make these difficult choices.

TEAM APPROACH

The decision to operate on a child with IBD should be made by the child and family in collaboration with both the surgeon and the pediatric gastroenterologist and with the help and support of social workers, nurse clinicians, psychologists, dietitians, and other allied health professionals. It is helpful if the surgeon becomes involved in discussions with the family early in the process. This gives the surgeon the opportunity to educate the family with respect to the risks and benefits of surgery and permits a rapport to be established between the family and the surgeon. Having a surgeon consult with the family should not be considered as a "failure" on the part of the gastroenterologist. Ideally, the family should meet periodically with the team as a whole to ensure that the information being transmitted to the child and family is consistent and clear.

CHAPTER 42

NECROTIZING ENTEROCOLITIS

Erika C. Claud, MD
Michael Caplan, MD

Neonatal necrotizing enterocolitis (NEC) is an inflammatory bowel necrosis that primarily afflicts premature neonates.[1,2] Despite the significant morbidity associated with this disease, the pathophysiology is poorly understood. NEC differs from other conditions in that the inherent immaturity of the premature intestine appears to be the greatest risk factor rather than any particular insult. Thus, this chapter reviews the clinical features and pathophysiology of this disease with particular attention to what is understood about the unique susceptibility of the preterm intestine. Although full-term infants may develop this disease, these infants generally have specific underlying risk factors for gut compromise such as birth asphyxia, polycythemia, exchange transfusion, intrauterine growth restriction, cyanotic congenital heart disease, gastroschisis, or myelomeningocele (Table 42-1).[3–7] In these patients, NEC often presents within the first days of life. Thus, the pathophysiology in full-term infants may be quite different from that in premature infants and is not considered further in this chapter.

CLINICAL FEATURES

NEC affects approximately 1 to 5% of all neonatal intensive care unit (NICU) admissions and 12% of premature infants < 1,500 g, characteristically between 7 and 14 days of life.[8–10] Increasingly, NEC has been documented several weeks after birth, particularly in very low birth weight infants.[11] Susceptibility to NEC appears inversely related to gestational age, with the primary risk being gut immaturity itself.[12–15] NEC presents with variable symptoms, which may include evidence of gastrointestinal dysfunction such as abdominal distention, feeding intolerance, gastric aspirates, bilious vomiting, and hematochezia, with progression to pneumoperitoneum and/or systemic signs of shock and rapid death in severe cases.[16,17] Laboratory values are significant for leukocytosis, thrombocytopenia, electrolyte imbalance, and acidosis. The pathognomonic feature is pneumatosis intestinalis, which is detected on abdominal radiograph. The disease progression has classically been defined by the Bell staging system (Table 42-2). Stage I or suspected NEC is characterized by abdominal distention, increased gastric residuals, hematochezia, vomiting, lethargy, apnea, bradycardia, and hemeoccult positive stools. Stage II or definite NEC is stage I plus pneumatosis intestinalis (Figure 42-1) or portal venous air. Stage III or advanced NEC is progression to shock, disseminated intravascular coagulation, acidosis, thrombocytopenia, neutropenia, peritonitis, or pneumoperitoneum. There does not appear to be a sex or race predilection. Mortality is reported at 10 to 40% of infants with NEC. Other sequelae include stricture, short gut syndrome, abscess formation, and recurrence of disease

TABLE 42-1 RISK FACTORS FOR NECROTIZING ENTEROCOLITIS

PRETERM INFANT	FULL-TERM INFANT
Prematurity—immature intestine	Birth asphyxia
Ischemia	Polycythemia
Enteral feeds	Exchange transfusion
Bacterial colonization	Intrauterine growth restriction
Cyanotic congenital heart disease	
Gastroschisis	
Myelomeningocele	

PATHOLOGY AND HISTOLOGY

NEC primarily affects the terminal ileum and proximal colon, a watershed area for the superior and inferior mesenteric arteries. Pathologic and histologic specimens have shown a combination of ischemic necrosis, acute and chronic inflammation, bacterial overgrowth, and tissue repair, suggesting that NEC is an evolving process rather than an acute event.[18,19] Specifically, surgical specimens reveal evidence of apoptosis of enterocytes in apical villi.[20] Inflammation can be limited to the mucosa and submucosa of the intestine or progress to transmural involvement in the most severe cases. In addition, lesions may include submucosal or subserosal collections of gas, which may represent bacterial fermentation of intraluminal substrates.[19]

PATHOGENESIS

Multiple theories have been proposed for the pathogenesis of this disease; however, despite multiple epidemiologic and animal studies, a single explanation has eluded investigators. The primary risk factors appear to be prematurity, ischemia, enteral feeding, and bacterial colonization. The classic theory of the pathogenesis of NEC, as described by Santulli and colleagues in 1975, suggests that the disease is

TABLE 42-2 BELL STAGING CRITERIA

STAGE	SYSTEMIC SIGNS	INTESTINAL SIGNS	RADIOLOGIC SIGNS
Stage I: suspected NEC	Temperature instability; apnea; bradycardia; lethargy	Abdominal distention; gastric residuals; vomiting; hematochezia	Normal or mild ileus
Stage II			
Definite NEC	Same as I	Same as I plus abdominal tenderness	Pneumatosis intestinalis or portal air
Advanced NEC	Progression to shock; DIC; metabolic acidosis; thrombocytopenia; neutropenia	Peritonitis	Pneumoperitoneum

DIC = disseminated intravascular coagulation; NEC = neonatal necrotizing enterocolitis.

caused by the triad of injury to the intestinal mucosa, bacteria, and a substrate such as formula feedings in the bowel wall.[19,21] Although the pathogenesis for NEC appears to be multifactorial, the major risk factor appears to be prematurity because more than 90% of NEC occurs in premature infants, and gestational age and birth weight correlate inversely with a higher incidence of disease.

Several factors potentially make the preterm infant more susceptible to NEC, including immature intestinal host defense,[22,23] blood flow regulation,[24,25] bacterial colonization,[26–30] and inflammatory response.[31–33] Furthermore, it is known that the fetal intestine is exposed to amniotic fluid containing hormones and peptides that may have a role in intestinal maturation. Preterm infants may not have completed this maturation process when colonized by bacteria and initially fed, potentially placing them at higher risk for NEC. At this stage, the fetal intestine is normally protected in its sterile environment and may not be prepared to respond to bacterial interaction.

HOST DEFENSE

Several aspects of the gastrointestinal host defense are developmentally regulated, putting the premature infant at a disadvantage (Figure 42-2). First, there are physical barriers such as mucous membranes, intestinal epithelia and microvilli, epithelial tight junctions, and mucin. Animal studies have shown that pathogenic organisms adhere and translocate across the intestine to a greater extent in immature versus mature animals. Abnormal peristaltic activity in these infants may increase bacterial adherence, allowing for bacterial overgrowth that could increase endotoxin exposure and predispose the infant to NEC.[34–36] Cell surface glycoconjugates serve as adhesion sites for a variety of microbes, and the immature intestine has a different pattern of carbohydrate residues than the adult intestine, which may result in increased pathogenic colonization in preterm infants.[37,38] Furthermore, it is known that intestinal mucus, which protects against bacterial and toxin invasion, is different in developing animals and perhaps in premature infants.[39]

Next, there is immaturity of the functional barrier that limits growth of bacteria that breach the physical barrier. This functional barrier is composed of the immunologic host defense and various biochemical factors. It is known that numbers of intestinal B and T lymphocytes are decreased in neonates and do not approach adult levels until 3 to 4 weeks of life. Newborns also have reduced levels of secretory immunoglobulin (Ig)A in salivary samples, presumably reflecting decreased activity in the intestine.[40–42]

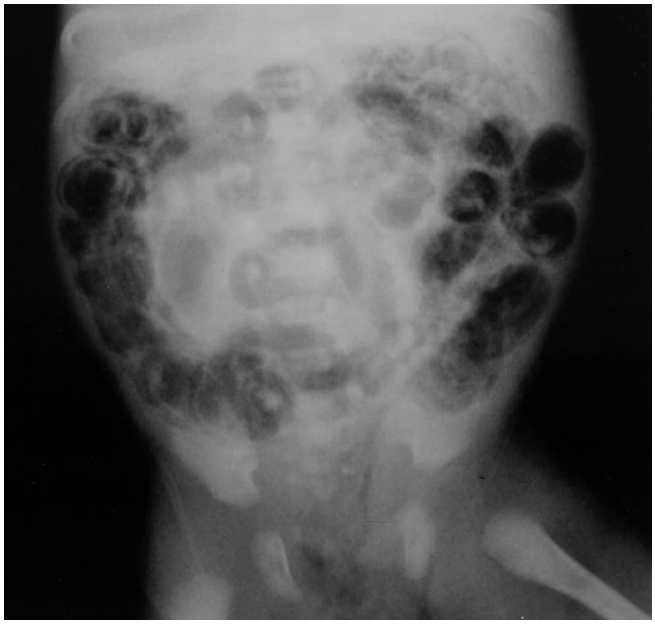

FIGURE 42-1 Abdominal radiograph depicting pneumatosis intestinalis in a premature infant with necrotizing enterocolitis.

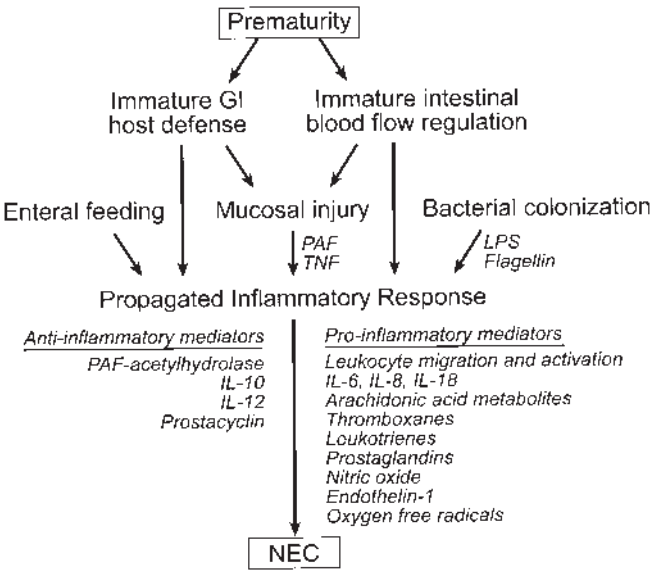

FIGURE 42-2 Aspects of immature intestinal host defense in the premature infant that may contribute to susceptibility to necrotizing enterocolitis. GI = gastrointestinal; IL = interleukin; LPS = lipoplysaccharide; NEC = neonatal necrotizing enterocolitis; PAF = platelet activating factor; TNF = tumor necrosis factor.

Additionally, the premature infant has lower gastric acid production than do older children, and immature proteolytic enzyme activity may lead to incomplete breakdown of toxins.[40] Finally, key bacteriostatic proteins are secreted from the intestinal epithelium. Intestinal trefoil factor is one such molecule that appears to be developmentally regulated and deficient in premature infants.[43–45] Human defensins (or cryptidins) are bacteriostatic proteins synthesized and secreted from Paneth cells that protect against bacterial translocation and are also altered in premature infants and those with NEC.[46,47]

INTESTINAL BLOOD FLOW REGULATION

Early observations suggested that profound intestinal ischemia was a critical predisposing factor for NEC.[48,49] It was hypothesized that similar to the diving reflex observed in aquatic animals, in periods of stress, blood flow was diverted away from the splanchnic circulation, resulting in intestinal necrosis. Although early epidemiologic observations identified asphyxia as an important risk factor, subsequent studies have shown that the majority of NEC cases are not associated with profound impairment of intestinal perfusion.[16]

Neonatal animals have been shown to have differences in intestinal circulation that may predispose them to NEC. Studies have shown that the newborn has compromised intestinal flow in response to circulatory stress. In response to hypotension, newborn animals appear to have defective pressure/flow autoregulation, resulting in decreased intestinal oxygen delivery and tissue oxygenation.[23,50,51] In addition, in the face of arterial hypoxemia, the newborn intestinal circulatory response differs from that of older animals. Although following modest hypoxemia, intestinal vasodilation and increased intestinal perfusion occur; severe hypoxemia causes vasoconstriction, intestinal ischemia, and/or hypoxia, mediated in part by loss of nitric oxide production. Multiple chemical mediators (nitric oxide, endothelin, substance P, norepinephrine, and angiotensin) impact on intestinal vasomotor tone, and in the stressed newborn, abnormal regulation of these may result in compromised circulatory autoregulation, leading to perpetuation of intestinal ischemia and tissue necrosis.[52–54]

ENTERAL FEEDING

Enteral alimentation has long been considered an important risk factor for the initiation of NEC. Feeds are thought to play a major role because 90 to 95% of all infants with NEC have been enterally fed, although the majority of fed premature infants do not develop the disease.[13] Although the precise relationship between enteral feedings and NEC remains poorly understood, studies have identified volume and rate of feeding advancement, osmolality, and substrate fermentation as important factors.[55,56] Preterm infants are unable to fully digest carbohydrates and proteins, leading to the production of organic acids, which may be harmful to the developing intestine.[57] Furthermore, human studies and carefully controlled animal models have shown that formula-fed infants have a higher incidence of NEC than breastfed infants.[13,30] Breast milk contains multiple bioactive factors that influence host immunity, inflammation, and mucosal protection, including secretory IgA, leukocytes, lactoferrin, lysozyme, cytokines, growth factors, enzymes, oligosaccharides, and polyunsaturated fatty acids. Specific host defense factors acquired from breast milk, such as epidermal growth factor, polyunsaturated fatty acids, acetylhydrolase, IgA, and macrophages, are effective in reducing the incidence of disease in animals, and some have been effective in human trials.[31,41,58,59]

BACTERIAL COLONIZATION

Although clusters of cases of NEC have been reported, no specific organism has been linked to this disease. It is unclear whether bacteria are a primary effector of NEC or are passive participants, entering the bowel wall through a breech in the intestinal mucosal barrier. Only about 30% of infants with this disease have positive blood cultures, and, in general, organisms present in the usual intestinal flora (eg, *Escherichia coli*; *Klebsiella*, *Enterococcus*, *Clostridium* species; and coagulase-negative *Staphylococcus*) have been found in the stool samples of affected infants.[18,27,60]

Colonization of the newborn intestine is affected by the environment, variation in pH, intestinal peristalsis, bacterial opposition, and type of feeding. Before birth, the infant gut is sterile, and no cases of NEC have been described in utero, supporting the importance of bacterial colonization in the pathophysiology. The intestine is initially colonized with a complex flora that reflects maternal flora.[61,62] The preterm infant is next exposed to bacteria in the NICU, with colonization frequently affected by the use of broad-spectrum antibiotics.[40,60] Although a wide range of aerobic and anaerobic flora colonizes normal infants by 10 days of age, infants in the NICU undergo delayed colonization with a limited number of bacterial species that tend to be virulent.[9,63]

Feeding is another variable in the acquisition of intestinal flora. In breastfed infants, bifidobacterium is a primary organism, with lactobacillus and streptococcus as minor components. In formula-fed infants, similar amounts of bacteroides and bifidobacterium are found with minor components of the more pathogenic species, *Staphylococcus*, *E. coli*, and *Clostridium*.[62,64–67] Animal models have shown that certain bacteria, such as adherent *E. coli*, produce disease in a rabbit model of NEC, whereas nonpathogenic strains of gram-positive organisms prevent disease.[68] Furthermore, preliminary work has suggested that early colonization by probiotics (facultative anaerobes such as bifidobacteria and lactobacilli) reduces the risk of NEC in animal and human studies.[29,69] In preterm infants, colonization with *Bifidobacterium* is delayed for several weeks. Because binding of pathogenic organisms can be influenced by the underlying microbial ecology through competition for binding sites or nutrients, production of inhibiting agents, alteration in pH, and synthesis of growth factors, promotion of the growth of competitive nonpathogenic strains of bacteria may protect the infant.[63,68,70]

INFLAMMATORY CASCADE

Evidence from human and animal studies suggests that various perinatal insults to the immature intestinal mucosal barrier lead to an inflammatory cascade, resulting in NEC in some patients.[30,58] Inflammation can be initiated by exogenous stimuli such as bacteria and bacterial products such as lipopolysaccharide and flagellin, as well as by endogenous inflammatory mediators such as tumor necrosis factor-α (TNF-α) and interleukin (IL)-1β.[71–75] In response to stimuli, enterocytes can release cytokines, such as IL-6, TNF-α, and IL-8.[76] These stimuli have distinct interactions with the intestinal epithelium and collectively result in a propagated inflammatory response (Figure 42-3). Asphyxia and/or ischemia-reperfusion also activate the early mediators of inflammation in many tissues, including in the intestine. Neonatal animal studies have shown that the stress of formula feeding stimulates phospholipase A_2 gene expression, intestinal platelet activating factor (PAF) production, and stimulation of apoptosis and the inflammatory response, with resulting NEC.[58,59] If counterregulatory responses to these inflammatory events are insufficient, pathologic changes to gut mucosa occur.

Intestinal specimens from patients with acute NEC demonstrate increased IL-1β, IL-8, IL-11, and TNF-α messenger ribonucleic acid compared with controls.[77–79] Other studies have documented increased IL-6 levels in patients with NEC, with some studies suggesting that IL-6 levels may correlate to severity of disease.[27,80,81] Furthermore, patients with NEC have elevated serum PAF and TNF-α levels but decreased acetylhydrolase levels compared with age-matched controls (Figure 42-4).[32] Acetylhydrolase is a PAF breakdown enzyme; thus, the higher PAF levels may result from decreased PAF catabolism and from increased PAF production. PAF is a potent phospholipid inflammatory mediator associated with NEC.[32,82] In rat models, PAF has been shown to produce bowel necrosis similar to NEC, an effect that can be inhibited by PAF receptor antagonists.[83,84]

The balance of pro- and anti-inflammatory influences appears to be a fundamental issue. Evidence suggests that the premature neonate may be predisposed to intestinal inflammation. Neonates are markedly deficient in their ability to degrade PAF owing to decreased activity of the specific PAF degrading enzyme PAF acetylhydrolase.[32,82] PAF acetylhydrolase is present in breast milk but absent in commercial formula, and this may, in part, explain the beneficial effects of breast milk feeding. In neonatal rats, maternal milk feedings increased amounts of the anti-inflammatory cytokine IL-10 and reduced the incidence of NEC, whereas in human milk specimens, a significant percentage of NEC patient-pairs was deficient in this important cytokine.[85,86] Studies have compared the proinflammatory response to lipopolysaccharide and IL-1β in intestinal cell lines and have found that IL-8 secretion is significantly higher in fetal intestinal epithelium compared with mature, adult intestine.[33] These results suggest that the neonatal balance of the inflammatory response may be weighted toward the proinflammatory side and is more likely to result in the pathologic outcome of NEC.

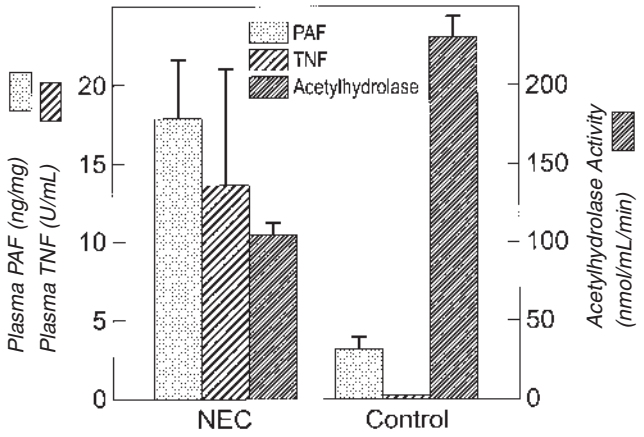

FIGURE 42-3 Potential mechanism by which risk factors for necrotizing enterocolitis (NEC) in preterm infants lead to propagation of an inflammatory response, resulting in NEC. PAF = platelet activating factor; TNF = tumor necrosis factor.

TREATMENT

Treatment remains supportive care only, and specific preventive steps have not been conclusively identified (Table 42-3). Treatment depends on prompt recognition of the disease. Therapy includes cessation of enteral feeds, nasogastric decompression, vigorous fluid resuscitation, broad-spectrum antibiotics, correction of anemia and thrombocytopenia, and respiratory support as needed. Patients need to be closely monitored by clinical examination and abdominal radiography for evidence of perforation. Radiographs may show nonspecific signs, such as intestinal distention and ileus, as well as pathognomonic pneumatosis intestinalis. Surgery is indicated for extraintestinal air (intestinal perforation or portal venous gas), evidence of ongoing necrosis (persistent metabolic acidosis indicating necrotic tissue, progressive shock, persistent thrombocytopenia), abdominal wall cellulites, or a fixed loop on serial abdominal radiographs.

PREVENTION

Several studies have explored measurement of cytokine levels to determine which infants will progress to severe NEC. IL-8, IL-10, and IL-1 receptor antagonist levels have been found to correlate to disease severity but are currently not used clinically.[86] Studies have indicated that early, hypocaloric, or trophic feeds are safe and improve gastrointestinal function in very low birth weight infants.[10] In addition, mother's milk has been found to be more protective than formula in humans and in animal models of the disease.[13,31,87–89] The specific protective factor(s) in human milk has yet to be conclusively identified, and studies are ongoing. Animal and human studies have documented decreased NEC in response to orally administered polyunsaturated fatty acids.[58,90] Epidermal growth factor given with feeds decreased the incidence of NEC in an animal model and has been used intravenously to treat an older child with intestinal necrosis in one clinical case report.[31,91]

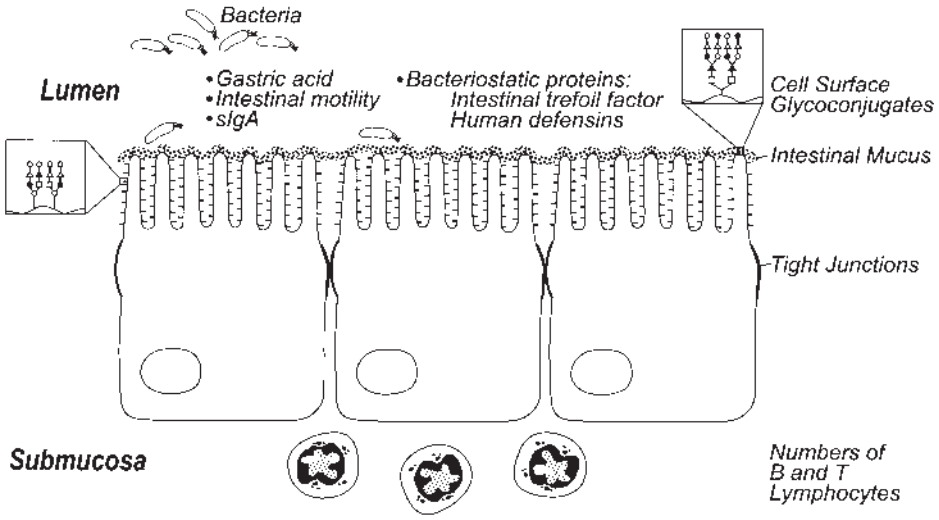

FIGURE 42-4 Plasma platelet activating factor (PAF) levels (*open bars*), plasma tumor necrosis factor (TNF) levels (*horizontally hatched bars*), and plasma acetylhydrolase activity (*vertically hatched bars*) in patients with necrotizing enterocolitis (NEC) and control subjects. Plasma PAF and TNF levels were higher in NEC patients than in control patients. Plasma acetylhydrolase activity was lower in NEC patients than in age-matched control subjects. Reproduced with permission from Caplan MS et al.[32] sIgA = secretory immunoglobulin A.

Halac and colleagues have shown that prenatal steroids reduce the incidence of NEC.[92] Cortisone acetate is known to accelerate maturation of the immature intestine, and studies in a rat model of NEC have shown that prenatal cortisone decreased the morbidity and mortality secondary to NEC.[93] Other studies have suggested prevention of NEC by IgA-IgG feeding of low birth weight infants.[41] Lastly, supplementation with *Bifidobacterium* has been shown to reduce NEC in a rat model of the disease.[29]

CONCLUSION

NEC is a devastating condition without a precise etiology. It specifically affects preterm infants and appears to be the result of an inflammatory response to risk factors, including bacterial colonization, intestinal ischemia/hypoxia, and formula feeding. The balance of pro- and anti-inflammatory influences appears to be a fundamental factor. The premature infant differs from term infants and older patients in multiple ways, including the complex system of intestinal host defense, intestinal motility, bacterial colonization patterns, autoregulation of splanchnic blood flow, and regulation of the inflammatory cascade. Preterm infants are uniquely susceptible because of an immature immune system that is unable to sufficiently protect against pathogenic organisms; in fact, the immature enterocyte may itself increase injury by excessive cytokine production in response to gram-negative organisms. Although preventing prematurity would be the most successful approach to prevent NEC, strategies to modulate inflammatory reactions may decrease intestinal injury.

TABLE 42-3 TREATMENT

Cessation of enteral feeds
Nasogastric decompression
Fluid resuscitation
Broad-spectrum antibiotics
Correction of anemia and thrombocytopenia
Respiratory support as needed
Careful monitoring of clinical examination
Serial abdominal radiographs
Surgical indications: extraintestinal air, ongoing necrosis, abdominal wall cellulitus, fixed loop on serial abdominal radiographs

CHAPTER 43

CONGENITAL DISEASE OF DYSFUNCTION AND ABSORPTION

1. *Genetically Determined Disaccharidase Deficiency*

Hassan Y. Naim, PhD
Klaus-Peter Zimmer, MD

The hydrolysis of carbohydrates, essential constituents of mammalian diet, in the intestinal lumen is achieved by a family of microvillar enzymes, the disaccharidases. Prominent members of this family are the enzymes sucrase-isomaltase (SI), maltase-glucoamylase (MGA), and lactase-phlorizin hydrolase (LPH).[1–5] Starch, glycogen, sucrose, and maltose are examples of well-known diet carbohydrates that comprise monosaccharides associated with each other through α-glycosidic linkages and are hydrolyzed by SI and MGA to monosaccharides, which are eventually transported across the brush border membrane of epithelial cells into the cell interior. Only a few examples of α-glycosidically linked monosaccharides are known, such as that present in one of the major and most essential carbohydrates in mammalian milk, lactose, which constitutes the primary diet source for the newborn.[6]

The digestive enzymes are membrane-bound glycoproteins that are efficiently expressed at the apical or microvillus membrane of the enterocytes.[2–4] The absence of these enzymes in the intestinal lumen is associated with carbohydrate malabsorption. Malabsorption following maldigestion causes diarrhea with soft to watery, often acid, but rarely fatty stools. Osmotic diarrhea arises when the intestine cannot digest and/or absorb one or more nutrients. Molecules (especially those of smaller size) cause an osmotic force, which drives water into the gut lumen. Stool volumes are smaller than in secretory diarrhea and depend on the amount (and size) of undigested and unabsorbed molecules (mainly carbohydrates) concentrated in the bowel. Osmotic diarrhea regresses with discontinuation of oral feeding. Ion gap and osmolarity are increased in the stool while the pH is below 6.0.

Bacterial flora of the colon salvage carbohydrates, which were not digested and absorbed in the small intestine, by fermentation to gases (hydrogen, methane, and carbon dioxide) and to lactic acid as well as to volatile short-chain fatty acids (acetic, propionic, butyric, isobutyric, valeric, and isovaleric), the last being absorbed by the colonic mucosa.[7] Indeed, fermentative diarrhea develops when the salvaging capacity of the colonic flora to an undigested carbohydrate is exhausted.

Diarrhea attributable to carbohydrate malabsorption is usually more severe in children (especially infants) than in adults because the intestinal passage of nutrients is more rapid in children. Further impact of unabsorbed carbohydrates on intestinal motility consists of inhibition of gastric emptying and acceleration of small intestinal transit.[8] These effects are more tremendous when malabsorption is associated with conditions such as irritable bowel syndrome[9,10] that are known to accelerate bowel transit.

Diagnosing a disaccharidase deficiency starts with a precise nutritional history, which often points the way to the diagnostic and therapeutic approach. The onset of clinical features often coincides with the introduction of specific disaccharides, such as sucrose and lactose. The parents may already have started a dietary restriction based on empiric observations. In contrast, the causal needs of some patients are suitable to overestimate some unspecific complaints. The assessment of symptoms associated with disaccharidase deficiencies, such as vomiting, abdominal pain, meteorism, and diarrhea, can be difficult because the clinical features show a broad heterogeneity and change with age. Therefore, it is important to evaluate noninvasive tests such as stool examinations (pH and reducing substances), oral tolerance, and, preferentially, hydrogen breath test in the context of specific loads with suspected disaccharides. Breath testing uses the bacterial carbohydrate metabolism in the colon with the production of hydrogen, which is absorbed

by the mucosa of the colon and excreted in breath. The (invasive) determination of enzyme activities from homogenates of proximal small intestinal biopsies is required independent of the clinical (therapeutic) relevance. Finally, the therapeutic (long term) effect of disaccharide restriction must be considered in the conclusive consultation of the patient. Taken together, the diagnosis of a disaccharide deficiency should not be founded only on the result of one of the mentioned diagnostic approaches but in the context of the patients' complaints and sensitive and specific laboratory evaluations.

SUCRASE-ISOMALTASE

Structure, Biosynthesis, and Polarized Sorting

The SI enzyme complex (EC 3.2.1.48-10), the most abundant glycoprotein in the intestinal brush border membrane, is an integral membrane protein that is composed of two subunits, sucrase and isomaltase (isomaltase ~ 145 kDa and sucrase ~ 130 kDa).[11] Sucrase and isomaltase are enzymatically active toward α-glycosidically linked carbohydrates, the most abundant sugars in mammalian diet. Sucrase digests primarily 1,2-α- and 1,4-α-glucopyranosidic bonds and is responsible for the terminal digestion of dietary sucrose and starch. Isomaltase hydrolyzes mainly α-1,6 linkages. By virtue of these hydrolytic properties, the SI enzyme complex belongs to a superfamily of α-glucosidases in higher organisms, including, for example, brush border MGA (see later), mammalian lysosomal α-glucosidase, invertase and glucoamylase of *Saccharomyces cerevisiae*, and glucoamylase of *Schwanniomyces occidentalis*.[12]

SI is a type II membrane glycoprotein in which the N-terminal end exhibits a cytosolic orientation and the C-terminal extrudes into the lumen, that is, SI has an N_{in}/C_{out} orientation. The transmembrane domain in this type of membrane protein also comprises the signal sequence required for translocation of the newly synthesized protein into the endoplasmic reticulum (ER) (Figure 43.1-1 depicts a schematic presentation of the structure and biosynthesis of SI).[13] An interesting structural feature of SI is a heavily *O*-glycosylated serine and threonine-rich stalk domain in the immediate vicinity of the membrane.[2,13] The extensive *O*-glycosylation of this short domain imposes rigidity and inflexibility, resembling that of a stalk. These structural features may play a role in protecting SI from being digested by pancreatic secretions at the membrane interface (thus decreasing the turnover rate), thus prolonging the life cycle of this molecule in the intestinal lumen. Another important region is the cytoplasmic tail, which contains 12–amino acid residues and has been proposed to undergo phosphorylation in vivo at the conserved Ser_6, raising the possibility that this post-translational event may be implicated in essential regulatory processes of the protein.[14] Cloning of full-length complementary deoxyribonucleic acids (cDNAs) encoding the rabbit and human species of SI have shown that 38% of the amino acid sequences of sucrase and isomaltase are identical, and an additional 34% show conservative changes.[13] The striking similarity between the two subunits has led to the concept that SI has emerged from one cycle of duplication of a single gene. Furthermore, sequence comparison of SI with the human lysosomal α-glucosidase and the glucoamylase from the yeast *S. occidentalis* suggests that these proteins have evolved from the same ancestral gene.[12] Although no three-dimensional structure of this large protein is so far available, the striking sequence similarities between sucrase and isomaltase and algorithmic predictions suggest the existence of subdomains within the two species that reveal similar folding patterns, and the native folded state of the SI enzyme complex can be referred to as a pseudodimer.[13] This is further favored by the behavior of sucrase and isomaltase toward proteases. With the exception of the major extracellular cleavage step of the mature precursor form, pro-SI, by luminal trypsin (see later), both species are resistant toward pancreatic proteases and do not reveal altered proteolytic maps, as would be expected for differently folded proteins.[2] It is likely that both subunits can function as autonomous and independent units within the

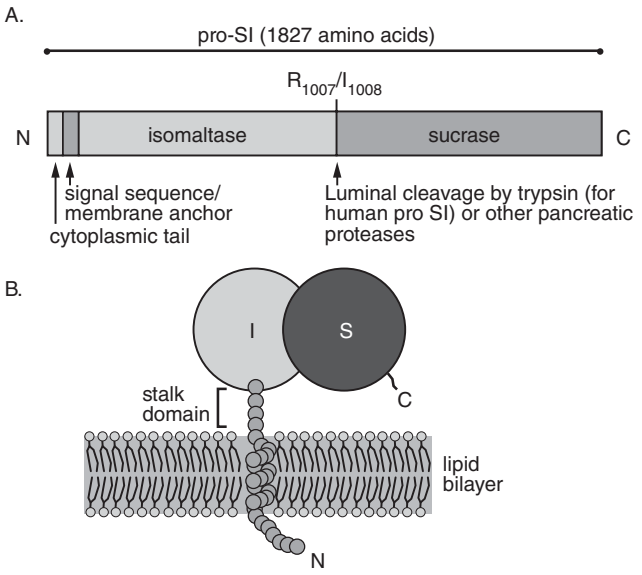

FIGURE 43.1-1 Structure and biosynthesis of pro–sucrase-isomaltase (pro-SI) in human small intestinal cells. *A*, Pro-SI is a type II integral membrane glycoprotein that is synthesized with an uncleavable signal sequence for translocation into the endoplasmic reticulum and consists of 1,827 amino acids. Pro-SI therefore has an N_{in}/C_{out} orientation. The N-terminal starts with a cytoplasmic tail (Met_1-Ser_{12}) followed by a membrane anchor that also contains the signal sequence Leu_{13}-Ala_{32}. A serine/threonine-rich stalk region encompasses the sequences Thr_{33}-Ser_{61} and is the site of extensive *O*-glycosylation of pro-SI. Isomaltase ends with amino acid residue Arg_{1007}, and sucrase starts immediately thereafter with Ile_{1008}. The Arg/Ile peptide sequence between isomaltase and sucrase is a trypsin site where the mature large precursor pro-SI is cleaved in the intestinal lumen by pancreatic secretions. The human enzyme is cleaved by pancreatic secretions (trypsin in the case of the human enzyme and elastase for the rat enzyme). Sucrase and isomaltase remain strongly associated with each other through ionic interactions. The membrane orientation of pro-SI is depicted in *B* with the cytosolic N-terminal, a luminal C-terminal, and the stalk domain next to the membrane. I = isomaltase; S = sucrase.

same polypeptide precursor. Nevertheless, individual expression of the subunits in heterologous transfection systems revealed the necessity of isomaltase for the presence of sucrase, which functions as a C-terminally located intramolecular chaperone in the folding of isomaltase.[15] In contrast, it is independent of the presence of isomaltase and acquires correct folding, enzymatic activity, and competent intracellular transport. The enzyme complex is expressed and synthesized exclusively by differentiated intestinal epithelial cells initially as a mannose-rich polypeptide precursor of an apparent molecular mass of 210 kD. The transport of this form from the ER to the Golgi cisternae occurs at a relatively slow rate (half-time of ~ 105–110 minutes) (for comparison, the intestinal proteins dipeptidyl peptidase IV and aminopeptidase N are transported at a half-time of ~ 15 minutes and 20 minutes, respectively).[2,4] Major post-translational processing of pro-SI occurs in the Golgi apparatus, leading to the generation of a complex *N*- and *O*-glycosylated mature pro-SI.[2] In particular, *O*-glycosylation is an essential modification that has implications for the further transport of pro-SI to the brush border membrane. Initial evaluation of the role of *O*-glycans on the sorting of pro-SI employed the inhibitor of *O*-glycosylation, benzyl-*N*-acetyl-β-D-galactoseaminide (benzyl-*N*-acetylgalactosamine), in the intestinal cell line Caco-2 cells.[16] This reagent leads to a drastic reduction in the size of pro-SI owing to impaired *O*-glycosylation. Concomitantly, the sorting behavior is dramatically altered from an efficient exclusive apical targeting to a random delivery of the modified pro-SI glycoform to both membranes, the apical and basolateral.[16] Deletion analyses have enabled the identification of the apical sorting signal within the stalk region of pro-SI.[17] The mechanism by which the sorting of pro-SI occurs is through association of SI with detergent-insoluble membrane microdomains enriched in glycosphingolipids and cholesterol, known as lipid rafts. In fact, inhibition of sphingolipid synthesis by fumonisin results in a random delivery of pro-SI to the apical and the basolateral membranes. A direct involvement of *O*-linked glycans in the association of pro-SI with lipid rafts is likely to be the driving mechanism for apical sorting of pro-SI.[16,17]

The isomaltase and the sucrase subunits are *O*-glycosylated. Moreover, *O*-glycosylation of the sucrase subunit is heterogeneous, as revealed by the presence of at least four glycoforms of differently *O*-glycosylated sucrase species, whereas the *O*-glycosylation pattern of the isomaltase subunit is more unique, suggesting a more efficient and consistent glycosylation of isomaltase compared with that of sucrase.[2] The variations in the *O*-glycosylation pattern of the subunits are presumably the consequence of spatial constraints, whereby isomaltase is readily *O*-glycosylated because it contains a serine/threonine-rich stalk region that is located in immediate proximity of the membrane, whereas the sucrase is more distal.[13] *O*-Glycosylation of pro-SI is not only required for correct targeting of pro-SI to the apical membrane, it also modulates the activity of isomaltase, which increases concomitantly with *O*-glycosylation.[2]

The final step along the biosynthetic pathway of pro-SI is the proteolytic cleavage in the intestinal lumen of the fully glycosylated precursor (pro-SI_C; c stands for complex glycosylated, 245 kD) by trypsin[11] or other pancreatic proteases into its two mature, enzymatically active subunits, sucrase (S_C, 130 kD) and isomaltase (I_C, 145 kD). These two subunits remain associated with each other through noncovalent strong ionic interactions.

The expression of pro-SI depends exclusively on the differentiated state of the intestine. In many tissues, cell differentiation is associated with altered gene expression owing to activation or repression of gene transcription. Gene activation and subsequent expression by tissue-specific transcription factors generate novel cellular phenotypic markers that are associated with significant morphologic and functional alterations of the differentiated cell. Differentiation of intestinal crypt cells to columnar epithelial cells, for example, results in the generation of two structurally and functionally different domains, the apical and basolateral domains,[18] and is characterized by the expression of genes encoding cell surface proteins that are implicated in the final steps of digestion of micromolecular nutrients, transports, and receptors. Among these genes are those encoding the disaccharidases, SI, LPH, and MGA.[19] Functional, immunohistochemical, and in situ hybridization studies have demonstrated that the pattern of expression of these disaccharidases, which are barely detectable in the crypts, reaches maximum levels between the lower and midvillus and decreases at the villus tip.[4,20]

Meanwhile, the structure and sequence of the SI gene are known.[21] Much of the information about the structure of the SI gene has described 5′-flanking regions and their role in transcription and regulation.[22] In addition to this, the sequences of the full-length cDNAs of the chicken, rabbit, rat, and human species are known.[22–25] One of the intriguing features of the gene structure of SI, which is perhaps unique for this enzyme, is that its first exon is untranslated, and the second exon starts with the initiation ATG codon.

Molecular Basis of Congenital Sucrase-Isomaltase Deficiency

The expression of SI and its activity increase during weaning and persist at high levels in adulthood.[26] The regulation of the SI activity is a transcriptional event that implicates SI- and intestine-specific nuclear factors. Meanwhile, several studies have identified several of these factors, as well as the structure of the SI gene. The SI gene consists of 48 exons, many of which reveal a predicted β-sheet or βα-barrel secondary structures. A very similar exon-intron junction organization reveals the gene of MGA, suggesting a close evolutionary structural and functional relation between the two genes.[21] A critical factor in regulating the SI promoter is *Cdx2*, an intestine-specific caudal-related homeobox gene that may also have a broader role in intestinal development and morphogenesis.[18]

Expression studies of promoter regions of the SI gene have assigned the intestine-specific promoter elements to a region between –183 and +54. On the other hand, several stretches within the sequence –3424 to +54 have an inhibitory effect on the level of transcription of SI. Assessment of the interaction of nuclear proteins with the pro-

moter by footprint analyses has identified three specific footprints for SI (denoted SIF1, SIF2, and SIF3 for SI footprints 1, 2, and 3, respectively).[27,28] Only SIF1 was found to be intestine specific because it was not identified in the nonintestinal cell line HepG2, in contrast to SIF2 and SIF3. Nevertheless, all three elements are implicated in positive regulation of SI gene transcription.[27]

Negative regulation of SI expression is potentially possible. Modulatory effects of certain additives, such as glucose, on the expression levels of SI in the intestinal cell line Caco-2 cells proposed negative regulatory mechanisms that operate at the messenger ribonucleic acid (mRNA) level of SI.[29] Fructose has also been reported to suppress post-translationally the expression of brush border enzymes.[30]

Post-translational regulation is the most common mechanism that significantly affects the physiology and cellular expression of SI. These effects are elicited by altered structural features: impaired, defective, or abnormal post-translational processing of an otherwise normally expressed SI protein and aberrant distribution of SI on the apical and basolateral domains of the enterocytes. These abnormalities in the cell biology and protein chemistry of SI constitute the basis for the congenital sucrase-isomaltase deficiency (CSID) in humans.[27,31–33] In addition to its clinical relevance, CSID has been used as a promising approach to characterize various steps in the biosynthesis, transport, and sorting of SI as a general model for cell surface membrane proteins and highly polarized proteins in epithelial cells.

Substantial progress has been made to elucidate the molecular basis of CSID. Different molecular defects or mutations in the SI gene have been proposed to be responsible for CSID. A number of studies with duodenal biopsy specimens from patients with this disorder at the subcellular and molecular levels have led to the identification of several phenotypes of SI in CSID that could be discriminated on the basis of subcellular localization, type, and nature of the mutation or residual enzymatic activities (Table 43.1-1 and Figure 43.1-2).[31–33] The emerging concept from all of these studies is that these phenotypes are generated by point mutations in the coding region of the SI protein. Our group was the first to successfully clone and characterize a cDNA encoding SI from a biopsy sample of a patient with CSID and to identify a single point mutation that is responsible for the impaired transport behavior of SI in phenotype II.[34] In the meantime, mutations correlating with other CSID phenotypes have been identified, and in what follows, a survey of the features of the individual phenotypes is presented (see also Table 43.1-1 and Figures 43.1-2 and 43.1-3).

Phenotype I Is Blocked in the ER. Phenotype I is characterized by a misfolded immature form of SI that is not capable of passing through the quality control machinery and is blocked in the ER as a mannose-rich glycosylated protein that is ultimately degraded.[33] Immunoprecipitation with several epitope-specific monoclonal anti-SI antibodies followed by enzymatic measurements demonstrated that the activity of this phenotype is below the detection limit. This phenotype is the predominant one among the CSID phenotypes. Most of the mutations that affect the trafficking of SI generate a misfolded form that is blocked in the ER. Recently, a CSID case with properties similar to those of phenotype I has been analyzed at the molecular and cellular levels.[35] Whereas biosynthetic labelings of an intestinal biopsy specimen and immunoelectron microscopy reveal predominant localization of SI in the ER and hence are similar to phenotype I, a partial conversion of the SI protein to a complex glycosylated mature form suggests a classification of this case as a subtype of phenotype I. The SI cDNA in this phenotype revealed a point mutation that results in an exchange of a leucine by a proline at position 620 (L620P) of the isomaltase subunit. The expression of this mutation in a heterologous cell line generates a protein with similar characteristics and intracellular localization to the intestinal phenotype. Thus, it was partially complex glycosylated and localized predominantly in the ER and, to

TABLE 43.2-1 NATURALLY OCCURRING PHENOTYPES OF CONGENITAL SUCRASE-ISOMALTASE DEFICIENCY

PHENOTYPE	CELLULAR LOCALIZATION OF SI	ENZYMATIC ACTIVITY	MOLECULAR FORMS	MUTATION	REFERENCE
I	ER	Completely inactive	Mannose-rich 210 kDa pro-SI	L620P	31–33,35
II	ER, ER/*cis*-Golgi intermediate compartment and *cis*-Golgi	Completely inactive	Predominant mannose-rich 210 kDa pro-SI and partial complex 245 kDa pro-SI	Q1098P	31, 33, 34
III	Brush border membrane	Completely inactive	Mannose-rich 210 kDa pro-SI and complex 245 kDa pro-SI	Not identified	31
IV	Random on apical and basolateral membranes	Active sucrase and isomaltase	Mannose-rich 210 kDa pro-SI and complex 245 kDa pro-SI	Q117R	33, 39
V	Intracellular cleavage, degradation of sucrase, isomaltase is correctly located at the apical membrane	Active isomaltase and absent sucrase activity	Mannose-rich 210 kDa pro-SI, complex 245 kDa pro-SI, and 150 kDa isomaltase	Not identified	33
VI	Intracellular cleavage, enzyme secreted	Active sucrase and isomaltase	Mannose-rich 210 kDa pro-SI and mannose-rich 207 kDa cleaved pro-SI and complex glycosylated 240 kDa cleaved pro-SI	L340P	40

ER = endoplasmic reticulum; SI = sucrase-isomaltase.

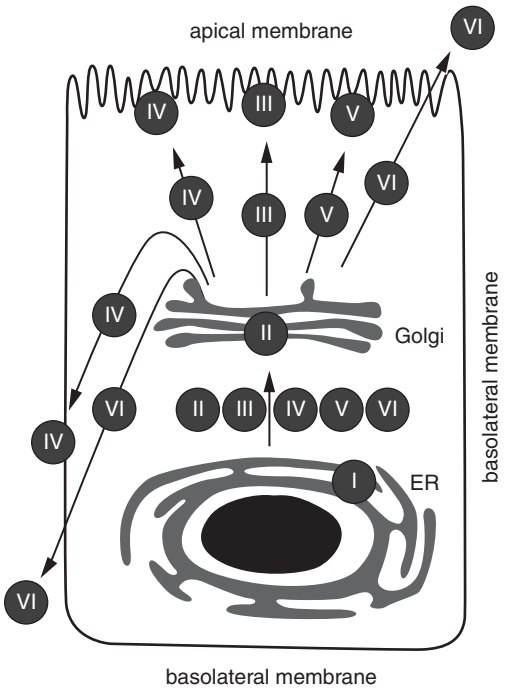

FIGURE 43.1-2 Schematic representation of the phenotypes of congenital sucrase-isomaltase deficiency. Phenotype I is blocked in the endoplasmic reticulum (ER) and phenotype II in the ER/*cis*-Golgi intermediate compartment and *cis*-Golgi.[31,34,37] Phenotype III is transported normally to the cell surface, but the sucrase subunit is enzymatically inactive.[31] Phenotype IV is randomly distributed on the apical and basolateral membranes.[33,39] In phenotype V, only the isomaltase subunit is transported to the apical membrane, whereas sucrase undergoes intracellular degradation.[33] Phenotype VI is characterized by an intracellular cleavage of pro-SI in the ER, generating a pro–sucrase-isomaltase that lacks its membrane-anchoring domain and stalk region and is secreted from both sides of the membranes of the enterocytes as an active protein.[40]

a lesser extent, at the cell surface. In addition, examination of the folding pattern in a proteolytic sensitivity assay results in an entire degradation of this mutant with the protease trypsin owing to additionally exposed cleavage sites in the malfolded protein.

Phenotype II Is Blocked in the *cis*-Golgi and ER Golgi Intermediate Compartments. The second most common phenotype of CSID is phenotype II. One of the most significant cellular features of phenotype II is an intracellular accumulation in the Golgi apparatus.[33] Some cases of CSID reveal the SI protein in the *cis*-Golgi in addition to the ER and the ER/*cis*-Golgi intermediate compartment (ERGIC), and in other cases, an accumulation in the medial and *trans*-Golgi has been observed.[32] In all of these cases, an enzymatically inactive mannose-rich polypeptide could be immunoisolated. Work done in the laboratory has succeeded in the identification of a mutation in this phenotype that results in a substitution of a glutamine by a proline in the sucrase subunit of SI at amino acid 1098 (Q1098P).[34] One of the consequences of this mutation is the synthesis of a temperature-sensitive form of SI that accumulates in the *cis*-Golgi compartment and ERGIC.[36] This observation and type of localization are surprising for membrane proteins because the consensus has emerged that proteins fulfilling the requirements of the quality control machinery in the ER and exiting this organelle acquire transport competence up to their final destination. For SI, this destination should be the cell surface; in phenotype II, however, the SI protein is blocked in the *cis*-Golgi. As such, this observation has important implications for current concepts of membrane and protein transport because this suggests that the Q1098P mutation generates a recognition site for a protein involved in a hypothetical quality control mechanism that operates beyond the ER, and such an event has not yet been described. The Q1098P substitution has therefore been investigated in more detail, and we could demonstrate that it is not only functional in intestinal epithelial cells but also produces a similar phenotype when expressed in nonpolarized COS-1 cells.[37] It is apparent therefore that (1) the Q1098P mutation is responsible for the generation of the SI phenotype II and (2) the onset of this CSID phenotype does not involve cellular factors specifically expressed in the small intestine. One important observation is that the folding state of the mutant SI protein is not as stable as its wild-type counterpart and is degraded within a relatively short period of time. The interesting aspect of these folding experiments is that the sucrase and the isomaltase subunits in the mutant phenotype II are degraded. Although malfolding of

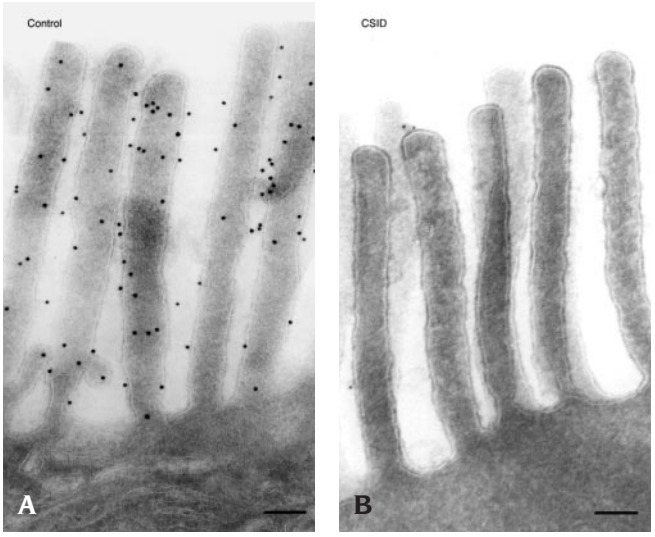

FIGURE 43.1-3 Immunogold labeling of sucrase-isomaltase (SI) within a thin frozen section of a duodenal biopsy of a control and a patient with congenital sucrase-isomaltase deficiency (CSID). Strong immunogold labeling corresponding to SI could be detected at the microvillar membrane of enterocytes from normal controls. In one case of CSID, the microvillar membrane was devoid of immunogold labeling owing to a defective intracellular transport behavior of SI. The absence of SI at the apical membrane could be observed in CSID phenotypes I, II, and VI.[31,34,37,40] Phenotype III is characterized by normal levels of SI in the brush border membrane,[31] whereas phenotype IV reveals marked reduction in the appearance of SI in the apical membrane, with the concomitant labeling of the basolateral membrane.[33,39] In phenotype V, only isomaltase could be detected in the brush border membrane.[33]

the sucrase subunit as a result of the mutation Q1098P is plausible, the altered structure of the isomaltase in the context of SI suggests that the association between sucrase and isomaltase takes place very early in the ER, whereby the sucrase subunit plays a decisive role in the folding of isomaltase and could be designated an intramolecular chaperone. In fact, more recent evidence has proven this hypothesis and provided further data in which an alternating association between the ER chaperones immunoglobulin binding protein (BiP) and calnexin, together with sucrase, occurs during the folding process of isomaltase.[15] Therefore, it is clear that sucrase is an important and crucial player in the acquisition of isomaltase to its physiologic function and transport competence within the cell on its way to the cell surface.

One of the interesting features of the Q1098P mutation is its presence in a region that shares striking homologies among human, rat, and rabbit sucrase and isomaltase variants, as well as human lysosomal α-glucosidase and *S. occidentalis* glucoamylase.[12] The fact that all of these proteins, which have been suggested to have evolved from a common ancestral gene, are transported along the secretory pathway to their final destinations proposes a key role for the region containing the Q1098P mutation in the sorting of these proteins from the ER and proposes a common function of this or structurally similar regions in other proteins along the secretory pathway. Indeed, we could show that the Q1098P mutation of sucrase elicits a similar effect when introduced at the corresponding amino acid position 244 in lysosomal α-glucosidase.[37] The mutated lysosomal α-glucosidase precursor does not undergo maturation in the Golgi, is not cleaved into mature enzyme, and is not transported through the Golgi cisternae. It is therefore conceivable that the Q1098P mutation has introduced a retention signal for the *cis*-Golgi or the mutation has led to a structural alteration in lysosomal α-glucosidase that functions as a recognition site for a quality control machinery operating in the intermediate compartment or *cis*-Golgi. The components of this hypothetical machinery must be unraveled.

Phenotype II Is a Temperature-Sensitive Mutant. One striking feature of phenotype II, in addition to the unusual block of SI in the *cis*-Golgi and ERGIC, is that the mutation Q1098P generates a temperature-sensitive mutant SI protein. In fact, biochemical and confocal microscopy analyses could unequivocally demonstrate that correct folding, intracellular transport, and full enzymatic activity can be restored by expression of the mutant SI (indicated $SI_{Q/P}$) at the permissive temperature of 20°C instead of 37°C.[36] Moreover, the acquisition of normal protein trafficking and function appears to use several cycles of anterograde and retrograde steps between the ER and the Golgi, implicating the molecular chaperones calnexin and BiP. A similar temperature-sensitive feature has also been proposed to be generated by the main genetic alteration in cystic fibrosis, the ΔF508 deletion in the cystic fibrosis transmembrane regulator.[38] However, the Q1098P mutation in phenotype II of SI is the first of its kind to generate a temperature-sensitive mutant implicated in an intestinal enzyme deficiency or an intestinal disorder.

Identification of New Cases of Phenotype II. Screening a cohort of patients with CSID has led to the identification of the Q1098P mutation in three more cases (H. Y. Naim and M. Keiser, unpublished data, 2003). All of these cases revealed a pattern of biosynthesis and processing similar to that obtained in the original case. The new cases were from East European patients, whereas the original one was from a West European individual. Despite the different ethnic origins of the patients, a similar mutation was identified, strongly suggesting that the genetic basis for phenotype II is exclusively caused by Q1098P mutation and is phenotypically characterized by a temperature-sensitive protein that is blocked in an early Golgi compartment. These new cases therefore provide strong support for the existence of a hypothetical quality control mechanism beyond the ER.

Normal Intracellular Protein Transport and Absent Enzymatic Activity in Phenotype III. In sharp contrast to the phenotypes I and II is phenotype III. Here SI is transported to the cell surface with kinetics similar to that of the wild-type protein. It is correctly folded because it reacted efficiently with different epitope-specific monoclonal antibodies and is correctly sorted to the apical membrane.[31] These criteria are adequate to propose that gross structural alterations did not occur in this specific phenotype of SI. Although further information about the location of the putative mutation in this phenotype is lacking, it is reasonable to assume that the mutation has immediately affected the catalytic site of sucrase, Asp^{1349}, or is located in immediate vicinity of the catalytic domain of sucrase, which is the Asp Gly Leu Trp Ile Asp Met Asn Glu (DGLWIDMNE) stretch.[13] The isomaltase subunit, on the other hand, expresses normal activity and is therefore not affected in this phenotype.

Random Delivery of SI to the Apical and the Basolateral Membranes Is the Characteristic of Phenotype IV. SI is almost exclusively (95%) located at the apical membrane of intestinal epithelial cells. This striking polarity and high sorting fidelity are required for an efficient function of the protein in the intestinal lumen. Deviation from this polarity pattern and an impaired sorting profile are associated with reduced function of SI and subsequent malabsorption. Analysis of two cases of CSID using immunoelectron microscopy demonstrated an altered distribution of SI from an exclusive apical to a random localization at the apical membrane and basolateral membranes.[33,39] Molecular characterization of this novel phenotype revealed a point mutation in the coding region of the SI gene that results in an amino acid substitution of a glutamine by arginine at residue 117 (Q117R) of the isomaltase subunit.[39] This amino acid exchange is located in a domain revealing features of a trefoil motif or a P domain in the immediate vicinity of the heavily *O*-glycosylated stalk domain. In wild-type SI, the stalk domain itself is directly involved in the targeting of the SI molecule to the apical membrane through an interaction of its *O*-glycosylated carbohydrate content with a putative lectin receptor that recruits SI to lipid rafts.[16] Although the location of the muta-

tion in the P domain of SI did not affect *O*-glycosylation of the mutant SI protein per se, random targeting of SI to the apical and basolateral membranes occurred. Unlike wild-type SI, the mutant protein is completely extractable with Triton X-100, despite the presence of *O*-glycans, which are required for the association of SI with detergent-insoluble lipid microdomains. This finding indicated that the *O*-glycan units were not adequately recognized in the context of the mutant SI by a putative lectin-like sorting receptor owing to a sterical hindrance or altered folding of the P domain generated by the mutation Q117R. Importantly, this naturally occurring mutant phenotype was the first of its kind of an apically sorted protein; moreover, it provided strong support to the notion of an active apical sorting mediated by sorting signals and a corresponding receptor.

Intracellular Proteolytic Cleavage at Two Different Sites in Phenotypes V and VI. Human SI is transported to the brush border membrane as a single-chain polypeptide, pro-SI, which is cleaved in the intestinal lumen by pancreatic trypsin to isomaltase and sucrase.[2] In phenotypes V and VI, the pro-SI precursor is intracellularly cleaved.[33,40] The cleavage sites are, however, different. In phenotype V, the cleavage occurs relatively late in the biosynthesis, in the *trans*-Golgi or *trans*-Golgi network.[33] In fact, biosynthetic labeling of an intestinal biopsy specimen and immunoisolation of SI revealed normal levels of the ER-located, mannose-rich polypeptide at an early labeling time point of 30 minutes. Within 4 hours of labeling, the complex glycosylated mature SI appears to be concomitant with the detection of a polypeptide of an apparent molecular weight similar to that of isomaltase.[33] The sucrase subunit was not detected by immunoprecipitation with monoclonal antisucrase antibodies. This observation was supported by immunolabeling of intestinal biopsy specimens. Here only the isomaltase subunit was detected at the apical membrane with an anti-isomaltase antibody. Obviously, the sucrase subunit in this phenotype undergoes an intracellular degradation immediately after being proteolytically processed from the precursor protein, whereas the isomaltase is transported correctly to the apical membrane. This phenotype provided the first indication that the isomaltase contains all of the necessary information required for apical transport of SI. Later, this hypothesis was experimentally verified, and the signals for apical sorting were identified in the *O*-glycosylated stalk region, and the membrane-anchoring domain and both domains are located in the isomaltase subunit.[16,17] The putative mutation in this phenotype has not yet been identified. Another mode of cleavage characterizes phenotype VI.[40] Biosynthesis of SI in intestinal explants revealed, in addition to the mannose-rich pro-SI polypeptide precursor, another band of smaller apparent molecular weight. The glycosylation pattern of this species was also of the mannose-rich type, suggesting that this band is a truncated form of the mannose-rich polypeptide and that the cleavage occurs within the ER. This view was supported by cDNA cloning of the SI from this phenotype and identification of the point mutation, as well as expression of the mutant cDNA in COS cells. The molecular basis of this phenotype is a point mutation isomaltase subunit that converts a leucine to proline at residue 340 of isomaltase. Expression of the mutant in COS cells and biosynthetic pulse-chase experiments revealed that pro-SI is cleaved early in the biosynthesis, in the ER, and the cleaved protein is transported efficiently along the secretory pathway, processed in the Golgi apparatus, and ultimately secreted into the exterior milieu as an active enzyme. This is a novel pathogenetic mechanism of a disorder that is elicited by the conversion of an integral membrane glycoprotein into a secreted species that is lost from the cell surface.

Epidemiology

The prevalence of CSID is 0.2% in individuals of European descent[41] and appears to be much higher in Greenland, Alaskan, and Canadian native people. It has been estimated to be 5% in indigenous Greenlanders.[42] Heterozygotes, which are defined as sucrase activity level below the lower limit for the normal population and with normal small bowel morphology, represent about 2 to 9% of European Americans.[43,44] CSID is transmitted by autosomal recessive inheritance. It was first described by Weijers and colleagues in 1960.[45]

Pathophysiology

Several factors, some of them less favorably present in infants, contribute to the development and extent of symptoms in CSID patients:

- Residual enzyme activity
- Amount of fed carbohydrate (in association with other foods)
- Gastric emptying
- Small bowel transit
- Degree of fermentation of unabsorbed carbohydrates by colonic bacteria
- Absorption of the colon

Sucrase hydrolyzes α-1,2- and α-1,4-glucosidic bonds, whereas isomaltase cleaves α-1,6-linkages. Sucrase-isomaltase overlaps with MGA, which digests the end and intermediary products of α-amylolysis of starch, such as maltose, maltotriose, and low- and high-molecular-weight branched dextrins, by hydrolyzing α-1,4-glucosidic linkages. However, only 20% of maltase activity is covered by MGA and 80% by SI.[5] Several factors led to the observation that patients with CSID tolerate starch better than sucrose:

1. MGA activity is preserved.
2. Starch fed to infants and toddlers has a low amount of α-1,6-glucosidic bonds, which may by sufficiently hydrolyzed by the residual isomaltase activity.
3. Colonic bacteria ferment starch in infants by 6 months of age.

Clinical Features

SI-deficient infants receiving human milk and lactose-containing formulas do not develop symptoms. Some parents introduced empirically a low-sucrose diet. Populations such as the Greenland Eskimos use traditionally low-carbohydrate

diets with a high amount of protein and fat. Later, introduction of sucrose and its reduction in quantity led to a delay in the onset of diarrhea.[46] Characteristic symptoms of patients with CSID are crying spells, vomiting, meteorism, watery diarrhea, mild steatorrhea, and chronic diarrhea.[47] Occasionally, dehydration, malnutrition, failure to thrive and to grow, developmental retardation, and muscular hypotonia were observed, indicating broad clinical heterogeneity.[41,48]

Presenting symptoms depend more on age and the amount of ingested sucrose than on the intestinal levels of SI activity. Symptoms and especially starch tolerance spontaneously improve with age. Chronic watery diarrhea and failure to thrive are common in infants and toddlers, chronic diarrhea with normal growth is usually found in preschool children, and irritable bowel syndrome and recurrent abdominal pain are typical symptoms of schoolchildren.[41] Adult patients present with refractory diarrhea or unspecific complaints.[49–51] Symptoms may present at the time of puberty, possibly unmasked by gastroenteritis. Onset of symptoms in adulthood with diagnosis up to the age of 59 years has been reported.[52]

Clinical heterogeneity includes (adult) patients with CSID who do not develop diarrhea following ingestion of large amounts of sucrose. In a few cases, CSID was associated with nephrocalcinosis, renal calculi,[50,51] metabolic acidosis, and hypercalcemia.[50,53]

The diagnosis of CSID is often missed or delayed because diseases such as food allergy, cystic fibrosis, and celiac disease or other causes of recurrent diarrhea are suggested. Transient hypoglycemia, acidosis, and lethargy may even lead one to consider inborn errors of metabolism.

Diagnostic Evaluation

A major step in diagnosing CSID is to recognize the complaints and clinical features of patients in relation to age-dependent alterations and composition of nutrition; sometimes, the parents started an empiric low-sucrose diet.

Stool and urine examinations serve as screening methods with limited sensitivity and specificity. A stool pH between 5.0 and 6.0 is an indicative but, finally, unreliable screening test for the diagnosis of sugar malabsorption.[54] The detection of reducing substances estimated with Clinitest tablets (normal < 0.5%) in stool, whose sucrose is hydrolyzed by boiling with 0.1 N HCl, has been proposed as a screening test for the diagnosis of CSID.[55] However, this method is not specific for sucrose.[54] Stool pH and reducing substances are falsely negative as soon as nonabsorbed carbohydrates are totally fermented in the colon. In contrast, reducing substances tend to be falsely positive in neonates and patients who have undergone a colectomy. The differential urinary excretion of sucrose in relation to lactulose can be used to diagnose SI deficiency[56]; however, this noninvasive sugar absorption test has not been approved in a larger series of patients.

A rise of blood glucose of less than 20 mg/dL after a 2.0 g/kg sucrose load indicates sucrose intolerance. Capillary blood samples show higher peak rises up to 25 mg/dL in blood glucose compared with venous samples.[57] Oral tolerance tests produce false-positive results between 24 and 33% owing to delayed gastric emptying.[58] False-positive results are also due to increased intestinal transit time. Monitoring of symptoms and determination of reducing substances in the stools within 6 hours improve the diagnostic values of this method.

Patients with CSID show a rise of breath hydrogen of more than 20 ppm over baseline between 90 and 180 (240) minutes after an oral load of 2.0 g/kg sucrose.[59,60] False-negative results are obtained by a delay in gastric emptying, the acid milieu of the colon (unrestricted diet prior to the test),[61] and nonhydrogen producers (following antibiotic therapy).[62,63] Up to 18% of patients who are referred for the evaluation of lactose intolerance are hydrogen nonexcretors.[64] Fast intestinal transit produces false-positive results on the breath test. The sucrose tolerance test, the hydrogen breath test, and sucrase activity did not strictly correlate in children who suffered from chronic diarrhea.[65]

The diagnosis of CSID requires the determination of SI activity with normal histology of the mucosa and the level of other disaccharidases (lactase, MGA, and alkaline phosphatase) in the normal range (differential diagnosis: secondary deficiency owing to general mucosa damage). Enterocytes of patients with CSID lack the sucrase activity of the enzyme SI, whereas the isomaltase activity can vary from absent to practically normal. Disaccharidase activities show a 40% reduction in the duodenum compared with the proximal jejunum.[66,67] In some SI-deficient patients, MGA activity is reduced in addition to isomaltase activity.[68] Combined deficiency of sucrase, lactase, and MGA, which seems to be caused by pleiotropic regulatory factors, has recently been described.[69] The differential diagnosis of CSID is broad, including the various causes of chronic diarrhea in childhood.

Therapy

Lifelong sucrose restriction is an effective therapeutic option for patients with CSID; it works well and is cheaper (as supplementation with sucrase). Because patients with CSID tolerate smaller or larger amounts of sucrose, the degree of restriction finally depends on the individual complaints of a patient. Foods with nutrients with high sucrose concentrations are beetroot (6.0), pea (4.5), honey (3.0), soybean flour (4.5), and onion (2.9 g/100 g edible parts). Care has to be taken with sucrose included in glucose polymer formulas[70] and medications. Because isomaltase function is also affected, the diet also excludes starch and glucose polymers, that is, foods with a high amylopectin content such as wheat (cereals, bread, pasta) and potatoes, especially in the first years of life. Tolerance to starch improves during the first 3 to 4 years. Rice starch and maize starch are the best digested. Arguing with compliance problems of a sucrose-restricted diet, it has to be considered that no short- or long-term complications of noncompliance are known, with the exception of severe (missed) cases.[50]

Lyophilized baker's yeast (*S. cerevisiae*), which is not very palatable, possesses sucrase activity, low isomaltase and maltase activity, and virtually no lactase activity. It has been shown that viable yeast cells reduce hydrogen excretion by 70%, with loss or reduction of clinical symptoms.[71]

Recently, sacrosidase (invertase), a liquid preparation produced from *S. cerevisiae* (Sucraid) that has already been used to hydrolyze unrefined sucrose solutions, has been successfully used in the treatment of patients with CSID.[72] It is a β-fructofuranosidase that is tasteless and resistant to pH changes down to 1.5, but it has no activity with oligosaccharides containing α-1,6-glucosyl bonds.

LACTASE-PHLORIZIN HYDROLASE

Structure, Biosynthesis, and Polarized Sorting

LPH (EC 3.2.1.23/62) is a type I integral membrane glycoprotein of the intestinal brush border membrane that comprises two major hydrolytic activities[73]: lactase activity, which is responsible for the hydrolysis of milk sugar lactose, the main carbohydrate in mammalian milk, and phlorizin hydrolase, which digests β-glycosylceramides, which are part of the diet of most vertebrates. A physiologic role of phlorizin hydrolase activity is still unknown.[73]

The LPH gene is located on chromosome 2 and consists of 17 coding domains, or exons.[74–76] The amino acid sequence deduced from the cDNA encoding LPH consists of 1,927 amino acids (Figure 43.1-4 summarizes the structural and biosynthetic features of LPH). The LPH molecule is highly *N*- and *O*-glycosylated. The primary sequence of the human enzyme predicted 15 potential *N*-glycosylation sites (the rabbit and rat enzymes possess 14 and 15, respectively). *N*- and *O*-Glycosylation are crucial in the folding, maturation, and enzymatic activity of LPH.[77,78] A study of the effect of glycosylation on the intracellular transport of human LPH in biopsy samples in the presence or absence of glycosidase inhibitors demonstrated that carbohydrate modification affects the transport rates from the ER to the *cis*-Golgi but is not important in the transport of LPH from the *cis*-Golgi to the cell surface.[3,78] Moreover, processing of N-linked carbohydrates has direct effects on the *O*-glycosylation of LPH, which is essential for the acquisition of LPH for an efficient enzymatic function. In fact, a mature *N*- and *O*-glycosylated LPH protein is almost fourfold more active than a LPH glycoform that is only *N*-glycosylated.[78]

All cloned LPH species have shown that the molecule consists of four highly conserved structural and functional regions.[74] These domains, denoted I to IV, reveal 38 to 55% identity to one another. The catalytic activity of lactase is localized to Gln_{1249} in the homologous region III and of phlorizin hydrolase is localized to Gln_{1773} in the homologous region IV.[79] Because of the four homologous regions, LPH may have arisen from two subsequent duplications of one ancestral gene.[74] An evolutionary and developmental example supporting this notion is given by the sequence similarities of LPH and each of its homologous regions with β-glycosidases from archebacteria, eubacteria, and fungi. It is possible that LPH belongs to a superfamily of β-glucosidases and β-galactosidases. The prokaryotic β-glycosidases are, on average, about 50 kDa in size, which corresponds to approximately one-fourth of the size of full-length LPH or roughly to the size of one homologous region (I–IV).

The biosynthesis and processing of LPH in several mammalian intestinal epithelial cells follow essentially similar pathways.[3,80,81] In what follows, the post-translational processing of the human enzyme most relevant to this book is described (see Figure 43.1-4). LPH is synthesized as a single-chain 215 kDa pro-LPH precursor that is *N*-glycosylated while translocating into the ER. *N*-Glycosylation is a critical covalent modification that is directly implicated in the attainment of pro-LPH to a correct protein folding, which, in turn, is a prerequisite for homodimerization, another modification step that takes place in the ER and is absolutely required for pro-LPH to exit the ER.[82,83] Dimerization is not only important for efficient transport from the ER, it is also crucial for the acquisition of enzymatic activity.[82] A correctly folded monomeric pro-LPH is not sufficient per se for a functional protein. The transmembrane domain of pro-LPH is a crucial structure in the dimerization event of pro-LPH, and its elimination results in a monomeric, inactive pro-LPH. Complex *N*- and *O*-glycosylation of pro-LPH in the Golgi apparatus precedes a proteolytic cleavage step that takes place in a late Golgi compartment, most likely the *trans*-Golgi network, and eliminates the large profragment

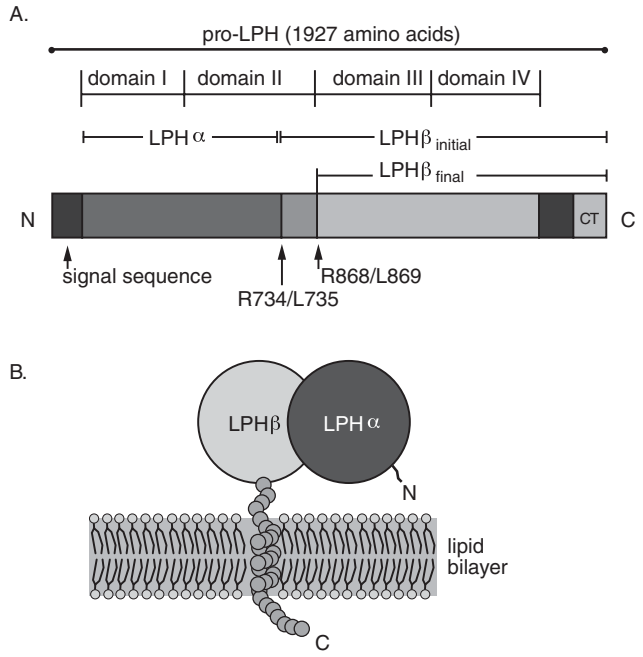

FIGURE 43.1-4 Schematic representation of the structure of pro–lactase-phlorizin hydrolase (LPH) in human small intestinal cells and the two constructs LPHβ and LPHα. *A*, Some important structural features of pro-LPH in human small intestinal cells. Shown is the cleavable sequence Met^{1}-Gly^{19} at the N-terminal. The ectodomain encompasses amino acid residues Ser^{20} to Thr^{1882}. Four internal homology domains within the pro-LPH amino acid sequence are indicated. The intracellular proteolytic cleavage takes place between Arg^{734} and Leu^{735} to generate $LPH\beta_{initial}$. The luminal extracellular cleavage occurs at Arg^{868} to generate the brush border mature enzyme, $LPH\beta_{final}$ (Arg^{868}-Phe^{1927}).[84,85] *B*, Schematic drawing of the membrane orientation of pro-LPH. The C-terminal on the cytosolic side of the membrane, the luminal N-terminal, and the subunits LPHα and LPHβ are depicted. CT = cytoplasmic tail; MA = membrane anchoring.

LPHα at Arg_{734}/Leu_{735}, leaving the membrane-bound LPH-$\beta_{initial}$, which extends from Leu_{735} to Tyr_{1927}.[84,85] LPH$\beta_{initial}$ is sorted with high fidelity to the apical membrane, where it is cleaved by pancreatic trypsin at Arg_{868}/Ala_{869} to LPHβ_{final} (Ala_{869}–Tyr_{1927}), which comprises the functional domains of the enzyme and is also known as mature brush border LPH of 160 kDa.[3,80,81] The proteolytic cleavage of pro-LPH neither activates LPH nor is required for the correct transport of LPH to the brush border membrane.[86–88] The profragment LPHα undergoes intracellular degradation immediately after intracellular cleavage, as has been shown in pulse-chase experiments of intestinal biopsy samples.[89] The LPHα polypeptide is neither *N*-glycosylated, despite the presence of five potential *N*-glycosylation sites, nor *O*-glycosylated. This, together with its high content of hydrophobic amino acids and its tendency to form a compact, rigid, and trypsin-resistant structure immediately after translation, endows LPHα with the characteristics of an intramolecular chaperone that is directly involved in the folding of the LPH$\beta_{initial}$ domain. Individual expression of a cDNA encoding LPH$\beta_{initial}$ generated a protein that was not as transport competent as pro-LPH. Only when LPH$\beta_{initial}$ was coexpressed with LPHα were correct folding and enzymatic activity of LPH$\beta_{initial}$ restored.[90] It is clear, therefore, that LPHα is required in the context of correct folding of pro-LPH. Finally, LPHα does not express enzymatic activities toward lactose, despite the strong structural homologies between regions LPHα and LPHβ.[86]

To achieve its physiologic function, pro-LPH or its membrane-bound form must be transported to the luminal surface of epithelial cells, that is, to the brush border membrane. The sorting to the apical membrane of proteins such as LPH is signal mediated. Until present, several types of signals have been described; some of them are associated with membrane detergent-insoluble glycophosphatidylinositol (DIG)/cholesterol membrane microdomains,[91] whereas some do not associate with DIGs. LPH is not associated with microdomains, and its sorting is not mediated through *O*-glycans as SI.[16,92,93] Recent observations have strongly suggested that putative sorting signals of pro-LPH are exclusively located in the domain corresponding to the brush border–associated LPHβ_{final}, precisely in the homologous region IV that also harbors the catalytic domain of LPH.[88,94]

Epidemiology of Adult-Type Hypolactasia

Primary adult-type hypolactasia affects the majority of the world's human population. More than 75% of the human adult population shows a decline to about 5 to 10% of the level at birth during childhood and adolescence ("post-weaning decline"). The incidence of adult-type hypolactasia varies between different populations because the expression of lactase is genetically determined. Up to 80% of blacks, Arabs, and Latinos, as well as up to 100% of American Indians and Asians, reveal adult-type hypolactasia; the lowest prevalences (< 5%) are detected in populations in northwestern Europe.[95] The persistence of lactase activity is most likely a consequence of a dominant gene defect with failure to repress the synthesis of lactase after weaning in regions with an abundant milk supply, which implies the "culture historical hypothesis."[96]

Molecular Basis

Genetic analysis of homozygotes and heterozygotes of lactase-persistent and lactase-nonpersistent families supported the initial idea that lactase activity is inherited as a single autosomal dominant gene.[97] There are currently several ideas that attempt to explain the late onset of lactase activity. Initial concepts suggested that lactase regulation may be a post-translational event, as is the case in CSID (see above). Alterations in the structural features of LPH itself may generate an inactive protein or lead to a defective post-translational processing and possibly intracellular degradation of the protein. This hypothesis was later discussed when the mRNA levels of lactase in the intestine of adult rats were found to be almost similar to the mRNA levels in fetal rats.[98] Another study used biopsy material to demonstrate that appreciable levels of lactase mRNA were detected in the intestines of hypolactasic individuals in southern Italy.[99] These observations were compatible with post-translational regulatory mechanisms of adult-type hypolactasia.

A study of a race- and sex-balanced cohort in which levels of jejunal lactase protein, activity, and mRNA were measured showed that black heritage predicts low lactose-digesting capacity (LDC) and white heritage predicts high LDC.[100] A decisive criterion in these studies was the assessment of the lactase-to-sucrase ratio (L:S) in jejunal biopsy specimens. All subjects with a high LDC had an L:S ratio > 0.5, immunodetectable LPH protein, and measurably higher LPH mRNA levels than subjects with low LDC. Further, LPH mRNA levels correlated highly with lactase-specific activity (r = .80) and L:S ratio (r = .88). The direct correlation between LPH mRNA levels and lactase expression argues that the gene responsible for the human lactase polymorphism regulates the level of LPH mRNA. Similarly, studies in the rat small intestine have essentially described a similar coordinate pattern of interrelationship between mRNA and protein levels of LPH.[98] The regional distribution of lactase activity, although clearly dependent on the presence of the LPH mRNA pattern, did not absolutely correlate with the mRNA and protein levels along the proximal-distal axis. This suggests that additional secondary mechanisms, perhaps post-translational, influence the lactase activity. One potential modification is *O*-glycosylation that commences in the *cis*-Golgi and increases the activity of LPH fourfold.[78] It is known that variations in the extent of *O*-glycans are associated with the differentiation state of intestinal cells to polarized enterocytes. These events are associated with dramatic alterations in the gene expression of intestinal proteins and increased enzymatic activities of typical intestinal markers such as SI and LPH. Along this, a regulatory mechanism of the enzymatic function of LPH (and also SI) that depends on the carbohydrate moiety and therefore the differentiation state of the intestinal cell cannot be excluded. Despite this, the major mechanism of regulation of LPH is transcriptional because the majority of the accumulated data have clearly demonstrated that adequate levels of LPH mRNA must be present to detect LPH

activities.[97,100,101] Meanwhile, the structure of the LPH gene has been published, as well as data on the interaction of specific regulatory elements with 5′ flanking regions of the gene. The gene for LPH is approximately 55 kb and is made out of 17 exons, which all encode LPH.[75] Transcription factors such as CTF/NF-1 and AP2 bind to regions in the LPH gene located within 1 kb of the 5′-flanking region of rat and human genes.[102] The lactase activity has been demonstrated to be enhanced in rats by glucocorticoids during the first weeks in life. Glucocorticoids also have regulatory effects on human lactase.[103] Responsive elements to glucocorticoids have not been, however, in the 5′-flanking region of LPH. Analysis of 5′-flanking sequences employed, fused to human growth hormone as a reporter gene in transfected Caco-2 cells or the nonintestinal cell line HepG2, has demonstrated the exclusive and specific function of these sequences in cells of intestinal lineage.[104] Footprint analysis of the promoter region has led to the identification of a nuclear protein (NF-LPH1) that binds to a 15 bp region just upstream from the transcription site (between –54 and –40), which is functional in the adenocarcinoma cell line Caco-2 and is probably involved in regulation of lactase activity.[102,105]

A specific region in the LPH promoter, CE-LPH1, has been identified that interacts with NF-LPH1 and is strongly associated with the regulation of gene transcription of LPH.[105,106] Nevertheless, differences in the promoter region of LPH between individuals with low LDC and those with high LDC have not been detected. Likewise, there is no evidence that describes variations in the levels of particular transcription factors associated with low or high LDC. Also, sequence analyses of the coding and promoter regions of the gene encoding LPH did not reveal DNA variations associated with low LDC. More recently, however, Enattah and colleagues identified a variant associated with adult-type hypolactasia.[107] Linkage dysequilibrium and haplotype analyses of nine extended Finnish families, the locus to a 47 kb interval on chromosome 2q21, were restricted. Sequence analysis revealed a DNA variant, C/T-13910, about 14 kb upstream from the gene locus of LPH that associates with low LDC in Finnish families and 236 individuals from four different populations. Another variant, G/A-22018, 8 kb telomeric to C/T-13910, is also associated with adult-type hypolactasia in 229 of 236 cases. Significant effects of these variants on the levels of LPH mRNA and the L:S ratio were demonstrated. Here the expression of LPH mRNA in the intestinal mucosa in individuals with T(-13910) A(-22018) alleles was found to be manyfold higher than that found in individuals with C(-13910), G(-22018) alleles.[108] Likewise, a significant elevation of the L:S ratio in the T(-13910) A(-22018) allele could be observed.

Clinical Features

Symptoms of adult-type hypolactasia increase with age, with many patients developing signs of lactose intolerance in adolescence and adulthood. They start briefly after consumption of milk, causing abdominal discomfort (colicky pain), flatulence, loose stools, diarrhea, and flatus. Symptoms are related to the amount of lactose administered, showing a broad heterogeneity in response among patients.

A major issue is the clinical relevance of lactose intolerance. The milk rejection rate has been 31% among the lactose malabsorbers and 12% among the lactose-tolerant individuals. However, 70% of the lactose-intolerant patients drink some milk.[109] Fifty-nine to 75% of lactose malabsorbers develop symptoms within 3 or 4 hours after ingesting 12 g of lactose (equivalent to 240 mL of milk) or less, 2 of 20 subjects had symptoms with 3 g of lactose, and 5 of 20 subjects had symptoms with 24 to 96 g of lactose.[109,110] Individuals with low lactase levels have revealed persistently low polyethylene glycol concentrations, representing fluid accumulation in the jejunum of 6 g of fed lactose and in the ileum of 12 and 24 g of fed lactose.[110] This study found no consistent correlation between jejunal lactase levels and the threshold for lactose-inducted symptoms. Symptoms in most lactose malabsorbers do not appear to be caused by small amounts (0.5–7.0 g) of lactose.[111] Other studies have identified lactose malabsorbers who tolerate one (240 mL) or even two cups of milk per day.[112,113]

The question has been raised as to whether symptomatic lactose malabsorbers have an additional gastrointestinal affection, such as irritable bowel syndrome.[112,114] Because about 70% of patients with milk intolerance and patients with irritable bowel syndrome revealed a positive lactose hydrogen breath test[115] and bowel transit is increased in irritable bowel syndrome,[9,10] it is hypothesized that fast intestinal transit contributes to the complaints of lactose malabsorbers.

Diagnostic Evaluation

Symptoms and nutritional history lead to the diagnosis of adult-type hypolactasia. Laboratory assessment of this diagnosis includes, preferentially, a lactose hydrogen breath test and, exceptionally, confirmation by lactase activity of a duodenal biopsy. The diagnostic values of other procedures, such as reducing substances, which are positive in the feces of patients with lactose malabsorption, implying no specificity for lactose malabsorption, are limited and depend more on the context of the patients' complaints and the results of additional laboratory evaluations. The lactose tolerance test is considered to be less sensitive than the lactose breath test. The latter does not reliably predict tolerance toward lactose in infants recovering from diarrhea.[65,116] Another study has found the relationship between the lactose breath hydrogen test and lactase activities not to be uniform.[117] A bad correlation among the lactose tolerance test, lactase activity, and hydrogen breath test has been found in children who suffered from chronic diarrhea.[65]

Lactose tolerance and hydrogen breath tests must be performed after a 6-hour (overnight) fast. Conditions that cause false-positive results are a low gastric emptying rate[58,118] and fast intestinal transit time.[119] False-negative results of the breath test are obtained by hydrogen nonexcretors or are due to prior treatment with antibiotics. Hydrogen breath tests are falsely negative in nonexcretors because hydrogen is metabolized by bacteria to methane. The daytime breath

hydrogen profile, which includes breath sampling at home at half-hour intervals during 1 day from awakening until bedtime, was abnormal in children with abdominal pain and diarrhea,[120] suggesting that the prevalence of lactose malabsorption underlying these conditions is high.

Diagnosis of adult-type hypolactasia on the enzyme level requires lactase activity in jejunal (duodenal) biopsies of less than 8 U/g protein or 0.7 U/g wet weight.[117] Disaccharidase activities are reduced in the duodenum compared with the proximal jejunum.[66,67] Other disaccharidase activities, as well as the morphology of the mucosa, must be in the normal range to exclude a secondary lactase deficiency. Therefore, the ratios of maltase to lactase and sucrase to lactase have been proposed as additional parameters.[121] Disaccharidase (lactase, sucrase, maltase) activity in aspirated fluid correlates with that measured in the mucosal microvillus membrane,[122] but this method has not been widely adopted.

Concerning the clinical relevance of lactose intolerance, it is a crucial diagnostic step to determine the response of the patient to a lactose-reduced diet. It allows one to estimate which symptoms are solely caused by lactose intolerance and not to additional affections, such as irritable bowel syndrome. The differential diagnosis of adult-type hypolactasia includes other causes of chronic diarrhea in childhood, especially infectious, immunologic (cow's milk allergy), and inflammatory disorders of the intestinal mucosa, many of them causing secondary lactase deficiency owing to mucosal damage. A reduction of duodenal lactase ($p = .024$) and pathologic lactose breath testing ($p = .005$) has been reported in patients with active Crohn disease in contrast to Crohn disease patients in remission.[123] Another study has not found lactase activity levels to be different in a cohort of patients with inflammatory bowel disease (37%) in comparison with control patients with chronic abdominal pain.[123,124]

Therapeutic Aspects

An increased frequency of osteoporosis has been reported in lactose malabsorbers that is due to the dietary calcium restriction as a consequence of milk avoidance.[125,126] Calcium is essential for adequate mineralization of bone matrix. Because lactose malabsorbers cannot use the main source of calcium, that is, dairy products, they need calcium supplementation to prevent osteoporosis.[127] Two hundred forty milliliters of milk contains 300 mg of calcium, with linkage to casein and optimal bioavailability. The National Academy of Science (NAS) recommends a dietary calcium intake of 210 mg/d for age 0 to 6 months, 270 mg/d for age 6 months to 1 year, 500 mg/d for age 1 to 3 years, 800 mg/d for age 4 to 8 years, and 1,300 mg/d for age 9 to 18 years.[128] Many lactose malabsorbers tolerate small amounts of milk without complaints so that they can improve calcium intake by solid cheeses and yogurt. Yogurt is a fermented milk product containing live active culture of *Lactobacillus bulgaricus* and *Streptococcus thermophilus*, which reveal lactase activity. The lactase of yogurt, cultured buttermilk, and curds ferments lactose to lactic acid; however, pasteurization of these products reduces digestion of lactose. *Lactobacillus acidophilus* also possesses lactase activity and is available as "sweet acidophilus milk," with a taste similar to that of milk.[129] Alternatives to dairy products represent calcium-fortified fruit (orange) juice, vegetables, or lactose-free milks.

Lactase (β-galactosidase) is produced from yeast (*Kluyveromyces lactis*) or fungi (*Aspergillus oryzae*). Preincubation of milk with lactase was associated with a significant lower breath hydrogen and crying time in infants with colic compared with placebo.[130] Formulation of stable lactase microparticles with enteric release seems to preserve the activity of acid-labile lactase for enteric release.[131] However, warming of breast milk and formulas treated with lactase for 15 minutes significantly increases osmolality by 87 to 122 mOsm/kg owing to hydrolysis of lactose.[132]

Addition of lactase to a preterm formula may enhance weight gain.[133] Preterm infants have relative lactose malabsorption because lactase activity is only 30% of its full-term level by 26 to 34 weeks gestation.[134] Lactase activity is depressed in rabbit fetuses with intrauterine growth retardation.[135] Hypoxia in newborn rats causes delayed maturation of lactase.[136] Enteral feeding of preterm infants is suggested to increase lactase activity,[137] which has been confirmed in preterm pigs.[138] Sphingomyelin, the major phospholipid of human milk, reduces lactase in the intestine of 2-week-old rats, promoting enzymatic and morphologic maturation of the neonatal gut.[139]

Gene technological strategies to lower the lactose content in milk are developed[140] because more than 75% of the the adult human population is affected by hypolactasia, and long-term complications of lactose malabsorption, such as osteoporosis, represent an endemic disease. There are inconsistent studies regarding the hypothesis that lactase deficiency protects against parasite infections such as malaria.[141,142] The strategy to reduce the lactose content in milk includes benefits even for individuals without lactase deficiency, taking into account that the potentially harmful effects of lactose consumption, such as arteriosclerosis and ovarian cancer, can be overcome. A high incidence of galactose-induced senile (cortical) cataracts has been found in lactose absorbers.[143,144] Ischemic heart disease and ovarian cancer have also been attributed to the consumption of high amounts of lactose (galactose).[145–147] In contrast, there is some evidence that lactose may be beneficial against lower intestinal diseases such as Crohn disease because of its prebiotic potential.[148] Prebiotics are essential for the establishment of intestinal colonization of newborns. On the other hand, *Bifidobacterium bifidum*, as well as conventional colonization of the germ-free intestine, induces biochemical maturation of enterocytes in gnotobiotic mice, promoting the postnatal decline of lactase activity.[149]

Congenital Lactase Deficiency (Alactasia)

Congenital lactase deficiency is a rare disorder inherited by an autosomal recessive mode. Since the first report in 1959,[150] few cases of this disease have been described.[151,152] To date, the molecular basis of this deficiency is still obscure. However, post-translational mechanisms are likely to be implicated in the lactase activity in these cases, as has been described for CSID (see above).

The typical symptoms of congenital lactase deficiency start from a few days after birth with the onset of breastfeeding (or lactose-containing formula feeding). They consist of liquid and acid diarrhea, meteorism, and severe malnutrition. The patients are hungry; vomiting is rarely noted. Some patients present with hypercalcemia and nephrocalcinosis, which may be provoked by the metabolic acidosis and/or the calcium absorption–increasing effect of lactose.[153]

When congenital lactase deficiency is suspected, a lactose-free diet should be started. In the case of a positive effect, this diagnosis is further confirmed. Finally, the diagnosis needs to be based on a deficient lactase activity in a duodenal or jejunal biopsy. Other disaccharidases, as well as the morphology of the intestinal mucosa, should be in the normal range.

Because of the severe symptoms, congenital lactase deficiency requires a strong restriction to a lactose-free diet (see above). In the further course of the disease, some patients may cope well with lactase supplementation.

MALTASE-GLUCOAMYLASE

Structure and Biosynthesis

Another brush border enzyme with digestive properties similar to those of isomaltase, MGA (EC 3.2.1. 20 and 3.2.1.3) contributes to the overall digestion of α-glycosidic linkages of carbohydrates. MGA compensates the lack of SI in a number of cases of CSID. MGA activity has been proposed to serve as an alternate pathway for starch digestion when luminal α-amylase activity is reduced because of immaturity or malnutrition, whereby MGA plays a unique role in the digestion of malted dietary oligosaccharides.[21] Similar to SI, MGA is a type II integral membrane glycoprotein of the intestine. Immunoprecipitation with specific monoclonal antibodies and electrophoretic analysis of the precipitates under denaturing conditions reveal a 335 kD single polypeptide in the presence or absence of reducing agents.[1] Examination of the quaternary structure of MGA by cross-linking analyses demonstrated a monomeric form of MGA in the brush border membrane. Biosynthetic studies in intestinal biopsy samples revealed two forms of MGA: the ER 285 kD mannose-rich polypeptide and the mature, complex, glycosylated 335 kD brush border protein. Unlike SI, mature MGA does not undergo extracellular cleavage in the brush border membrane by pancreatic secretions because the 335 kD polypeptide was the dominant form in the presence or absence of pancreatic secretions. In a fashion similar to SI, MGA is heavily *N*- and *O*-glycosylated, and it is likely that its trafficking to the brush border membrane is mediated by *O*-glycan units located in the stalk region—again, a structural similarity with SI.

The cDNA of human small intestinal MGA cDNA has recently been isolated from mRNA using reverse-transcriptase polymerase chain reaction.[154] The deduced amino acid sequence of 1,857 amino acids corresponds to an unglycosylated protein of an apparent molecular mass of 210 kD. The substantial difference between this size and the biosynthetic forms of MGA in biopsy samples is probably due to glycosylation and the electrophoretic behavior of the glycoforms on sodium dodecyl sulfate–polyacrylamide gel electrophoresis. It is also possible that splice variants of MGA exist. MGA and SI are strikingly homologous (59% homology) and, correspondingly, share several common structural features, such as the presence of an *O*-glycosylated stalk region immediately following the membrane-anchoring domain, a trefoil or P domain, and two identical catalytic sites.[154]

The recent cloning and sequencing of the human MGA gene could demonstrate its close evolutionary relationship to SI. The gene is located at chromosome 7q34 and consists of 58 exons.[21] Expression of the gene product results in a protein that hydrolyzes maltose and starch, but not sucrose, and is thus distinct from SI. Another similarity of both genes is their identical exon structures. These similarities strongly support the notion that MGA and SI have evolved by duplication of an ancestral gene, which itself had already undergone a gene duplication.

Molecular Basis of Deficiency

The hypothesis that villus atrophy accounts for the reduced maltase enzyme was examined in mucosal biopsy specimens.[155] It was observed that the drastic reduction in the maltase activity and the MGA mRNA levels of about 45% paralleled the reduction in the villin mRNA used as a marker for villus integrity. Likewise, the levels of the SI mRNA were also decreased in proportion to villus atrophy of malnourished infants. Congenital cases of MGA deficiency are rare, and one case has recently been characterized at the molecular level.[69] In this case, however, sucrase deficiency and lactase deficiency have also been detected. Isolation and sequencing of the MGA cDNA revealed homozygosity for a nucleotide change in the patient that resulted in a substitution of serine by leucine at amino acid residue 542 (S542L), very close to the catalytic site aspartic acid. Analysis of the function of this mutation by its introduction into the wild-type MGA cDNA did not reveal any alteration in the biosynthesis, processing, and enzymatic activity of mutant MGA. The promoter region of MGA in this patient was also analyzed, and no nucleotide changes could be observed. This case led to the conclusion that the reduced activities of MGA, SI, and LPH are caused by shared, pleiotropic regulatory factors.

Clinical Implications

In 1994, glucoamylase deficiency was reported in a large group of children suffering from chronic diarrhea; the morphology of their mucosa was normal.[156] The incidence was estimated to be 1.8% among children with chronic diarrhea. Although these patients have revealed normal pancreatic amylase activities, other disaccharidases, most notably isomaltase, have shown marked reduced activities in addition to glucoamylase. This could be due to the known overlap of isomaltase and glucoamylase activities toward maltose as a substrate.

Primary MGA deficiency should be suspected in the differential diagnosis of chronic diarrhea of infants and toddlers. Besides diarrhea, patients present with abdominal dis-

tention and bloating. Symptoms start with the introduction of starch and formula containing short polymers of starch at 4 to 6 months of age or later until the fifth year of life.

Some of these MGA-deficient patients show a positive response to challenge with 2 to 4 g/kg starch and to re-elimination of starch. The starch digestive capacity can be evaluated by the $^{13}CO_2$ breath test using ^{13}C-starch oligomers as a loading substrate.[69,157] Reducing substances are inconsistently found to be positive. The diagnosis is established by low activity of glucoamylase of a duodenal biopsy and evidence of a normal pancreatic amylase. A high percentage of glucoamylase-deficient subjects have been found in a group of dyspeptic children with normal duodenal histology, some of them presenting additionally with low activity of sucrase and lactase.[158]

An elimination diet excluding starches and short polymers of glucose within lactose-free infant formulas should be given for 3 to 4 weeks, documenting any relief of symptoms. Patients who do not show symptoms should stick to this diet to an extent, which keeps them free of symptoms.

TREHALASE

Structure and Function of Trehalase

Trehalase is another member of α-glucosidases of the small intestine.[159] It is also present in the human serum.[160] Because plasma trehalase activity is increased in diabetes[161] and reduced in rheumatoid arthritis,[162] it is not used to diagnose trehalase deficiency. Its substrate, trehalose, is a disaccharide composed of two glucose molecules. It is contained in mushrooms, lower plants (algae), insects, *Ascaris lumbricoides*, and *Artemia salina*. Because trehalose improves the quality of dried food, it became a food additive.

A complete cDNA clone encoding human trehalase has been isolated from a human kidney library.[163] The protein is composed of 583 amino acids with a calculated molecular weight of 66,595 kD. The enzyme is a type I membrane glycoprotein that is synthesized with a typical cleavable signal peptide at amino terminus and contains five potential glycosylation sites. Trehalase is associated with the membrane via a glycosylphosphatidylinositol type of membrane anchor. The sequence similarity of the human enzyme with those of the rabbit, silkworm, *Tenebrio molitor*, *Escherichia coli*, and yeast suggested a common old ancestral gene. The small intestine trehalase is also expressed in the liver and the kidney.

Trehalase Deficiency

The first case of trehalase deficiency, which is inherited as an autosomal recessive disorder, was reported in 1971.[164] Two years later, it was described in a family.[165] An autosomal recessive inheritance has been suggested as a genetic background owing to trehalase deficiency. Other brush border enzymes are not affected. Trehalase deficiency is found in 8% of Greenlanders.[166,167] It is rare in white Americans.[43] Only a few cases have been described in other populations. The implications and significance of this observation on molecular pathophysiology of the intestine are unclear, however.

The major source of trehalose for humans is young mushrooms.[168] Symptoms resembling those of lactose intolerance consist mainly of vomiting, abdominal pain, meteorism, and diarrhea. Two trehalase-deficient patients developed no symptoms after trehalose load and proclaimed themselves mushroom tolerant.[168]

Because the increases in breath hydrogen and blood glucose did not differ between trehalose-intolerant and -tolerant subjects, oral tolerance and breath tests seem to be unsuitable for diagnostic investigation.[168] Trehalase deficiency requires the performance of a duodenal biopsy with determination of trehalase activity. The normal range (mean ± 2 SD) of trehalase activity is 4.79 to 37.12 U/g protein.[166] Trehalase deficiency is diagnosed when the activity of duodenal trehalase is less than 8 U/g protein.[167] The activities of other brush border enzymes, as well as the duodenal histology, are normal, ruling out the presence of a general mucosa damage as an underlying cause of trehalase deficiency. The few studies performed indicate that there is a poor correlation among patient complaints, results of oral tolerance and breath testing, and trehalase activities.

The only available therapy is trehalose restriction, which includes reducing the consumption of mushrooms and trehalose-containing food additives. At present, several applications of trehalose in human nutrition are considered by the food industry.[169]

2. *Congenital Intestinal Transport Defects*

Martín G. Martín, MD, MPP
Ernest M. Wright, PhD, DSc

Disturbances in intestinal nutrient and ion transport can lead to clinical symptoms that range from severe life-threatening diarrhea in a neonate to neurologic deficits in early childhood. With few exceptions, most epithelial transport disorders are both exceedingly rare and inherited in an autosomal recessive manner. Given their genetic basis, the diagnosis of a transport defect should be entertained particularly when there is a family history of consanguinity but should also be considered when similar problems have not occurred in other family members.

The most common clinical manifestation of this large group of epithelial transport disorders is chronic diarrhea.[1] Recognition of severe diarrhea during early infancy may occasionally be missed when stool is mistaken for urine; therefore, careful attention should be made to separate and measure urine and feces. Categorizing the type of diarrhea into either malabsorptive or secretory is a useful first step in the evaluation of any child with chronic diarrhea. The type of diarrhea may be assessed by performing either a trial of fasting or by analysis of stool electrolytes while the child is on a full diet.[1] To calculate the stool osmotic gap, either cations such as Na^+ and K^+ or anions such as Cl^- and HCO_3^- may be measured in liquid fecal samples.[2,3] If the sum of twice their value (either cations or anions) is significantly lower than 290 mOsm, the predicted osmolarity, an osmotic gap is present, and the patient is malabsorbing dietary nutrients. In contrast, a low osmotic gap (< 50 mOsm) is seen in secretory diarrheas, which are generally large volume (1–2 L) and fail to abate in the fasted state.

Nutrient-specific malabsorption is an important characteristic of all inherited transport disorders and is generally not a feature of some of the more common chronic diarrheal disorders. However, defects of pancreatic and brush border enzyme function share many of the clinical characteristics seen in transport defects and will also lead to malabsorption of specific nutrients. In contrast, generalized malabsorption (ie, not nutrient specific) occurs in the clinical setting, where the intestinal absorptive capacity is insufficient to appropriately handle a normal dietary load.[4] Nonspecific abnormalities of intestinal absorption most often occur when either small bowel length is inadequate or intestinal villus or epithelial microvilli are abnormal. For instance, enteropathies such as hypersensitivity to cow and soybean proteins, and even more unusual disorders, such as autoimmune enteropathy, microvillus inclusion disease (Mendelian Inheritance in Man [MIM] #251850), and immunodysregulation-polyendocrinopathy-enteropathy (MIM #304790). generally present in early infancy with features of nonspecific malabsorption.[5,6] In fact, the majority of patients with an abnormal intestinal histology have a mixed form of diarrhea that has both osmotic and secretory components. Therefore, the identification of normal small bowel histology is an essential part of the evaluation of children with congenital transport defects.

Secretory diarrhea is due to an imbalance between absorption and secretion of electrolytes. During early infancy, chronic diarrhea that is purely secretory in nature is due almost exclusively to a small number of transport disorders and, as such, is not secondary to defects of enzymatic function, as is frequently seen in malabsorptive diarrhea. Several hormone-secreting tumors may present with severe secretory diarrhea and need to be distinguished from two disorders of intestinal transport, namely congenital chloride diarrhea (MIM #214700) and congenital sodium diarrhea (CSD) (MIM #270420; Table 43.2-1).[7] Table 43.2-1 is a summary of the molecular basis of all disorders of nutrient assimilation. For each disorder, the table contains its MIM number, inheritance pattern, and chromosomal localization; the name, number, and function of the defective protein; and the primary gastrointestinal symptom.

DISORDERS OF CARBOHYDRATE ABSORPTION

Complex sugars are digested by salivary and pancreatic amylases and further by brush border enzymes into monosaccharides that are absorbed in the small intestine (Figure 43.2-1). Enterocytes, which are renewed every 6 days, express the enzymes and transporters needed for carbohydrate digestion and absorption. The enterocytes' apical brush border membrane contains the sucrase-isomaltase and lactase-phlorhizin enzymes, the Na^+-dependent glucose-galactose cotransporter sodium-coupled glucose transporter (SGLT)1, and the fructose uniporter (GLUT5). The basolateral membrane contains the glucose-galactose-fructose uniporter (GLUT2) and the Na^+, K^+–adenosine triphosphatase (ATPase) pump. Fructose is passively transported across the intestine by the brush border fructose uniporter (GLUT5) and by the basolateral GLUT2 uniporter. The pump maintains the low intracellular Na^+ concentration by extruding Na^+ into the blood in exchange for K^+. The net result is that glucose stimulates Na^+ absorption across the intestine.

Disturbances of carbohydrate assimilation may be secondary to defective enzymatic processing of complex sugars and disaccharides or failure to transport monosaccharides across the apical membrane (see Table 43.2-1 and Figure

TABLE 43.2-1 MOLECULAR BASIS OF DISORDERS OF NUTRIENT ASSIMILATION

DISORDER	MIM NO.	IP	CHR	GENE/PROTEIN (HUGO NO.)	FUNCTION	CLINICAL SYMPTOMS
Carbohydrate digestion						
Congenital lactase deficiency	223000	AR	2q21	Lactase-phlorhizin hydrolase	Hydrolyzes lactose	Lactose-induced diarrhea
Hypolactasia	223100	AR	2q21	Lactase-phlorhizin hydrolase	Hydrolyzes lactose	Lactose-induced diarrhea
Congenital sucrase-isomaltase deficiency	222900	AR	3q25	Sucrase-isomaltase	Hydrolyzes sucrose	Sucrose-induced diarrhea
Glucoamylase deficiency	~	AR	7q34	Maltase-glucoamylase	Hydrolyzes starch	Starch-induced diarrhea
Carbohydrate absorption						
Glucose galactose malabsorption	182380	AR	22q13	Na^+–glucose-galactose cotransport (SGLT1); SLC5A1	Apical glucose-galactose transporter	Glucose-induced diarrhea
Fructose malabsorption	~	AR	1p36	Facilitative fructose transport (GLUT5); SLC2A5	Apical fructose transporter	Fructose-induced diarrhea
Fanconi-Bickel syndrome	227810	AR	3q26	Facilitative glucose transport (GLUT2); SLC2A2	Basolateral glucose transporter	Diarrhea and nephropathy
Protein digestion						
Enterokinase deficiency	226200	AR	21q21	Serine protease 7	Proenterokinase—hydrolyzes trypsinogen	Protein-induced diarrhea; edema
Trypsinogen deficiency	276000	AR	7q35	Trypsinogen	Hydrolyzes endo- and exopeptidases	Protein-induced diarrhea; edema
Amino acid absorption						
Cystinuria type I	220100	AR	2p16	rBAT; SLC3A1	Heavy-chain cysteine, dibasic and neutral AA apical trans.	Nephrolithiasis
Cystinuria type II/III	600918	AR	19q13.1	$b^{(0,+)}$AT; SLC7A9	Light-chain cysteine, dibasic and neutral apical AA transport	Nephrolithiasis
Lysinuric protein intolerance	222700	AR	14q11	y^+ L-type AA transporter 1; SLC7A7	$y^{(+)}$L-type AA basolateral transport	Vomiting, diarrhea, neurologic delay
Hartnup disorder	234500	AR	5p21	?	Neutral AA transport	Dermatitis, neurologic delay
Iminoglycinuria	242600	AR	~	?	Imino AA transport	Neurologic delay
Fat digestion						
Pancreatic lipase deficiency	246600	AR	10q26	Pancreatic lipase	Hydrolyzes dietary triglycerides to fatty acids	Steatorrhea
Fat assimilation						
Abetalipoproteinemia	200100	AR	4q22	Microsomal triglyceride transfer protein	Transfers lipids to apolipoprotein B	Steatorrhea
Hypobetalipoproteinemia	107730	AD/AR	2p24	Apolipoprotein B	Apolipoprotein that forms chylomicrons	Steatorrhea
Chylomicron retention disease	246700	AR	5q31	Sar1-ADP-ribosylation factor family GTPases	Targets intracellular protein-coated vesicles	Steatorrhea
Primary bile acid malabsorption	601295	AR	13q33	Sodium–bile acid transporter; SLC10A2	Ileal Na^+–bile acid transporter	Steatorrhea/bile acid diarrhea
Tangier disease	205400	AR	9q	ATP–binding cassette transporter 1	Controls intracellular cholesterol transport	Liver, spleen, lymph node enlargement
Sitosterolemia	21250	AR	2q21	ATP binding cassette, subfamily G, member 8; ABCG8	Dietary sterol absorption	Atherosclerosis

DISORDER	MIM NO.	IP	CHR	GENE/PROTEIN (HUGO NO.)	FUNCTION	CLINICAL SYMPTOMS
Ion and metal absorption						
Congenital sodium diarrhea	270420	AR	~	?	?	Sodium-secreting diarrhea
Congenital chloride diarrhea	214700	AR	7q22	Solute carrier family 26; SLC26A3	Na^+-independent Cl^-/HCO_3^- exchanger	Chloride-secreting diarrhea
Cystic fibrosis	219700	AR	7q31.2	Cystic fibrosis transmembrane regulator	cAMP-dependent chloride channel	Pancreatic insufficiency; ileus
Acrodermatitis enteropathica	201100	AR	8q24.3	Zinc-/iron-regulated transporter 4; SLC39A4	Zn^+ transporter	Diarrhea and dermatitis
Menkes disease	309400	XR	Xq12	Cu^{++} ATPase, α-polypeptide; ATP7A	Cu^{++} transporter	Neurologic delay
Primary hypomagnesemia	248250	AR/X	3q27	Paracellin 1; claudin 16	Mg^+ transporter/sensor	Seizures, deafness, and polyuria
Classic hemochromatosis	235200	AR	6p21.3	Hemochromatosis gene	Modulates endocytosis of the TfR-Fe^{++}	Cirrhosis, cardiomyopathy, diabetes
Juvenile hemochromatosis	602390	AR	19q13	Hepcidin	Hepatic antimicrobial peptide	Cirrhosis, cardiomyopathy, diabetes
Hemochromatosis type III	604250	AR	7q22	TfR2	Receptor for transferrin	Cirrhosis, cardiomyopathy, diabetes
Hemochromatosis type IV	606069	AD	2q32	Ferroportin; SLC11A3	Basolateral Fe^{++} transporter	Cirrhosis, cardiomyopathy, diabetes
Vitamin absorption						
Folate malabsorption	229050	AR		~	~	Anemia; diarrhea; neurologic delay
Congenital pernicious anemia	261000	AR	11q13	Intrinsic factor	Required for binding of cobalamin to cubilin	Anemia; neurologic delay
Imerslund-Graesbeck syndrome (Finland)	261100	AR	10p12.1	Cubilin	IF-cobalamin receptor	Anemia; proteinuria
Imerslund-Graesbeck syndrome (Norway)	261100	AR	14q32	Amnionless	Targets the IF-cobalamin and cubilin to endosomes	Anemia; proteinuria
Congenital deficit of transcobalamin II	275350	AR	22q11.2	Transcobalamin II	Primary transport protein for cobalamin in serum	Anemia; diarrhea; neurologic delay
Thiamine-responsive megaloblastic anemia	249270	AR	1q23.3	Thiamine transporter protein; SLC19A2	Thiamine transporter	Anemia; diabetes; cranial nerve defects
Familial retinol-binding protein deficiency	180250	AR	10q24	Retinol-binding protein 4	Binding protein for retinol transfer	Ophthalmologic problems
Selective vitamin E deficiency	277460	AR	8q13.1	α-Tocopherol transfer protein	Binding protein that adds vitamin E to VLDL	Vitamin E malabsorption

AA = amino acid; AD = autosomal dominant; ADP = adenosine diphosphate; AR = autosomal recessive; ATP = adenosine triphosphate; ATPase = adenosine triphosphatase; cAMP = cyclic adenosine monophosphate; CHR = chromosomal localization; GTPase = guanosine triphosphatase; HUGO = Human Genome Organization; IF = intrinsic factor; IP = inheritance pattern; MIM = Mendelian Inheritance in Man; VLDL = very-low-density lipoprotein; X = link recessive.

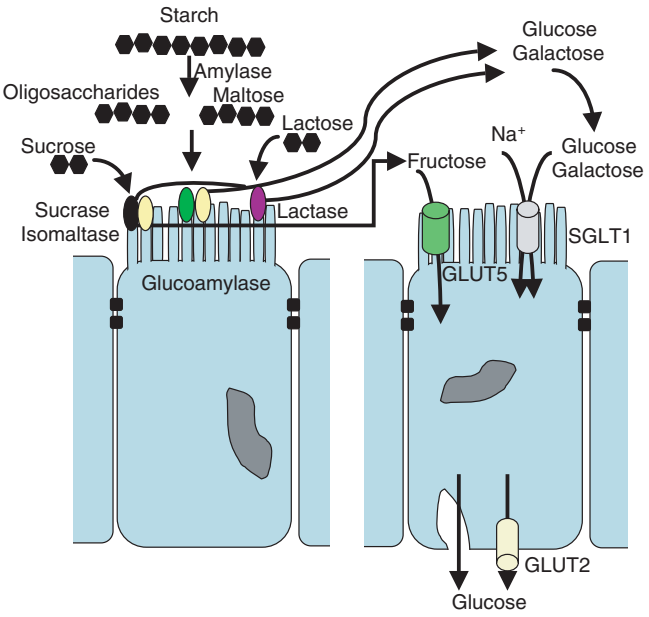

FIGURE 43.2-1 Carbohydrate assimilation. GLUT = glucose transporter; SGLT = sodium-coupled glucose transporter.

43.2-1). Abnormalities of carbohydrate assimilation may be categorized into three general forms: ontogenic forms that result from the normal immaturity of the digestive functions during the early stages of life, genetic forms that are congenital conditions, and an acquired form that is preceded by a period of normal function. The age at onset of clinical symptoms is an important characteristic to consider when evaluating the basis of carbohydrate-induced diarrhea (Figure 43.2-2).

Defective synthesis of lactase-phlorhizin hydrolase (LPH) may lead to chronic diarrhea, resulting from either primary lactase deficiency (MIM #223000) or hypolactasia (MIM #223100) (see Table 43.2-1).[8,9] Primary lactase deficiency is an extraordinary rare disorder that presents during the immediate neonatal period with diarrhea, whereas hypolactasia occurs after infancy in many individuals of African, Asian, and Hispanic origin. The presence of selective diarrhea in children on a sucrose-based diet may be secondary to abnormal synthesis of sucrase-isomaltase (MIM #222900).[10] Diarrhea induced by large complex carbohydrates is usually an indication of abnormal exocrine pancreatic function, such as is seen with cystic fibrosis, but may also be attributed to a deficiency of glucoamylase synthesis.[11,12] Distinguishing between these various disorders can be accomplished by analyzing small bowel disaccharidase activity and with carbohydrate-specific breath hydrogen testing.[13]

Carbohydrate intolerance is characterized by diarrhea that improves within hours when carbohydrates are reduced or eliminated from the diet. Therefore, abnormal carbohydrate assimilation results in the presence of major osmotic forces in colonic luminal fluid derived from oligosaccharides, lactose, sucrose, or glucose. Unabsorbed carbohydrates are fermented by the resident colonic microflora to gas (hydrogen, methane, and carbon dioxide) and volatile short-chain fatty acids (SCFAs) such as acetate, butyrate, and propionate. These SCFAs are absorbed by the colonic epithelium by poorly defined diffusion and transporter-mediated mechanisms.[14] The absorbed SCFAs are metabolized preferentially by colonic epithelia, where they are an important energy source and also facilitate the absorption of NaCl. Therefore, SCFA absorption leads to a reduction of luminal osmolarity and thereby facilitates the colonic absorption of water. Nevertheless, inadequate colonic salvage results in diarrhea when the amount of ileal effluent is too large for the normal colon and its flora to manage. The passage of unabsorbed and unfermented carbohydrates into the distal colon provides an additional osmotic load that results in the retention of water and subsequent diarrhea.

Glucose Galactose Malabsorption

Glucose galactose malabsorption (GGM) is a rare disorder that causes severe life-threatening diarrhea and dehydration during the neonatal period (MIM #182380) (see Table 43.2-1). GGM was first established when investigators demonstrated evidence of an inherited disorder of active glucose and galactose transport.[15–17] Conformation was provided by in vitro studies carried out on duodenal biopsies of patients with GGM.[18–21] In these studies, autoradiographic techniques demonstrated that epithelial cells from the patient were unable to accumulate galactose owing to a reduction in the number of transporters binding phlorhizin in the brush border membrane (Figure 43.2-3).

Genetics. The relative abundance of GGM in consanguineous unions and the absence of vertical transmission suggest an autosomal recessive pattern of inheritance. Although obligate heterozygotes may have an impaired capacity to absorb glucose, clinical evidence of malabsorption and its clinical symptoms have not been documented.

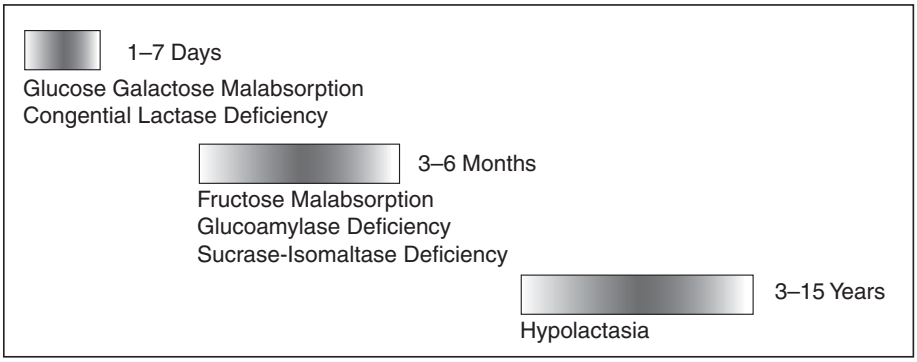

FIGURE 43.2-2 Carbohydrate assimilation: age at onset.

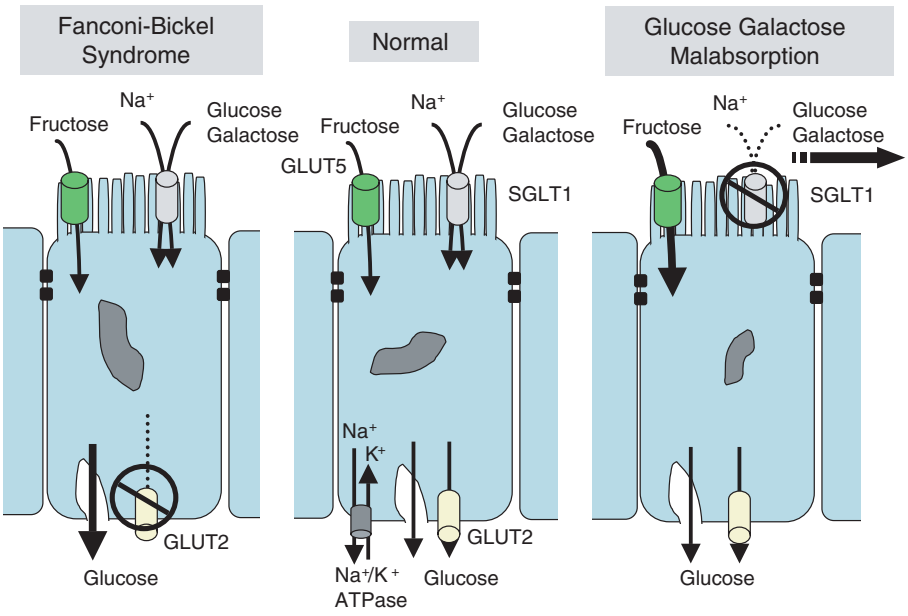

FIGURE 43.2-3 Carbohydrate absorption across the enterocyte in normal control, glucose galactose malabsorption, and Fanconi-Bickel syndrome. ATPase = adenosine triphosphatase; GLUT = glucose transporter; SGLT = sodium-coupled glucose transporter.

Although the disorder is rare, we are aware of some 300 patients, and it is most frequent in populations that have a high incidence of consanguinity. Recent genetic testing was performed on 82 patients in 74 unrelated families from the United States (of north European, African, Hispanic, and Mediterranean descent), France, the Netherlands, Japan, the United Kingdom, Belgium, and Sweden.[22–25] Analysis of these probands led to the identification of 46 mutations that account for GGM, and all but one patient were determined to have mutations. Identical mutations were identified on both alleles in 65% of our patients, and the remainder were compound heterozygotes.

No mutations were identified in only three GGM cases. Virtually every patient had a unique mutation; only one mutation, C355S, has been found in three unrelated patients (Figure 43.2-4). The majority of the mutations are missense,[22] but we have also identified six nonsense, seven frame shift, and seven splice site mutations. The nonsense, frame shift, and splice site mutations all produce truncated proteins, which are expected to be nonfunctional. The truncated proteins are nonfunctional based on assays using the oocyte expression system.

The missense mutations are distributed throughout the protein (see Figure 43.2-4). Two methods have been used to distinguish between mutations that produce GGM and those that are benign polymorphisms. The first was to express the wild-type and mutant proteins in oocytes and to measure sugar transport activity and the second was to see if the mutated reside was conserved in other mammalian members of the *SGLT* gene family. It should be noted that all mutated residues causing defects in sugar transport in oocytes are conserved within the 18 closely related genes, including eight SGLT1s from different species. However, the two missense mutations that do not impair sugar transport, F405S and H615Q, are not conserved and rarely occur in the general population. In con-

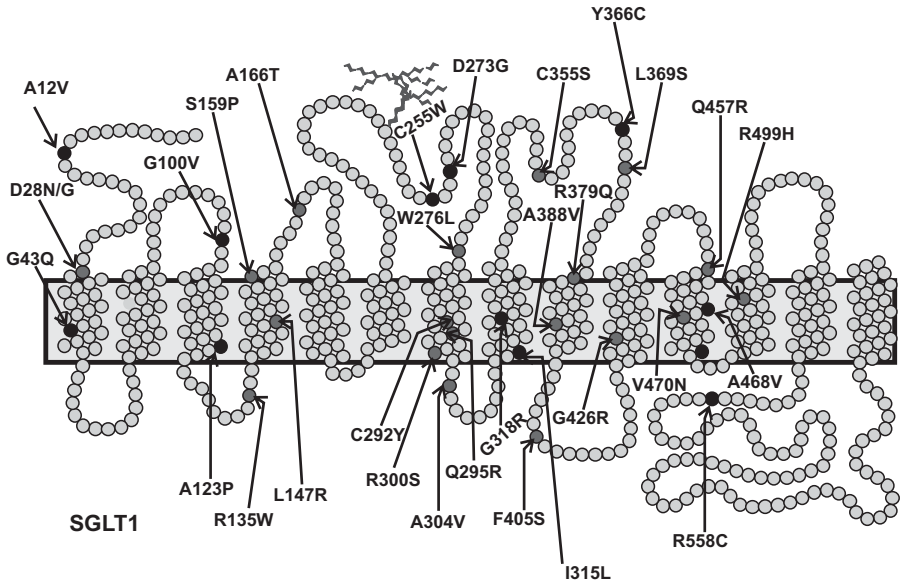

FIGURE 43.2-4 Location of missense mutations in sodium-coupled glucose transporter (SGLT)1 and patients with glucose galactose malabsorption.

trast, the N51S variant occurs in the general population at a frequency of 4% in over 552 alleles analyzed. On this basis, we also suggest that A12V is a benign polymorphism, whereas the other eight untested mutants are mutations that may be responsible for the impaired sugar transport in these GGM patients.

Molecular Pathophysiology. The primary carbohydrate present in breast milk is lactose (50–90 g/L) that is hydrolyzed by lactase on the external surface of the intestinal brush border. The liberated glucose and galactose are then transported across the brush border membrane by SGLT1 and accumulated within the enterocyte (see Figure 43.2-3). Lactose is the primary source of dietary galactose, whereas complex carbohydrates provide the major source of glucose in older children. Until recently, the facilitated carrier GLUT2 was believed to be responsible for transport of glucose and galactose across the basolateral membrane; however, this is now doubtful in light of studies on humans and mice with defective GLUT2.[26,27]

SGLT1 is responsible for the tight coupling of two Na^+ ions and one sugar molecule across the membrane during one catalytic turnover. The rate of Na^+-sugar cotransport depends on the magnitude of the glucose and galactose concentrations. The basolateral Na^+-K^+ pump maintains the low intracellular sodium concentration by pumping sodium out of the cell, and this results in the net transport of sodium (chloride or bicarbonate), sugar, and water across the epithelium.[28] Because the osmolarity of stool in both secretory and malabsorptive diarrhea is always isomolar with serum (290 mOsm), the addition of undigested solutes (glucose and galactose) and SCFAs that are present in the colon of a GGM patient on a carbohydrate meal will result in an excessive amount of fluid to maintain the required fecal osmolarity.

Although the upper and mid–small intestine has a large capacity to absorb salt and water, ~ 6 L/d, little occurs in the absence of dietary carbohydrate and protein. Glucose stimulates salt and water absorption, and this is generally explained by the coupled transport of Na^+ and glucose across the brush border and the subsequent pumping of Na^+ out of the enterocyte across the basolateral membrane by the Na^+-K^+ pump. It is then thought that water follows solute absorption by a process referred to as local osmosis. However, it has recently been postulated that there is a more direct link between sodium, sugar, and water transport across the brush border membrane, that is, water cotransport, but this hypothesis is not widely accepted.[29] Nevertheless, the link between salt, sugar, and water absorption provides the rationale for oral rehydration therapy. In principle, other sodium-coupled transporters, for example, those for amino acids, also may be used in oral rehydration therapy.

Clinical Manifestations. The majority of patients with GGM present clinically with severe life-threatening diarrhea during the neonatal period (see Figure 43.2-2). However, on rare occasions, adult patients have been identified with milder symptoms.[30] Diarrhea is most frequently detected during the first 2 days of life, while the patient is still hospitalized, and this usually results in a severe metabolic acidosis and hyperosmolar dehydration. The diarrhea in GGM results from the presence of unabsorbed carbohydrate in the gut. If not properly diagnosed in a timely manner and if dietary management is not implemented, GGM is frequently fatal.

Isolated carbohydrate malabsorption is distinctly unusual during the first several days of life, and its presence should initiate the workup for both GGM and primary lactase deficiency. The diarrhea seen in GGM patients will persist while they remain on standard formulas, including protein-hydrolysate formula, because they generally contain glucose.

Diagnostic Criteria or Laboratory Investigations. Three key features are necessary to establish the diagnosis of GGM: elimination of glucose and galactose (and lactose) from the diet results in the complete resolution of diarrheal symptoms, a positive glucose breath hydrogen test, and a normal intestinal biopsy. Specifically, the small bowel architecture should have a normal villus-to-crypt ratio and an absence of abundant inflammatory cells in the lamina propria and intraepithelial compartments.

When considering the diagnosis of GGM, several general and specific diagnostic tests may be performed. The hospitalized patients should have standard stool analysis, including pH, occult blood, and leukocyte analysis and evaluation for the presence of reducing and nonreducing sugars (Clinitest). Carbohydrate malabsorption and subsequent colonic bacterial fermentation result in the synthesis of high concentrations of SCFAs (acetate, butyrate, propionate), which leads to the acidification of stool ($pH < 5.3$).[2] Stool electrolytes (Na^+, K^+, and Cl^-) should be obtained, and a large osmotic gap of greater than 40 mOsm when compared with serum osmolarity would suggest carbohydrate malabsorption. In contrast, a low osmotic gap (< 50 mOsm) would be more consistent with secretory diarrhea. After sufficient stool samples have been obtained, and the quantity and characteristics of the diarrheal pattern have been established, a fasting trial should be performed. Diarrhea will abate during the fasting state if it is osmotic in nature. The stools of a patient with GGM should be acidic, with detectable levels of reducing substance and an electrolyte analysis consistent with osmotic diarrhea while the patient is on a glucose-based diet.

Small bowel biopsies should be performed early in the evaluation of a patient with chronic diarrhea. Analysis of the mucosa provides several important clues that would assist in establishing the diagnosis. Mucosal defects such as flattened villi and a low villus-to-crypt ratio are inconsistent with the diagnosis of GGM or any other disorder resulting from a primary transport defect. Therefore, GGM patients should have normal-appearing microvilli on electron microscopy, with normal villus architecture on light microscopy.

Mucosal biopsies can also be used to assess lactase and sucrase activity, which may be helpful in distinguishing GGM from primary lactase or sucrase deficiency. Glucose and galactose uptake studies of mucosal samples are very useful but are difficult to perform and are generally not available. Biopsy samples may also be useful in establishing GGM by immunohistochemical analysis using antisera

to SGLT1. As we reported earlier, most SGLT1 mutations result in either targeting defects to the plasma membrane or incomplete synthesis in the form of a nonsense mutation.[22] Immunohistochemical analysis of mucosa has shown an absence of SGLT1 on the apical membrane of individuals with mutations that result in improper targeting to the plasma membrane. Unfortunately, commercial antibodies to SGLT1 are generally unreliable.

The glucose breath hydrogen test is another useful test that should be performed in a patient in whom the diagnosis of GGM is being considered. Carbohydrate breath hydrogen testing is an easily performed test that may assist in the diagnosis of several types of carbohydrate malabsorption disorders, including lactose, sucrose, and fructose malabsorption. The test relies on the colonic fermentation of unabsorbed carbohydrate by bacteria that produce methane, hydrogen, and carbon dioxide gas. This gas chromatographic analysis quantifies the level of hydrogen gas in exhaled air following the administration of either glucose (or galactose) at 2 g/kg body weight or a maximum of 50 g for patients who weigh more than 25 kg. Although an elevation of more than 20 ppm above the fasting baseline is consistent with the diagnosis of glucose malabsorption, most patients with GGM have levels that are frequently higher than 100 ppm (unpublished observations of authors, 2004). Therefore, it is reasonable and probably safer to consider using a much lower glucose load (< 0.5 g/kg) when performing a breath hydrogen test in a patient who is believed to have GGM.

The recent use of antibiotics diminishes the usefulness of carbohydrate breath hydrogen tests over the short term, and lactulose, an obligate nonabsorbable carbohydrate, may be used to assess its sensitivity. More specifically, the inability to mount a significant elevation in hydrogen or methane gas after a lactulose challenge would suggest the absence of a significant amount of gas-producing colonic bacteria. The development of abdominal pain and diarrhea following a carbohydrate challenge should raise the suspicion of a false-negative breath hydrogen test. The specificity of an abnormal glucose breath hydrogen test may be confirmed by performing a fructose breath hydrogen test that should be normal in GGM patients because fructose is absorbed via the unaffected uniporter, GLUT5. However, although slight fructose malabsorption is particularly common in younger children, breath hydrogen levels in a GGM patient will be substantially higher with glucose compared with fructose administration.[31] Interestingly, 10% of healthy adults are glucose malabsorbers, as judged by breath hydrogen tests.[32]

Genetic testing for GGM is currently not justified unless the patient is related to a GGM patient with known mutations in *SGLT1*. Testing involves the screening of SGLT1's 15 exons for mutations by single-stranded conformational polymorphism and the subsequent sequencing of genomic deoxyribonucleic acid (DNA). Identified missense mutations are studied using a heterologous glucose uptake system in *Xenopus* oocytes. This conformational test has been essential to distinguish disease-causing mutations from inconsequential polymorphisms. The abundance of private mutations has made molecular testing costly, cumbersome, and rather slow. Therefore, although genetic testing can be used as a final verification for the diagnosis of GGM, it is clearly not necessary to establish the diagnosis. Genetic testing has been used successfully to perform prenatal diagnosis on a family at risk for GGM.[33]

Treatment. With GGM, as with other disorders of carbohydrate malabsorption, symptoms resolve on an elimination diet free of glucose and galactose. Several formulas are available for managing GGM patients during early infancy. Ross Carbohydrate Free Formula (Ross Products, Columbus, OH) is frequently used in North America and may be supplemented with fructose (4 g fructose per 30 mL of concentrated formula and diluted further with water to a final volume of 60 mL). In Europe, Galactomin 19 (Nutricia, Zoetermeer, The Netherlands) formula is generally used and is supplied with fructose. Care should be exercised with formulas containing fructose because fructose absorption is limited in young children. Although these formulas are necessary only for the first several years of life, they are frequently used as nutritional supplements well into late childhood.

The dietary management of GGM patients becomes particularly challenging as children enter into late infancy and begin to exert more independence. Guidance from a well-trained dietitian is frequently invaluable. Highly motivated parents will generally benefit from dietary manuals that list the sugar content of selected foods. Reviewing with parents such a dietary list will help identify particular foods that have a relatively low glucose level. Galactose in its monosaccharide form is rarely present in sufficient amounts in foods and is primarily found in lactose-containing products such as dairy products. Nevertheless, the required diet of a GGM patient is very restricted and inevitably high in fat and protein. The required lifelong glucose- and galactose-free diet may, in the long term, have significant renal and cardiovascular consequences; however, none have been reported in GGM patients up to 40 years old.

Fructose Malabsorption

Fructose malabsorption has been implicated in both toddler's diarrhea and in a rare and poorly defined autosomal recessive disorder named isolated fructose malabsorption (IFM). Distinguishing between the more common toddler's diarrhea and IFM is particularly difficult, and it is unclear if they represent distinct disorders (see Figure 43.2-2). The clinical and genetic features of IFM are not as well defined as its other counterpart carbohydrate transport disorder, GGM. Although the ability of GLUT5 to transport fructose has been demonstrated, there remains insufficient information confirming that GLUT5 represents the main fructose transporter of the intestine; nevertheless, GLUT5 remains the best candidate gene for IFM (see Figure 43.2-1).[34]

Genetics. Eight patients with clinical evidence suggestive of IFM were previously evaluated for mutations in the *GLUT5* gene.[35] The analysis included the evaluation of the originally described kindreds with IFM. Analysis of both the coding region and intron and exon boundaries of the *GLUT5* gene failed to identify a deleterious mutation that could account for defective transport. Although the study

failed to evaluate the upstream regulatory region of the gene for mutations, defects in the promoter region of genes account for only less than 5% of the disease causing mutations in other disorders.[36] Because linkage analysis examining the inheritance pattern of this specific locus has not been described, the molecular basis of IFM remains undefined.

Molecular Pathophysiology. Current data suggest that fructose absorption in the small intestine occurs via GLUT5.[37] Fructose absorption is independent of glucose absorption and remains intact in patients with GGM. Studies performed primarily in rodents have demonstrated that GLUT5 expression is regulated in a tissue- and development-specific manner and is induced by dietary fructose.[37] Specifically, *GLUT5* messenger ribonucleic acid and protein levels are found at very low levels prior to weaning and increase dramatically in the proximal small intestine in weaned animals. The molecular mechanism that controls the expression of GLUT5 has not been established to date. An analysis of the age dependency of GLUT5 levels in human intestine has not been performed; however, fructose malabsorption as determined by the breath hydrogen test is certainly more common during early infancy.[31] Moreover, whether or not the fructose malabsorption that is present in toddler's diarrhea is secondary to inadequate GLUT5 expression has yet to be formally established.

Clinical Manifestations. Fructose is the primary monosaccharide found in fruits and fruit juices. Fruit juices that contain a high proportion of fructose to glucose or an excessive amount of the nonabsorbable carbohydrate sorbitol have been associated with infant diarrhea and abdominal pain.[38–40] Malabsorption of fruit juices is dose dependent, with diarrhea developing when the daily consumption of juice exceeds 15 mL/kg body weight, and may be well tolerated at a dose of 10 mL/kg^{-1}.[39] Whether children with toddler's diarrhea have a reduced capacity to absorb fructose compared with other similarly aged children has yet to be defined. Intolerance to dietary fructose has also been identified in infants with colic and adults with irritable bowel syndrome.[41,42]

It should be noted that IFM is a disorder that is distinct from hereditary fructose intolerance (MIM #229600), which results from a deficiency of aldolase B and the subsequent accumulation of fructose-1-phosphate in the cytoplasm.

Diagnostic Criteria or Laboratory Investigations. Fructose malabsorption can be assessed by either placing the patient on a fructose elimination diet or by performing a fructose breath hydrogen test. Fructose given at 2 g/kg body weight or a maximum of 50 g can be used to perform these studies.[13] To determine whether the malabsorption is fructose specific, intestinal biopsies should reveal normal intestinal histology, and malabsorption should be limited to fructose and not other monosaccharides. Neither in vitro intestinal uptake studies nor genetic testing is currently available.

Treatment. Children experiencing significant fructose-induced diarrhea should either reduce or eliminate their dietary fructose load to resolve symptoms. It has been established in rodent models that GLUT5 levels are dependent on the chronic load of dietary fructose; therefore, it is conceivable that fructose malabsorption may resolve by initiating a feeding regimen of incrementally increasing amounts of fructose. Because fructose malabsorption is generally limited to early infancy, attempts to reintroduce fructose should be considered as patients enter into the school-age years.

Fanconi-Bickel Syndrome

Fanconi-Bickel syndrome (FBS; MIM #227810) is a very rare autosomal recessive disorder that is characterized by carbohydrate malabsorption, tubular nephropathy, hepatomegaly and abnormal glycogen accumulation, failure to thrive, and fasting hypoglycemia (see Table 43.2-1).[43,44]

Genetics. In 1997, Santer and colleagues identified homozygote mutations in the facilitative glucose transporter GLUT2 in four patients with FBS.[45] Since this original description, over 60 patients with FBS have been investigated for mutations in the *GLUT2* gene, and over 30 mutations have been identified (see Figure 43.2-3).[27] Although most of the mutations are nonsense and result in a truncated transporter, several missense mutations were also identified. In vitro functional studies have not been performed to confirm that these mutations adversely alter the transport capabilities of the GLUT2 protein.

Molecular Pathophysiology. The mechanism by which mutation in the GLUT2 transporter alters the fasting- and feeding-induced changes in serum glucose is not well understood; however, impaired hepatocyte transport and glucose-sensing mechanism by pancreatic β cells are possible explanations.[44]

In the small intestine, GLUT2 is localized on the basolateral membrane and was believed for many years to be the primary method of monosaccharide exit from the enterocyte (see Figure 43.2-3). However, a severe osmotic carbohydrate diarrhea is generally not seen in most FBS patients, and mice containing a targeted deletion of GLUT2 also retain monosaccharide transport across the basolateral membrane. It has been suggested that a GLUT2-independent pathway for glucose transport exists in enterocytes.[26,46]

Clinical Manifestations. The diagnosis of FBS should be considered in patients with hepatomegaly and evidence of a renal tubulopathy. Although carbohydrate malabsorption has been reported in some but not all cases of FBS, it is certainly not a dominant feature in most reported cases. Failure to thrive, long-term short stature, rickets, and osteoporosis are clinical characteristics that are found in most patients with FBS.[44]

Diagnostic Criteria or Laboratory Investigations. Urine analysis will demonstrate evidence of glycosuria, a generalized aminoaciduria, and excessive urinary losses of phosphate and calcium. Histologic analysis of the small bowel, liver, and kidney generally reveal excessive glyco-

gen stores. Abdominal ultrasonography is useful to confirm the relative enlargement of the liver and kidney.

Treatment. Management is primarily focused on supplementing urinary electrolyte losses. Uncooked cornstarch has been used to prevent hypoglycemia and to minimize postprandial hyperglycemia.[47]

DISORDERS OF AMINO ACID AND PEPTIDE ABSORPTION

Assimilation of dietary proteins requires initial hydrolysis by multiple gastric, pancreatic, and brush border proteases with subsequent active and passive transport of dipeptides and amino acid across the apical membrane of the enterocytes (Figure 43.2-5). Intracellular peptidases hydrolyze dipeptides to single amino acids, which efflux across the basolateral membrane through a second series of transporters. The 21 common amino acids add to the diversity of dietary proteins whose digestion requires a host of endopeptidases and exopeptidases with specific yet overlapping specificities. Passive and ion-mediated transepithelial absorption is mediated by a diverse group of recently characterized transporters with broad amino acid specificities.[48–50] The redundant function of these enzyme and transport systems minimizes the physiologic consequences of a deficiency in most components of this process.

Protein digestion is initiated in the stomach by a family of pepsin proteases that are secreted by chief cells in the inactive form as pepsinogen (see Figure 43.2-5). Pepsinogen becomes activated by the acidic content of the stomach, where it produces nonabsorbable peptides. Under most circumstances, however, gastric hydrolysis is not essential for protein digestion. Dietary proteins that reach the intestine are further hydrolyzed into smaller peptides by a family of endopeptidases (trypsin, chymotrypsin, and elastase) and exopeptidases (carboxypeptidase A and B) that are secreted in their inactive form by the exocrine pancreas. Enterokinase, a serine protease located on the brush border membrane of enterocytes in the duodenum, converts the proenzyme trypsinogen to trypsin. Trypsin subsequently cleaves the precursor form of other endopeptidases and exopeptidases into their active equivalent. The luminal oligopeptides undergo further hydrolysis by another large family of oligopeptidases (aminopeptidase and carboxypeptidase) located on the brush border membrane. These proteolytic enzymes have well-defined substrate specificity and hydrolyze the dietary protein into either dipeptides or single amino acids that are subsequently transported by a group of uniporters.

Disorders of protein digestion are rare but should be considered when evaluating a patient for a potential defect of amino acid transport. The most well-characterized disorder of specific protein malabsorption is a deficiency of enterokinase synthesis (MIM #226200; see Table 43.2-1).[51] Enterokinase is the key upstream enzyme required for activation of endo- and exopeptidases and processes trypsinogen to trypsin. Children with enterokinase deficiency present with diarrhea, failure to thrive, and hypoproteinemic edema while on a diet of intact dietary proteins, whereas symptoms improve on an amino acid–based formula. Primary trypsinogen deficiency (MIM #276000) has also been reported and results in clinical symptoms that resemble enterokinase deficiency.[52] Nearly 90% of children with cystic fibrosis (MIM #219700) have a disruption of exocrine pancreatic function that impedes the digestion of dietary protein, fat, and carbohydrates.[11,12] A similar type of generalized malabsorption occurs in the late stages of other disorders of chronic pancreatitis, including the autosomal dominant disorder hereditary pancreatitis (MIM #167800).[53]

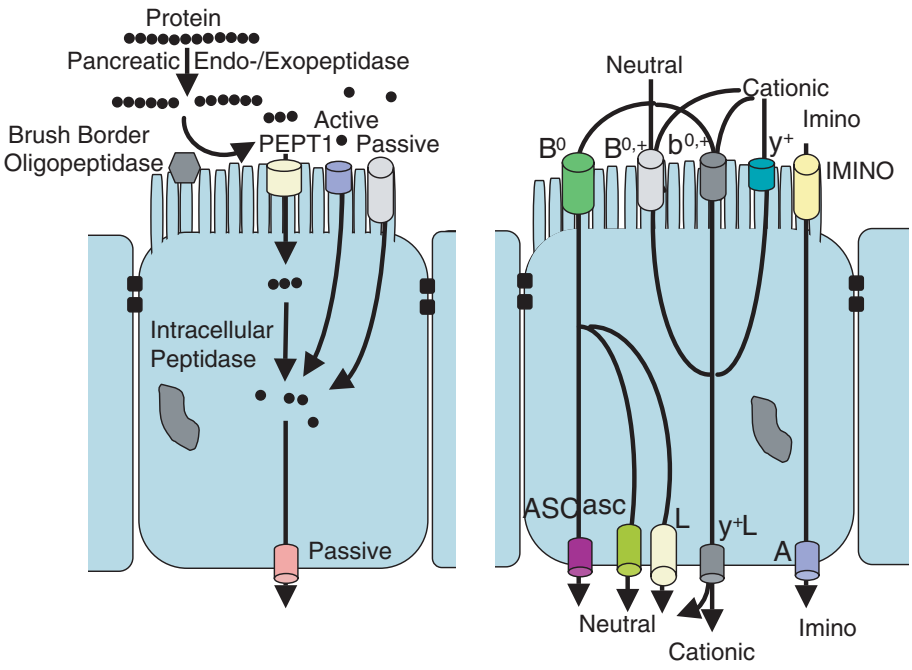

FIGURE 43.2-5 Protein and amino acid assimilation in the small intestine. Various amino acid transport systems are present on the apical (B^0, $B^{0,+}$, $b^{0,+}$, y^+, IMINO) and basolateral (ASC, asc, L, y^+L, A) Membrane. PEPTI = peptide cotransporter peptide transporter-1.

A large group of amino acid transporters have recently been cloned and characterized and are expressed either on the apical or basolateral membrane of the enterocyte (see Figure 43.2-5).[48,49] The brush border membrane contains the B^0 and $B^{0,+}$ Na^+-dependent systems that transport neutral amino acids. Anionic and cationic amino acids are selectively transported via system x_c^- and y^+, respectively. Proline and hydroxyproline are selectively transported by the imino system, which has yet to be isolated. In contrast, cationic and neutral (cystine) amino acids are transported by system $b^{0,+}$, which is defective in cystinuria (MIM #220100), an autosomal recessive aminoaciduria that is not associated with a significant gastrointestinal phenotype (Figure 43.2-6 and Table 43.2-1).[54] Although the $b^{0,+}$ system is expressed in the kidney and intestine, it has been postulated that dietary cysteine is absorbed in patients with cystinuria as a component of oligopeptides via the H^+-oligopeptide cotransporter peptide transporter-1.[55]

Intracellular neutral amino acids efflux across the basolateral membrane in a size-dependent manner; with system L carrying the larger and system ASC the smaller amino acids (see Figure 43.2-6). Small neutral amino acids also cross the basolateral membrane via a Na^+-dependent ASC system, whereas the A system is selective for both neutral and imino acids. In contrast, cationic amino acids are transported by the Na^+-dependent system y^+L, which is defective in lysinuric protein intolerance (LPI). Although the redundancy in the transport specificity of these various systems essentially minimizes gastrointestinal and nutritional consequences that are observed when an individual transport system is disrupted, LPI patients do experience significant gastrointestinal symptoms.

Lysinuric Protein Intolerance

LPI (MIM #222700) is an autosomal recessive disorder that results from mutations in the *SLC7A7* gene, which encodes for the cationic amino acid transporter y^+LAT-1 (see Figure 43.2-6 and Table 43.2-1).[56,57] The y^+LAT-1 transporter is located on the basolateral membrane of the enterocyte and renal tubules and transports cytoplasmic dibasic amino acids such as lysine, arginine, and ornithine in exchange for Na^+ and neutral amino acids.[58,59] Several gastrointestinal symptoms, including failure to thrive, diarrhea, and vomiting, are the main clinical symptoms associated with LPI.

Genetics. The *LPI* gene was discovered by positional cloning, and approximately 30 mutations have been identified in more then 100 patients with LPI.[56,57,60–62] Founder mutations have been identified in Finnish, Japanese, and Italian kindreds, in whom the incidence of LPI is particularly common.

Molecular Pathophysiology. The gene encoding for y^+LAT-1 is expressed in the small intestine, kidney, and lungs. Ornithine and arginine are important urea cycle intermediates that are not absorbed in either the kidneys or intestine of patients with LPI, and their relative deficiency, particularly during a high-protein diet meal, results in urea cycle dysfunction that leads to hyperammonemia and subsequent alterations in mental status.[63]

Clinical Manifestations. Undiagnosed patients with LPI frequently present with failure to thrive and a self-imposed restriction of dietary protein. Although diarrhea, emesis, and abdominal pain are frequent symptoms, the distinguishing feature of LPI is that the consumption of a high-protein diet results in hyperammonemia and dramatic changes in mental status. Chronic exposure to dietary protein is usually associated with various degrees of mental retardation. Marked hepatosplenomegaly and frequent bone fractures are also characteristic of LPI,[64] and patients' life spans are limited by complications associated with alveolar proteinosis and osteoporosis.[65] Recent reports have also suggested that arginine deficiency in patients with LPI may be associated with vascular endothelial dysfunction resulting from a decline in arginine-dependent nitric oxide production.[66] LPI is also associated with a relative deficiency of total and antigen-specific immunoglobulin, and although the function of T lymphocytes appears

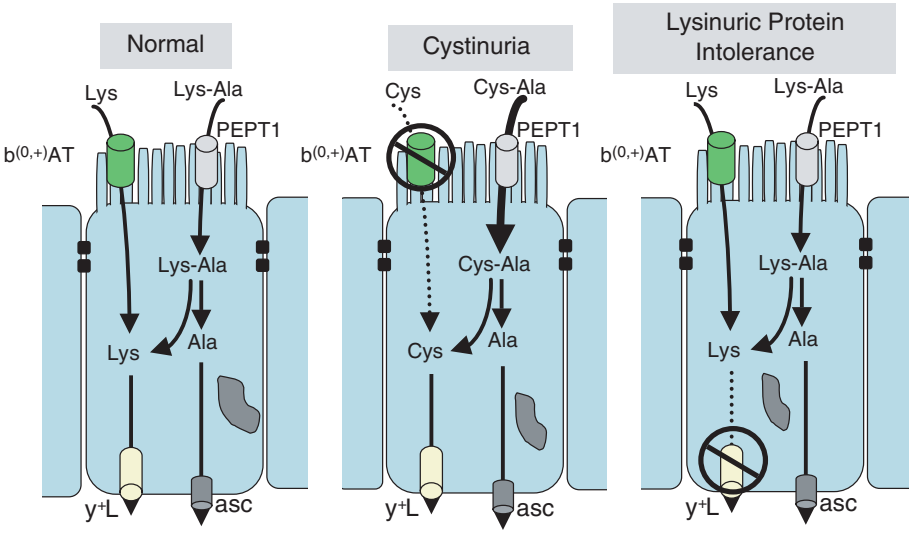

FIGURE 43.2-6 Amino acid transport in the small intestine of normal, lysinuric protein intolerance, and cystinuria patients. Lysine (Lys), alanine (Ala) and cysteine (cys) are transported across the apical ($b^{0,+}$AT) and basolateral (asc, y^+L) membrane. PEPTI = peptide cotransporter peptide transporter-1.

to be unaffected, fatal varicella infections have been described.[67,68] Hemophagocytic histiocytosis and systemic lupus erythematosus have also been described in several patients with established LPI.[69–72]

Diagnostic Criteria or Laboratory Investigations. Quantitative plasma amino acids and urinary organic acids provide useful hints into the possible diagnosis of LPI because plasma levels of diamino acids are low, whereas urinary levels of lysine and orotic acid are elevated.[58,59] Particular care should be given to the administration of an enteral bolus of a dietary protein load, which will result in the rapid impairment of motor function and mental status changes that are associated with hyperammonemia.

Treatment. Lysine is an essential amino acid, and serum levels are particularly low in patients with LPI. Short-term oral and intravenous supplements have been attempted in LPI patients, and whereas oral administration was poorly tolerated (diarrhea and vomiting), systemic administration was associated with only marginal symptoms.[63,73] Although long-term studies have not been reported, determining whether normal serum lysine levels diminishes the osteoporosis, failure to thrive, bone marrow dysfunction, and pulmonary complications that are associated with LPI would be of particular interest.

Citrulline supplements (200 mg/kg/d) and dietary protein restriction (1.5 g/kg/d) are currently used to manage patients with LPI.[63] Mealtime supplements of citrulline are readily absorbed and reduce postprandial hyperammonemia following a protein meal. Oral carnitine supplementation has been shown to be important in a subset of patients described with LPI and hypocarnitinemia.[74]

Other Defects of Amino Acid Transport

A second disturbance of amino acid transport has been characterized to date: system $b^{0,+}$, which is defective in cystinuria and is selective for cationic and neutral amino acid transport across the brush border membrane.[54] Hartnup disease (MIM #234500) and iminoglycinuria (MIM #242600) are two other autosomal recessive disorders that have been well characterized clinically; however, the molecular basis of either disorder has not been solved to date (see Table 43.2-1).[75,76] The diagnosis of these disorders can be established with analysis of urine amino acid profiles, and both disorders present with neurologic symptoms and an absence of significant gastrointestinal complications.

DISORDERS OF FAT ABSORPTION

Assimilation of dietary fats requires hydrolysis and subsequent repackaging of lipids by a complex group of intraluminal and intracellular events. The clinical consequences of disorders of fat assimilation include failure to thrive, steatorrhea, and neurologic deficits that result from the malabsorption of fat-soluble vitamins.

Lipolysis is initiated by gastric lipase in the stomach and concludes in the intestine through the action of pancreatic lipase. Because pancreatic exocrine function is particularly immature during early infancy, fat absorption in this age group primarily depends on the action of gastric lipase.[77] A congenital deficiency of pancreatic lipase (MIM #246600) is an exceedingly rare autosomal recessive disorder that leads to fat malabsorption.[78]

Fatty acid and diglyceride are the products of triglyceride hydrolysis, and their solubilization to the aqueous phase of luminal content requires adequate levels of conjugated bile salts. Various disorders of intrahepatic and extrahepatic cholestasis will impede the delivery of luminal bile salts and result in fat malabsorption. Bile salts are particularly important in the emulsification of long-chain fatty acids because of their lower aqueous solubility when compared with their medium-chain (12 to 6 carbons) counterpart.

A fatty acid transport protein (FATP4) was recently isolated, and its localization to the brush border membrane suggests that it may have a role in the absorption of luminal long-chain fatty acids.[79,80] A recent description of *FATP4*$^{-/-}$ knockout mice demonstrates a 40% reduction in fatty acid uptake and a neonatally lethal restrictive dermopathy.[81–83] In contrast, cholesterol export across the epithelial layer was recently established to occur via an adenosine triphosphate (ATP)-binding cassette transporter, ABCA1. The role of ABCA1 in cholesterol and phospholipid transport was confirmed when linkage analysis established it as the gene defective in Tangier disease (MIM #205400; see Table 43.2-1).[84,85] Tangier disease patients have a deficiency of high-density lipoproteins, which predisposes them to developing premature coronary heart disease despite hypocholesterolemia; they also accumulate cholesterol in tissue such as the liver, spleen, lymph node, and small intestine. Patients with sitosterolemia (MIM #210250) have the peculiar ability to absorb an excessive amount of the main plant sterol, sitosterol. Mutations in the ABC transporter, ABCG5 and ABCG8, have been associated with sitosterolemia.[86] These proteins form a heterodimer, which serves as the primary sterol efflux mechanism in the intestine. Despite defective processing of cholesterol and sterol, patients with Tangier disease and sitosterolemia have no significant gastrointestinal phenotype except hepatosplenomegaly. In contrast, disorders that result in defective packaging of re-esterified lipids into apolipoprotein-rich chylomicrons and very-low-density lipoprotein (VLDL) particles generally lead to fat malabsorption and failure to thrive (see Table 43.2-1).

Abetalipoproteinemia

Abetalipoproteinemia (ABL), or Bassen-Kornzweig syndrome (MIM #200100), is the classic and most well-characterized disorder of fat absorption and results from failure to reassemble dietary fat in the form of β-lipoproteins (see Table 43.2-1). Triglyceride and cholesterol esters are primarily transported in the plasma via β-lipoproteins; therefore, ABL patients have a severe deficiency of both of these neutral lipids. Patients generally present shortly after birth with failure to thrive and steatorrhea and if, untreated, will develop irreversible neurologic problems in late infancy. However, milder variants have been identified in asymptomatic adult patients who were identified by routine cholesterol screening.

Many of the original investigators studying the biology of ABL hypothesized it to be a defect secondary to the synthesis of apolipoprotein B synthesis; however, several studies failed to identify significant mutations in the *apoB* gene.[87] Subsequently, Wetterau and colleagues determined that the microsomal triglyceride transfer protein (MTP) was not detectable in the small bowel enterocytes of ABL patients and described homozygote mutations in the *MTP* gene.[88]

Genetics. MTP is a 97 kDa subunit that forms a heterodimer with a 55 kDa protein named disulfide isomerase (PDI).[89] Only a handful of mutations have been identified in ABL patients, and the majority result in the formation of a truncated and nonfunctional MTP.[90] Very few missense mutations have been isolated, and no mutations have been reported in the gene encoding the PDI protein. In fact, PDI is not required for MTP to properly bind and transfer lipids to apolipoprotein B.

Molecular Pathophysiology. Serum lipoproteins in patients with ABL are deficient in triglycerides and cholesterol-rich apolipoproteins B-100 and B-48, which form VLDL and chylomicrons. Apolipoprotein B-100 is synthesized by hepatocytes that produce VLDL, whereas the truncated protein (apolipoprotein B-48) is formed by enterocytes and is essential for chylomicron formation.

The role of MTP in chylomicron formation has been definitively established by investigating the consequences of ABL-causing mutations.[89] The role of MTP in lipoprotein formation has been performed using both in vitro cell lines and various types of MTP knockout mice.[91–93] These studies demonstrate that apolioprotein B alone is incapable of initiating lipoprotein formation and that MTP is specifically required to complete proper assembly. The protein component of apolipoproteins B-100 and B-48 is synthesized in the endoplasmic reticulum and must fold correctly to form a complex with lipids. Therefore, MTP has two distinct roles in lipoprotein assembly: first, to move lipids such as cholesterol and triglycerides into the lumen of the smooth endoplasmic reticulum and, second, to transfer small quantities of these lipids to the newly formed and unstable apolipoprotein B protein in a process that has been termed "lipidation."[92] In the absence of lipoprotein assembly, lipid droplets accumulate in the endoplasmic reticulum and are not transported to the *trans*-Golgi apparatus in the enterocyte and hepatocytes.[94] Small molecular inhibitors of MTP have been identified by high-throughput techniques, and it is anticipated that they potentially represent more potent cholesterol-lowering drug therapies.

Clinical Manifestations. As with any other autosomal recessive disorder, a history of parental consanguinity should alert the clinician to the possibility of APL. The typical clinical presentation in early infancy is one of failure to thrive, emesis, and low-volume diarrhea. Poor growth despite adequate caloric intake is an early clinical feature that should hasten the evaluation of a possible defect of fat malabsorption. In the long term, patients may develop an aversion to fatty meals as a way to minimize their diarrheal symptoms. The first evidence of neuromuscular abnormalities is usually the loss of deep tendon reflexes and results from long-term vitamin E deficiency; other neuromuscular manifestations, including retinitis pigmentosa, ataxia, and spinocerebellar degeneration, may be mistaken for various forms of Friedreich ataxia.

Diagnostic Criteria or Laboratory Investigations. Serum samples should be analyzed for evidence of β-lipoprotein (VLDL and chylomicron) deficiencies. Specifically, plasma triglyceride levels are generally < 10 mg/dL, whereas cholesterol levels range from 25 to 40 mg/dL. Acanthocytosis is usually seen in peripheral blood smears and results from abnormal lipoproteins in the plasma membrane of erythrocytes. Endoscopic evaluation of the small bowel can show yellow discoloration, and biopsies have characteristic fat-laden enterocytes located in the upper portion of the villus (Figure 43.2-7). Fat droplets within the cytoplasmic compartment of the enterocyte may be confirmed by electron microscopy.

Treatment. To minimize diarrheal symptoms, ABL patients are generally managed on a low-fat diet (~15 g/d), and serum levels of fat-soluble vitamins should be monitored periodically. Adequate serum levels of vitamins A and K can be achieved with supplementation of moderate oral doses; however, absorption of tocopherol is severely impaired and may require massive doses (2,000 mg in infants, and 10,000 mg in older children) of tocopherol to diminish the neuromuscular manifestations of vitamin E deficiency.

Hypobetalipoproteinemia

Hypobetalipoproteinemia (HBL; MIM #107730) is another very well-characterized disorder of fat absorption that results from the formation of abnormally truncated forms of apolipoprotein B (see Table 43.2-1).[95,96] The heterozygote state has been estimated to occur in approximately 1 in every 3,000 Americans.[96]

Genetics. The primary distinction between ABL and HBL is that the obligate ABL heterozygotes (biologic parents) have normal cholesterol and triglycerides levels, whereas HBL heterozygotes have low lipoprotein levels.[97] Therefore, HBL is inherited in an autosomal dominant manner; however, patients with only a single defective allele generally have no gastrointestinal and only minimal, if any, neuromuscular abnormalities. In contrast, individuals with two defective alleles are indistinguishable from ABL patients based on both physical and laboratory evaluation.

Many mutations have been described in the *APOB* gene in patients with HBL.[98] The mutations all result in proteins that are truncated either because of a nonsense or frame shift mutation that leads to a premature downstream stop codon. Several kindreds have been described that are clinically indistinguishable from HBL and ABL, yet mutations in either the apolipoprotein B or MTP alleles have not been identified.

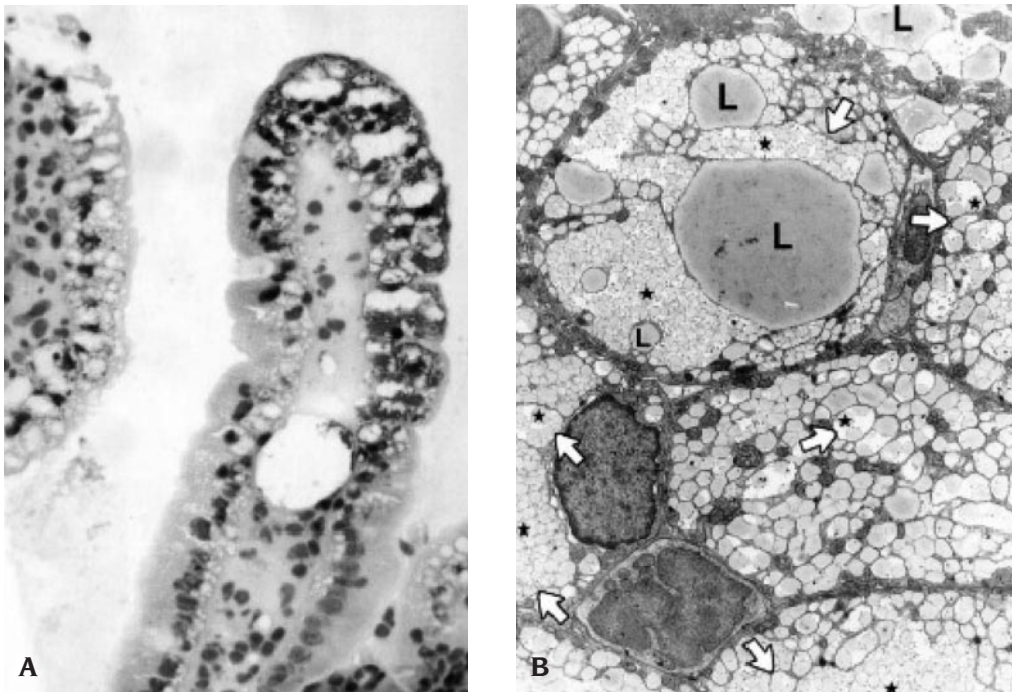

FIGURE 43.2-7 Classic lipid enterocytes seen in patients with abetalipoproteinemia, hypobetalipoproteinemia, and chylomicron retention disease. *A*, Intestinal biopsies from patients show vacuolization and marked staining with Oil Red O when examined by light microscopy (×10,003 original magnification). *B*, Electron microscopy of biopsies from patients shows the accumulation of large lipid droplets, free in the cytoplasm (L), and smaller chylomicrons and very-low-density lipoprotein–sized particles (stars) in membrane-bound vesicles (*arrows*) (×55,003 original magnification). Courtesy of Dr. Marie-Elisabeh Samson-Bouma, Faculté de Médecine X. Bichat.[94]

Molecular Pathophysiology. Various models have shown that truncation of the carboxy terminal of the apolipoprotein B protein influences the process of lipidation, as described earlier. Therefore, the inadequate addition of neutral lipids to the shortened apolipoprotein B protein leads to instability of the protein and its eventual degradation.

Clinical Manifestations. The clinical manifestations of patients with homozygote mutations of the *APOB* gene are identical to what was previously described in the ABL section of this chapter. In contrast, defects in a single allele (heterozygotes) may have subtle neurologic findings indicative of mild vitamin E deficiency.

Diagnostic Criteria or Laboratory Investigations. In heterozygote patients, cholesterol, triglyceride, and low-density lipoprotein levels are lower than in other unaffected members of the same kindred. In contrast, patients with homozygote mutations in the *APOB* allele have cholesterol, triglyceride, chylomicron, and VLDL levels that are similar to what was previously described in ABL patients. Moreover, characteristic findings such as acanthocytosis and fat-laden enterocytes are also seen (see Figure 43.2-7).

Treatment. Homozygote HBL patients should be managed as described in the ABL section, including the restriction of dietary fat and the supplementation of vitamin E. In contrast, the heterozygote patient should be given moderate doses of vitamin E.

Chylomicron Retention Disease

Chylomicron retention disease (CMRD; MIM #246700), or Andersen disease, is the least common of the classic disorders of lipid packaging in the intestine (see Table 43.2-1).[99] CMRD is an autosomal recessive disorder in which apolipoprotein B and MTP are produced; however, there is failure to secrete chylomicrons across the enterocyte's basolateral membrane.

Genetics and Molecular Pathophysiology. Recently, genome-wide screening was performed on patients with CMRD and a related disorder (Marinesco-Sjögren syndrome; MIM #607692), and a locus in chromosome 5q31.1 was identified as segregating with the disease locus.[100] A gene named *SARA2* resides in this locus and encodes for the Sar1b protein, which is a member of the Sar1–adenosine diphosphate–ribosylation factor family of small guanosine triphosphatases. This family of proteins has been shown to play an important role in the intracellular trafficking of proteins to organelles within a cell.[101] Various types of mutations (missense, nonsense, frame shift) were identified in the coding region of the *SARA2* gene that were unique to affected family members with CMRD and were not seen in either unaffected family members or the population at large. Moreover, each missense mutation alters a highly conserved residue in the guanine nucleotide-binding motif, which would presumably interfere with guanosine triphosphate binding. These data imply a role for Sar1b in the intracellular trafficking of chylomicrons to the *trans*-Golgi apparatus.

Clinical Manifestations and Diagnostic Criteria or Laboratory Investigations. Patients have been reported to present as neonates with severe diarrhea but may also first come to medical attention in early adolescence with neuromuscular manifestations of vitamin E deficiency. Interestingly, a large majority of patients with CMRD present with an intractable form of diarrhea with carbohydrate and amino acid malabsorption.[99] A low-fat diet will decrease the lipid distention of enterocytes and results in a hormalization of the tolerance for carbohydrates and

amino acids. However, the retinitis pigmentosa and neuromuscular manifestations are less severe when compared with either HBL or ABL. Enterocytes are also laden with fat, as is seen in HBL and ABL (see Figure 43.2-7).

Treatment. Treatment consists of restricting dietary fats and supplementation of vitamin E.

Primary Bile Acid Malabsorption

Efficient digestion and absorption of dietary lipids and lipid-soluble vitamins require their emulsification by bile salts (taurocholate) within the intestinal lumen.[102] The majority of dietary fats are absorbed in the jejunum, and residual bile salts are reabsorbed primarily by ileal enterocytes that express a Na^+-dependent bile salt transporter, apical sodium co-dependent bile acid transporter (ASBT) (*SLC10A2*), on its apical membrane. Primary bile acid malabsorption (PBAM; MIM #601295) is a very rare autosomal recessive disorder that results from an impairment of bile acid reabsorption secondary to a defect in the function of the ASBT transporter (see Table 43.2-1).[103,104] Taurocholate malabsorption more frequently results from the loss of an adequate amount of ileum, which may occur either because of surgical resection or because of extensive inflammation secondary to disorders such as Crohn disease.[105,106] The diarrhea that accompanies both primary and secondary forms of bile acid malabsorption may be attributed to both fat malabsorption (steatorrhea) and bile acid stimulation of colonocyte secretion of ions and fluid. Idiopathic adult-onset bile acid malabsorption has also been described in patients with presumably normal ileal function.[107]

Genetics. Oelkers, Dawson and colleagues screened the *SLC10A2* gene for mutations in patients with PBAM and identified four mutations, including three missense mutations (Ala171Ser, Leu243Pro, Thr262Met) and a splice site defect in exon 3.[103] In vitro analysis of these missense mutations failed to alter the proper targeting of ASBT to the cell membrane, however; the Leu243Pro and Thr262Met mutations impaired taurocholate transport.[108] The Ala171Ser mutation was found in 28% of asymptomatic individuals and appears to represent a benign polymorphism because bile acid absorption was not impaired by in vitro analysis. A missense mutation (Pro290Ser) was identified on a single ASBT allele (heterozygote), a patient with Crohn disease.[109] The Pro290Ser mutation abolishes taurocholate transport and in heterozygote carriers may influence cholesterol homeostasis and bile acid metabolism; however, the frequency and role of this and other polymorphisms in the general population await further investigations. No significant germline mutations were identified in a large cohort of adult patients with idiopathic bile acid malabsorption.[107]

Targeted deletion of the *SLC10A2* gene in a murine model causes only limited phenotypic changes, including fecal outputs that were indistinguishable from heterozygote ($SLC10A2^{-/+}$) or wild-type animals.[110] Fecal levels of bile acids were elevated 20-fold, whereas the size of the bile acid pool was reduced by 80%. Surprisingly, only mild steatorrhea was detected because fecal fat levels were fourfold higher in the null compared with the wild-type animals on a low-fat diet; however, more significant steatorrhea can be induced by augmenting the dietary fat content. Despite several limitations, this mouse model should improve our understanding of how the enterohepatic circulation influences absorption of dietary lipids.

Molecular Pathophysiology. The Na^+-dependent bile salt transporter ASBT is expressed on cholangiocytes and ileocytes and therefore plays an essential role in the enteric and hepatic phases of the enterohepatic circulation. Taurocholate is excreted in the biliary tree, where it is initially stored in the gallbladder and eventually enters the duodenum after cholecystokinin-induced gallbladder contraction in response to a meal. A small fraction of taurocholate is passively absorbed in the jejunum and colon. Along the horizontal axis of the intestine, ASBT expression is limited to the ileum, where it transports taurocholate via an electrogenic, Na^+-dependent mechanism. The reabsorption of taurocholate is about 95% efficient, and the 5% loss is replaced by hepatocyte conversion of cholesterol to bile salts.

Although the transport system that facilitates taurocholate transport across the basolateral membrane of the ileocyte has not been definitively established, the use of alternative splice sites (deletion of exon 2) appears to produce a truncated ASBT (348–154 amino acids) that may represent the bile acid efflux pump present on the basolateral membrane of the ileocyte. Nevertheless, bile salts enter the portal circulation and are transported across the sinusoidal membrane of the hepatocyte by a Na^+-dependent taurocholate cotransport polypeptide, NTCP (*SLC10A1*). Transport of recycled and newly formed taurocholate out of the hepatocyte occurs across the canalicular membrane via an ATP-dependent bile salt export pump, BSEP.

Clinical Manifestations. Patients with PBAM present during infancy with diarrhea, steatorrhea, failure to thrive, and low plasma levels of low-density lipoprotein cholesterol.[103,104] The diarrhea is generally secretory (persists while fasting) in character and is exacerbated by the addition of dietary fats.

Diagnostic Criteria or Laboratory Investigations and Treatment. The small intestine of patients with PBAM should be normal in length and architecture, and the extent of the diarrhea should improve with a trial of cholestyramine and a low-fat diet. Bile acid absorption by the ileum may be measured using the bile acid analogue ^{75}Se-homocholic acid–taurine test.

DISORDERS OF MINERAL AND ELECTROLYTE ABSORPTION AND SECRETION

Congenital Chloride Diarrhea

The most common cause of congenital secretory diarrhea in the presence of normal intestinal mucosa is the autosomal recessive disorder congenital chloride diarrhea (CCD; MIM #214700; see Table 43.2-1). Currently, over 250 cases of CCD has been described in the literature (Figure 43.2-8).[111]

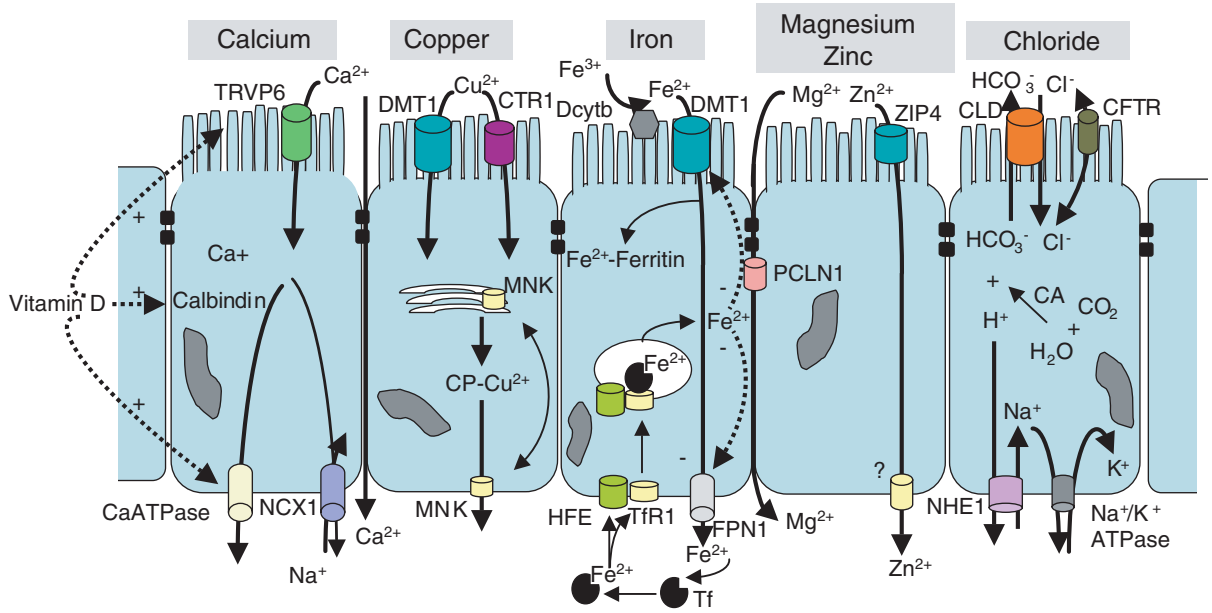

FIGURE 43.2-8 Ion and metal transport in the small intestine. ATPase = adenosine triphosphatase; CFTR = cystic fibrosis transmembrane regulator; CLD = congenital chloride diarrhea; CTR = copper transporter; Dcytb = duodenal cytochrome b; DMT = divalent metal transporter; FPN = ferroportin; HFE = haemochromatosis; IF = intrinsic factor; MNK = Menkes syndrome transport protein; NCX = Na^+-Ca^{2+} exchanger; NHE = Na^+-H^+ exchange; PCLN = paracellin; TfR = transferrin receptor; TRPV6 = transient receptor potential (vanilloid) 6; ZIP = zinc- and iron-regulated protein.

Nearly half of the reported cases have been confined to Finland, where it has been estimated to occur in 1 in 20,000 of the population, whereas it has been estimated to occur in 1 in 32,000 live births in the Persian Gulf.[112]

An earlier linkage analysis of several families identified the CCD locus to a region of chromosome 7q31 located in the vicinity of the cystic fibrosis gene, cystic fibrosis transmembrane regulator (*CFTR*).[113,114] The gene defective in CCD was originally named down-regulated in adenomas (*DRA*) and was subsequently renamed as the solute carrier family 26, member 3 gene (*SLC26A3*).[115] This gene encodes for a protein that was a viable candidate for CCD because it was expressed in colonocytes, and its chromosome localization matched previous linkage analysis.[116] The *SLC26A3* gene encodes a Na^+-independent Cl^-/HCO_3^- exchanger that is expressed primarily in the apical brush border membrane of intestinal enterocytes (see Figure 43.2-8).

Genetics. Makela and colleagues and Hoglund and colleagues identified several mutations in the *SLC26A3* gene in patients with CCD, including the prevalent Val317del mutation, which was found in a Finnish population.[111,115] Further in vitro studies demonstrated that the Val317del impaired chloride transport, confirming the role of the *SLC26A3* gene in CCD.[117] To date, over 30 disease-related mutations have been identified in over 100 patients studied with CCD.[111] One-third of the mutations are either microdeletions or missense and nonsense mutations. Three prominent founder mutations have been identified that account for the majority of cases of CCD in Finland (Val317del), Poland (I675-676ins), Saudi Arabia, and Kuwait (Gly187X). Therefore, genetic testing will be easier in a patient whose family linage originated in Finland, Poland, or the Middle East.[112] A small number of patients have been identified that fit the clinical characteristics of CCD but do not have detectable mutations in the *SLC26A3* gene. Furthermore, analysis of the precise transport function of this protein and the effects that the missense mutation has on its transport characteristics has not been described.

Molecular Pathophysiology. SLC26A3's main role as a Cl^-/HCO_3^- exchanger is to reabsorb chloride along the length of the distal intestine and colon (see Figure 43.2-8).[113] In the distal intestine and colon, salt (NaCl) absorption is secondary to SLC26A3 transport of chloride and Na^+-H^+ exchanger (NHE-3) transport of sodium. In normal physiologic conditions, the expression of NHE-3 in the proximal small intestine is low, and the Cl^-/HCO_3^- exchanger secretes bicarbonate into the lumen while absorbing chloride produced by gastric acid.[118,119] Thus, the exchanger serves the important role of neutralizing the acidity of gastric secretion once in the proximal small bowel. CFTR is a chloride channel whose primary role in the small intestine is to secrete chloride, which is then absorbed in the distal intestine and colon by the Cl^-/HCO_3^- exchanger. The impaired function of the Cl^-/HCO_3^- exchanger in CCD patients would disrupt the neutralization of gastric acid in the proximal small bowel and unabsorbable chloride levels in colon.

Clinical Manifestations. The earliest clinical symptoms may occur in utero with severe polyhydramnios and dilated loops of small bowel detectible by ultrasonography and may resemble a distal intestinal atresia.[120] The polyhydramnios and in utero diarrhea frequently result in prematurity. Patients with CCD generally present during the first week of life with severe life-threatening secretory diarrhea.

The serum electrolytes prior to treatment are unique among the various disorders of congenital diarrheal disorders and include metabolic alkalosis, hypochloremia, hypokalemia, and hyponatremia.

Diagnostic Criteria or Laboratory Investigations. The diagnosis of CCD would be suggestive if fecal chloride concentration exceeds the concentration of cations (Na^+ and K^+). This classic characteristic of CCD suggests that fecal HCO_3^- levels are particularly low and that another cation, presumably accounted for by H^+, contributes to the excessive electroneutral transfer of HCl. Patients with CCD have been found to experience intestinal and colonic ulcerations, which may be attributable to impaired HCl neutralization (personal observations, 2004).

Treatment. The mainstay of therapy is the oral or parenteral administration of KCl supplements. Although oral administration is the preferred route of electrolyte supplements, they are not well absorbed and may therefore contribute to the diarrhea. The administration of proton pump inhibitors has recently been shown to improve the degree of diarrhea, presumably by inhibiting meal-induced gastric acid secretion.[121] The investigators provided convincing data that poor absorption of gastric HCl contributes to the fecal electrolyte losses, and therefore diarrhea, in patients with CCD.

Congenital Sodium Diarrhea

CSD (MIM #270420) is an exceedingly rare autosomal recessive disorder that presents with secretory diarrhea and many of the same clinical characteristics seen in patients with CCD (see Table 43.2-1).[122,123] Currently, only six cases of CSD have been described in the literature, and the molecular basis of this condition has not been fully established.[124] Nevertheless, the available information suggests that the disorder results from impaired function of the intestinal Na^+-H^+ exchanger (see Figure 43.2-8). The gastrointestinal tract expresses primarily three Na^+-H^+ exchangers: NHE-2, -3, and -4.[125] NHE-4 is expressed largely by gastric mucosa, whereas both NHE-2 and -3 are present in the small intestine.

Genetics. A recent study of two large Austrian kindreds with five affected members confirmed that CSD is transmitted in an autosomal recessive manner.[124] The investigators performed multipoint linkage analysis to demonstrate that defects in none of the known Na^+-H^+ exchangers are responsible for the CSD in these kindreds.

Molecular Pathophysiology. Vesicle transport studies performed on brush border membrane samples confirmed that CSD is the result of a faulty Na^+-H^+ exchanger.[122] The NHE-3 exchanger is considered to be the primary transporter responsible for Na^+ absorption because deletion of the *NHE3* gene in mice results in sodium secretory that resembles CSD.[126,127] These mice also had a mild proximal tubular acidosis that was secondary to the role of NHE-3 in renal Na^+ and HCO_3^- reabsorption. Although mild diarrhea was reported in these mice, the primary finding in the gut was an excess amount of luminal fluids and an expanded surface area. Further understanding of the pathophysiology of CSD will require the elucidation of the loss of function mutations in the yet to be identified disease-causing gene.

Clinical Manifestations. Patients with CSD have high-volume secretory diarrhea that is very alkaline and contains high concentrations of Na^+. Therefore, patients generally experience hyponatremia, low or normal excretion of urinary Na^+, and metabolic acidosis. Polyhydramnios resulting from in utero diarrhea is also associated with CSD, and a recent report described choanal atresia in two patients with CSD.[124]

Although the intestinal biopsies of patients with selective impairment of transport function are generally considered to be normal, biopsies from three recently described cases that fit the clinical characteristics of CSD showed partial villous atrophy and a decreased villus-to-crypt ratio.[124] It is unclear if these abnormal histologic findings are a consequence of CSD or a result of the limited enteral intake of these patients who were on total parenteral nutrition. Electromicroscopy showed no evidence of microvillus atrophy or inclusion disease but demonstrated unexpected membranous whorls located in lysosomal bodies, vacuoles, and mitochondria.

Diagnostic Criteria or Laboratory Investigations. The diagnosis of CSD should be considered in patients who present as newborns with high-output secretory diarrhea and can be established by confirming the presence of elevated levels of fecal Na^+ and HCO_3^-. Unlike patients with CCD who have metabolic alkalosis, metabolic acidosis is typically found in CSD and in all other forms of congenital diarrhea.

Treatment. The medical management of CSD patients is to maintain their fluid and electrolyte balance with the use of oral or parenteral fluids and salts.

Acrodermatitis Enteropathica

Primary acrodermatitis enteropathica (AE; MIM #201100) is a rare autosomal recessive disorder of impaired intestinal absorption of zinc (see Table 43.2-1 and Figure 43.2-8).[128,129] Although secondary deficiencies in trace elements such as zinc and selenium are a common complication of chronic diarrhea, patients with AE present in early infancy with profound depletion of total-body zinc.

Genetics. Genome-wide screening for the AE allele was recently reported using two large consanguineous families, and a locus residing within chromosome 8q24.3 was identified.[130] Within this region of the genome resides a gene that encodes a member of the zinc- and iron-regulated transporter family of proteins (ZIP4; Figure 43.2-8).[131] Sequencing of the *ZIP4* gene identified five missense mutations in patients with AE.[132–134] Although the transport function of the mutant forms of the ZIP4 protein has not been evaluated, each mutation alters highly conserved and critical amino acid residues in the family of zinc transporters.

Molecular Pathophysiology. ZIP4 is expressed on the apical membrane of epithelia in the intestine, colon, stomach,

and kidney.[135] ZIP4 is a member of a recently described family of proteins that control the transport of zinc into the cytoplasm of various cells. Although patients with AE have a markedly reduced capacity to absorb luminal zinc, their responsiveness to high-dose oral zinc supplements raises the possibility that they retain a redundant but less efficient zinc transport mechanism in the intestine (see Figure 43.2-8).

Clinical Manifestations. During childhood, zinc deficiency may develop either because of a primary defect in absorption or secondary to either inadequate intake or excessive losses.[128,136] Zinc deficiency that is due to excessive fecal losses of zinc is a common finding in patients with acute and chronic diarrhea, and short-term oral supplements have been shown to reduce the duration and severity of diarrhea.[137] Infants who are exclusively breastfed are also predisposed to zinc deficiency because its supply by breast milk may be insufficient to provide adequate zinc requirements.[138]

AE patients generally present with anorexia, diarrhea, and severe failure to thrive.[128,129] The dermatitis located on the hands, feet, and perirectal and oral regions has a vesicobullous character, and the alopecia of the scalp and face is also a striking feature that occurs in patients with prolonged zinc deficiency. Humoral and cell-mediated immunodeficiencies have been reported in association with AE and may contribute to both poor wound healing and recurrent infections. Poorly characterized neurologic features such as mental lethargy and neurosensory abnormalities may also be present.

Diagnostic Criteria or Laboratory Investigations. Zinc deficiency results in low levels of serum alkaline phosphatase, a zinc-dependent metalloenzyme. Alkaline phosphatase levels decline with age, and lower than expected levels should raise the possibility of zinc deficiency. Both serum and urinary zinc concentrations are significantly reduced in untreated patients with AE. Radiolabeled zinc has been used to assess the absorptive capacity of the intestine using both mucosal biopsy samples and in vivo uptake studies.[128,129]

Histology of the small intestine has shown several abnormalities that may represent the consequence of inadequate zinc concentrations in patients with AE. Paneth cells and enterocytes of the small bowel have been shown to have inclusion bodies and abnormal intracellular organelles; villus atrophy has also been reported.[128,129]

Treatment. Patients with AE can be managed with large oral doses, 3 to 30 µmol zinc/kg body weight/d, of zinc supplements. Chronic supplementations with adequate doses of zinc will resolve the clinical and laboratory features of this disorder.

Calcium Absorption

Calcium absorption in the small intestine occurs by both active and passive transport mechanisms.[139] Passive absorption of dietary calcium occurs paracellularly along the entire length of the small bowel, and this pathway is predominant when the calcium supply is abundant. In contrast, the active calcium transport system is located primarily in the duodenum and is particularly important when the level of dietary calcium is low. The active transport system was recently identified as a member of the transient receptor potential vanilloid 6, or TRPV6, and is expressed primarily in the proximal small bowel.[140] This transporter has also been named ECaC2 and CaT1, and a homologous TRPV5 transporter is present primarily in the kidney (see Figure 43.2-8).

TRPV6 expression in the intestine is limited to the enterocytes, specifically the brush border membrane. Once within the cytoplasm, calcium forms a complex with a calcium-binding protein called calbindin D_{9k}, or CaBP. Calcium efflux out of the enterocyte takes place by either the CaATPase (PMCA1b) or by the Na^+-Ca^{2+} exchanger NCX1 (see Figure 43.2-8). Vitamin D (1,25-dihydroxyvitamin D_3) directly influences the expression of both TRPV5/6 and CaBP by directly activating vitamin D–responsive elements in the immediate promoter region of both genes and increasing transcription.[141] Congenital disorders that impair calcium absorption include pseudovitamin D deficiency rickets (MIM #264700), which is secondary to a defective synthesis of 25-hydroxyvitamin D_3 1α-hydroxylase.[142] Specific inherited defects in the transporters that control dietary calcium absorption have yet to be described.[143]

Disorder of Magnesium Transport

Congenital primary hypomagnesemia (MIM #248250) is a rare autosomal recessive disorder that is associated with impaired absorption of dietary magnesium and a renal tubular defect of magnesium transport (see Table 43.2-1 and Figure 43.2-8).[144] Hypocalcemia secondary to low parathyroid hormone and 1,25-dihydroxyvitamin D_3 levels is common and may result in infantile tetany. The molecular basis of primary hypomagnesemia was elucidated several years ago when linkage analysis led to the identification of a tight junction protein named paracellin 1 (PCLN1).[145] Mutations in the gene encoding the PCLN protein (also called claudin 16) were identified in 10 kindreds, and the protein was located in the tight junction region of the thick ascending limb of Henle. Whether paracellin is expressed by small intestinal epithelium has not been reported. The mechanism by which paracellin influences magnesium transport has not been identified; although paracellin may serve as a selective paracellular transporter of magnesium, it may also represent a sensor of magnesium concentration.

Disorders of Copper Transport

Copper is a critical cofactor required for the synthesis and function of numerous proteins whose roles range from antioxidants to enzymes required for mitochondrial function. The diet is an important source of copper, and our understanding of the complex process of copper absorption, intracellular processing, and efflux has improved by investigating the basis of two disorders of copper transport, Menkes syndrome and Wilson disease.[146,147] Menkes syndrome (MIM #309400) is a rare (1 in 100,000) X-linked recessive disorder of copper deficiency resulting from

defective synthesis of the Menkes syndrome transport protein (MNK) (see Table 43.2-1 and Figure 43.2-8).[148] In contrast, Wilson disease (WD; MIM #277900) is a more common autosomal recessive disorder that is the consequence of copper accumulation secondary to malfunctioning of the WD transporter.[149] Both transporters have been localized to the membranes of the *trans*-Golgi network (TGN), where they modulate copper transport into the network. When intracellular copper levels increase, both transporters redistribute to small vesicles and the plasma membrane, where they presumably control the efflux of copper out of the cell. MNK is expressed primarily by enterocytes and cells of the placenta and central nervous system, whereas expression of the WD transporter is limited mainly to hepatocytes. Given their tissue-specific pattern of expression, defects in the function of MNK result in inadequate efflux of copper from the gut, whereas an alteration of WD results in failure to excrete copper to bile, which subsequently accumulates in the liver.[146]

The mechanism of dietary copper absorption has not been definitively established; however, two active transporters located on the apical membrane of the enterocyte have been implicated (see Figure 43.2-8). The H^+–divalent metal transporter (DMT1) has a broad range of substrates, including copper, iron, manganese, and cobalt, to name a few.[150] A more specific family of high-affinity copper transporters, CTR1 and -2, has been isolated and is expressed in a broad range of tissue, including the intestine.[151]

Within the intracellular compartment of the enterocyte, copper may be either incorporated into copper-containing proteins or traffic into the TGN by way of the MNK transporter.[146,147] Copper binds ceruloplasmin within the TGN and subsequently enters the systemic circulation bound primarily to ceruloplasmin. Although copper levels do not influence the production of ceruloplasmin, the protein becomes unstable (shorter half-life) during copper-deficient states, resulting in low ceruloplasmin levels. Because defects of both MNK and WD lead to impaired trafficking of copper across the TGN membrane, Menkes syndrome and WD are both associated with hypoceruloplasminemia.

Genotype-phenotype relationships have been established in Menkes syndrome, and the clinical consequences of mutations in MNK are primarily the result of a copper-deficient state that leads to improper synthesis of copper-containing proteins. Patients generally present during early infancy with failure to thrive, various neurologic symptoms, hyperpigmentation, and morphologic changes of the hair. Most children with Menkes syndrome die by 4 years of age, and although copper supplementation has not been shown to be efficacious, recent anecdotal reports suggest that copper-histidine may delay the onset of various symptoms.[152] In contrast, WD generally presents during early adolescence with either neurologic or hepatic consequences of copper overload. Chelation therapy with D-penicillamine or ammonium tetrathiomolybdate augments renal excretion of copper while improving its positive balance in the liver and brain.[153] Oral administration of zinc has been shown to inhibit dietary intake of copper, presumably by competing for transport into the enterocyte via DMT (see Figure 43.2-8).[150,154]

DISORDERS OF IRON TRANSPORT

Our understanding of the mechanism of iron absorption has improved dramatically over the last several years with the discovery of the molecular basis of hereditary hemochromatosis (HH; MIM #235200; see Table 43.2-1).[155,156] HH is an autosomal recessive disorder characterized by excessive iron absorption by the intestine and secondary multiorgan failure related to excessive tissue iron content. Hemochromatosis is probably the most common genetic disorder among individuals of European ancestry, with an estimated carrier frequency of about 1 in 8.[155,156] The isolation of the defective gene responsible for HH was performed by linkage analysis and sequencing of an area within the major histocompatibility region of chromosome 6p. The most common form of HH is secondary to mutations in the gene that encodes a major histocompatibility class I–like protein, HFE. Several mutations, including Cys282Tyr, His63Asn, and Ser65Cys, account for the majority of abnormal alleles in the *HFE* gene.[157, 158]

The role of HFE in iron absorption was elucidated when HFE was found to interact with the transferrin receptor (TfR) with an affinity that was comparable to the diferric transferrins' interaction with the receptor (see Figure 43.2-8). Immunohistochemical analysis also confirmed that HFE and TfR were localized to both the basolateral membrane and the intracellular compartment of crypt cells of the intestine. It has been speculated that HFE facilitates the interaction of diferric transferrin and TfR, resulting in endocytosis in clathrin-coated vesicles and the eventual release of iron into the cell cytoplasm.

The primary apical iron transporter was identified by expression cloning to be the H^+-DMT1, which also transports copper (see Figure 43.2-8).[150] Because the absorption of dietary iron is limited to the reduced ferric (Fe^{2+}) form, the brush border enzyme cytochrome *b* (duodenal cytb) reduces the oxidized form (Fe^{3+}) prior to transport (see Figure 43.2-8). The efflux of iron across the basolateral membrane is mediated by a recently characterized transporter, ferroportin 1 (FPN1).[159] The transporters are both expressed primarily on duodenal enterocytes located along the upper portion of the villus, and their expression is dramatically up-regulated in iron-deficient states.

The common HFE mutation appears to inhibit its interaction with its heterodimeric partner, β_2-microglobulin, and diminish the level of HFE on the basolateral membrane. Because the endocytosis of the transferrin-TfR- Fe^{2+} complex requires adequate levels of HFE, mutations of the HFE protein would reduce cytoplasmic iron levels while augmenting the expression of DMT1 and FPN1 and increasing iron intake.[160,161] In contrast, in iron-abundant states associated with wild-type HFE, the endocytosis of the Fe^{2+}-containing complex would increase the cellular stores of iron and thereby reduce the synthesis of DMT1 and FPN1.

Deficiencies of proteins other than HFE have recently been implicated in the pathogenesis of other forms of hemochromatosis (see Table 43.2-1). Mutations in the

gene encoding ferroportin 1 have been identified in an autosomal dominant form of hemochromatosis (MIM #606069).[162] Defects in TfR 2 have also been identified in several kindreds (MIM #604250), whereas a juvenile form of hemochromatosis (MIM #602390) has been associated with mutations in hepcidin, an antimicrobial peptide synthesized by hepatocytes.[163,164]

DISORDERS OF VITAMIN ABSORPTION

Folate Malabsorption

Dietary folate is found primarily in green leafy vegetables, organ meats, and grains as polyglutamylated folates. Glutamate carboxypeptidase II, expressed on the brush border membrane of small bowel enterocytes, hydrolyzes folylpolyglutamates to a form (monoglutamyl folates) that can be transported by the reduced folate transporter 1 (RFC-1) (Figure 43.2-9). Once within the enterocyte, folylmonoglutamate is converted to 5-methyltetrahydrofolate (5-MTHF), which exits the basolateral membrane via the RFC-1 transporter. The folate-binding protein mediates the transport of 5-MTHF in hepatocytes, where it is stored in the form of polyglutamylated folates, an essential cofactor for nucleic and amino acid synthesis.

Folate deficiency generally results in hyperhomocysteinemia because 5-MTHF is required to synthesize methionine from homocysteine. A sufficient level of methionine is required for the synthesis of *S*-adenosylmethionine, an enzyme critical for DNA methylation. Congenital folate malabsorption (MIM #229050) is a rare autosomal recessive disorder associated with the clinical symptoms of diarrhea, glossitis, and seizures in the face of pancytopenia (see Table 43.2-1).[165] The underlying mechanism of the congenital form of folate deficiency has not been identified. Folic acid deficiency has been definitively associated with neural tube defects in neonates and an increased risk of cardiovascular disease in adults with elevated levels of homocysteine.[166] Serum folate and homocysteine levels are readily available assays that may be used to assess adequate folate stores.

Vitamin B_{12} Malabsorption

The absorption of vitamin B_{12} (cobalamin) is a complex process that is initiated by gastric acidity that removes cobalamin from dietary proteins and transfers it to haptocorrin (cobalamin-binding protein). Intrinsic factor (IF), produced by parietal cells, binds cobalamin after pancreatic proteases hydrolyze the cobalamin-haptocorrin complex in the duodenum. The ileal enterocytes express cubulin, which forms a heterodimer with amnionless and forms a receptor for the cobalamin-IF complex (see Figure 43.2-9).[167] Amnionless's role is to direct the receptor-vitamin complex to the endosomes, where it encounters a second receptor, megalin.[168] The cobalamin-IF complex is cleaved within the endosome, resulting in the formation of a cobalamin-transcobalamin 2 complex, which transverses the enterocyte and enters the systemic circulation.

The clinical consequences of vitamin B_{12} and folate deficiency overlap because cobalamin is a cofactor for methionine synthase, which uses a methyl group from 5-MTHF to convert homocysteine to methionine.[169] Hyperhomocysteinemia is thus the consequence of both vitamin B_{12} and folate deficiency. Defects of cobalamin absorption are, however, uniquely associated with methylmalonicacidemia because adenosylcobalamin is required for appropriate mitochondrial fatty acid metabolism.[170]

Vitamin B_{12} deficiency can be secondary to numerous problems, ranging from inadequate intake to disruption of any of the various steps required for absorption.[169] Primary or secondary achlorhydria is commonly associated with cobalamin deficiency because gastric acidity is required for the formation of the cobalamin-haptocorrin complex. Bacterial overgrowth in the small intestine may also disrupt the cobalamin-IF complex and lead to a decline in cobalamin levels. Because cobalamin is absorbed exclusively in the ileum, disorders resulting in an inadequate ileal absorptive capacity will also result in vitamin B_{12} deficiency.

There are three rare yet well-described autosomal recessive disorders associated with congenital forms of cobalamin deficiency. Congenital pernicious anemia (MIM #261000) is associated with an absence of IF, which facili-

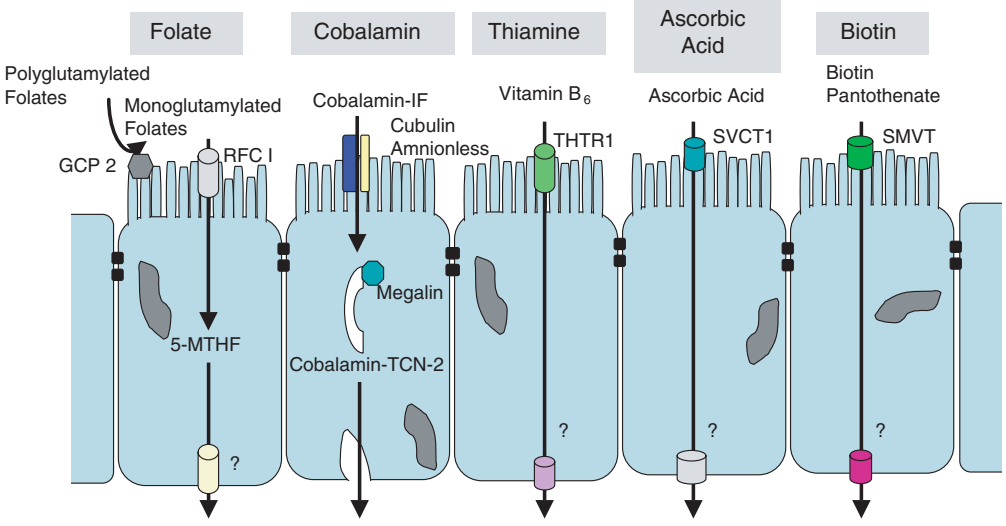

FIGURE 43.2-9 Water-soluble vitamin absorption in the small intestine. GCP = glutamate carboxypeptidase; MTHF = methyltetrahydrofolate; RFC = reduced folate transporter; SMVT = sodium multivitamin transporter; SVCT = sodium-vitamin C cotransporters; TCN = transcobalamin; THTR = thiamine transporter protein.

tates the binding of cobalamin to the cubilin-amnionless receptor.[171] Imerslund-Graesbeck syndrome (MIM #261100) was originally described in both Finland and Norway, and linkage analysis of the Finnish patients identified mutations in the cubilin receptor[172]; whereas the Norwegian cases were recently identified to be secondary to mutations in the amnionless gene (see Table 43.2-1).[167,173] Finally, congenital defects of transcobalamin 2 (MIM #275350) have also been shown to result in inadequate levels of vitamin B_{12} and in both bone marrow failure and a range of neurologic deficits.[174] Measurement of serum vitamin B_{12} levels and evidence of homocysteine and methylmalonic acid may be used to assess vitamin B_{12} stores. The Schilling test is particularly useful in assessing the various origins of cobalamin deficiency.[170]

ABSORPTION OF VARIOUS WATER-SOLUBLE VITAMINS

The molecular basis of several water-soluble vitamins has recently been elucidated. Vitamin C, or L-ascorbic acid, has been found to be transported across the intestinal epithelial layer by the Na^+-dependent vitamin C transporter sodium vitamin C transporter (SVCT)1 (see Figure 43.2-9).[175] Ascorbic acid transport via SVCT1 appears to be critical during the perinatal period because null SVCT1$^{-/-}$ knockout mice succumb immediately after birth.[176] Because the dietary deficiency of ascorbic acid has been well described, inherited forms of a congenital deficiency have not been reported. Although the pyridoxine (vitamin B_6) transporter has not been identified, recent reports have begun to determine various characteristics of this pH-dependent carrier-mediated system.[177]

Expression cloning techniques were also used to identify the biotin transporter. The Na^+-dependent multivitamin transporter sodium multivitamin transporter was also identified to transport pantothenate (vitamin B_5) and lipoate at high affinity (see Figure 43.2-9).[178] An abnormality of biotin transport was recently described in an encephalopathic child; however, the molecular mechanism has not been described.[179] Thiamine absorption across the intestinal brush border membrane is facilitated by the thiamine transporter protein 1 THTR1. The thiamine transporter resembles the structure of the folate transporter RFC-1, and mutations of THTR1 have been associated with a thiamine-responsive megaloblastic anemia syndrome (MIM #249270; see Table 43.2-1).[180,181] This is a rare autosomal recessive disorder that is associated with megaloblastic anemia, diabetes mellitus, and deafness.

ABSORPTION OF VARIOUS FAT-SOLUBLE VITAMINS

The most common cause of a generalized deficiency of fat-soluble vitamins includes specific dietary restrictions and a wide assortment of gastrointestinal disorders that impair fat absorption. All fat-soluble vitamins are absorbed by enterocytes primarily by passive diffusion, a process that is facilitated by the emulsification of fats by bile salts. Selective deficiencies are certainly more unusual and may suggest a defect in the interaction of vitamin with a specific transfer protein. For instance, vitamin A (retinol) is packaged in chylomicrons in the enterocyte and is eventually taken up by hepatocytes, where it is either stored or remains bound to retinol-binding protein for transfer to other cells. A rare inherited disorder of retinol-binding protein deficiency (MIM #180250) has been described and leads to an assortment of ophthalmologic findings and a low serum level of vitamin A.[182] A selective vitamin E deficiency (MIM #277460) has also been identified that is secondary to mutations in the α-tocopherol transfer protein and results in a form of spinocerebellar ataxia and undetectable serum vitamin E levels (see Table 43.2-1).[183]

3. Congenital Enteropathy Involving Intestinal Mucosa Development

Olivier Goulet, MD, PhD
Alan David Phillips, BA, PhD, FRCPCH

The definition, presentation, and outcome of intractable diarrhea of infancy (IDI) have changed considerably during the last three decades because of major improvements in nutritional management and better understanding of the pathology of the small bowel mucosa. Originally, the syndrome of IDI was described by Avery and colleagues in 1968 based on the following features: diarrhea occurring in an infant younger than 3 months of age, lasting more than 2 weeks, with three or more negative stool cultures for bacterial pathogens.[1] Most cases were managed in the hospital using intravenous fluids while the diarrhea was persistent and intractable, with a high mortality rate from infection or malnutrition. From a multicenter French study, Ricour and colleagues reported similar features of IDI, whereas, in most cases, no specific diagnosis was provided.[2] Recently, the term "severe diarrhea requiring parenteral nutrition" was proposed.[3,4] Within this group of patients with diarrhea, it seems possible to differentiate protracted diarrhea of infancy (PDI), which resolves despite its initial severity, and IDI, which requires long-term parenteral nutrition (PN) and, in some cases, intestinal transplant. From a recent French multicenter study involving 65 cases of severe diarrhea requiring more than 1 month of PN, Tables 43.3-1 and 43.3-2 show the main characteristics of infants with PDI and IDI and the diagnosis distribution, respectively.[5]

PDI is primarily due to either a specific immunodeficiency or a sensitization to a common food protein (eg, cow's milk and gluten) or to severe infection of the digestive tract (postenteritis syndrome). The so-called "intractable ulcerating enterocolitis" of early onset is difficult to classify.[6]

TABLE 43.3-1 MAIN CHARACTERISTICS OF INFANTS WITH PROTRACTED AND INTRACTABLE DIARRHEA OF INFANCY

CHARACTERISTIC	PDI	IDI	*P*
Gestational age (mo)	38.5 ± 1.2	38.2 ± 1.7	NS
Birth weight (g)	2,910 ± 340	2,930 ± 462	NS
Onset of diarrhea (d)	120 ± 49	38 ± 17	.02
PN duration (mo)	5 ± 11	24 ± 8	.01
Mortality (%)	2.5	23.8	.05

Adapted from Goulet O et al.[5]
IDI = intractable diarrhea of infancy; NS = not significant; PDI = protracted diarrhea of infancy; PN = parenteral nutrition.

IDI with persistent villous atrophy usually starts within the first 2 years of life and is associated with abundant diarrhea that persists in spite of protracted bowel rest. It rapidly becomes life threatening, and long-term PN is required. It is associated with a persistent histologic intestinal lesion and may continue for years despite various therapeutic trials, including steroids and/or cyclosporin A or tacrolimus. These characteristics clearly differentiate IDI from PDI, which responds to bowel rest and/or enteral nutrition, or to specific treatment in case of immunodeficiency or allergy, and always recovers even after several weeks or months of parenteral and/or enteral nutrition.

CURRENT VIEW OF INTRACTABLE DIARRHEA OF INFANCY

During the early 1980s, conditions such as autoimmune enteropathy[7] or microvillous atrophy/microvillous inclusion disease (MVA/MVID)[8,9] have been characterized within the heterogeneous group of patients with IDI. An attempt to classify enteropathy-associated intractable diarrhea was proposed on the basis of immunohistologic criteria emphasizing the presence or absence of activated T cells in the intestinal mucosa.[10] A multicenter survey

from the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) collected cases of IDI and villous atrophy (excluding MVA/MVID) with precisely defined light microscopic characteristics to study categorization of disorders within IDI.[11] Several groups were delineated on the basis of clinical and histologic analyses. The first one presented with extradigestive symptoms suggestive of autoimmune enteropathy, including arthritis, diabetes, nephrotic syndrome, dermatitis, anemia, and thrombocytopenia, and tended to have a later onset of diarrhea, which was of larger volume, compared with a group of patients who had only gastrointestinal symptoms and gut autoantibodies. Two other groups included patients who did not exhibit mononuclear cell infiltration of the lamina propria. Some patients were small for gestational age and presented with phenotypic abnormalities corresponding to the previously described "syndromatic diarrhea."[12] Some other infants presented with mucosal changes, including mild to moderate villous atrophy, epithelial cell tufts, and branching and/or pseudocystic glands.[13] Family history was noted in 40% of these patients. The last group included infants with epithelial dysplasia and infants with villous atrophy in whom histologic analysis did not result in specific features being recognized.

Histologic analysis seems to be the most important point for the diagnosis of IDI. Patients present histologically in two clearly different forms: the first one is characterized by mononuclear cell infiltration of the lamina propria and is considered to be associated with activated T cells. The second pattern includes early onset of severe intractable diarrhea with villous atrophy without mononuclear cell infiltration of the lamina propria but specific histologic abnormalities involving the epithelium. To date, several types of primary epithelial abnormalities inducing IDI have been described. The first described was MVA/MVID and, more recently, tufting enteropathy or intestinal epithelial dysplasia.

MICROVILLOUS ATROPHY/MICROVILLOUS INCLUSION DISEASE

In 1978, Davidson and colleagues reported five infants with severe, persistent diarrhea beginning in the newborn period in which light microscopy revealed a thin mucosa, described as crypt hypoplastic villous atrophy.[14] Electron microscopic examination of small intestinal biopsies from three of the patients showed severe brush border abnormalities and increased liposome-like bodies and, in one, the features now recognized as the diagnostic features of MVA/MVID, intracytoplasmic cysts made up of brush border and increased secretory granules.[8] Further children were reported, each of whom had the characteristic microvillous inclusions and secretory granules.[8,15] From these first clinical and histologic descriptions, MVA/MVID has been established as a distinct disease within the syndrome of IDI, including characteristic diagnosis features. MVA/MVID in its typical form is a congenital disorder of intestinal epithelial cells presenting as intractable secretory diarrhea within the first days of life.[16]

The name MVID[9] was first used some years after the disease had been described as MVA.[8,15] Although it correctly highlights the presence of microvillous inclusions, it ignores the increased presence of secretory granules, which is the first abnormality to become evident in the epithelial life cycle. Indeed, the formation of microvillous inclusions may be secondary to the presence of the secondary granules. No useful purpose would be served by attempting to find a comprehensive name for the disease, and it is perhaps best to wait for the cause of the disease to be identified and to reconsider matters then.

Typical Clinical Expression of MVA/MVID

In general, infants develop severe secretory diarrhea within the first days after birth. They pass over 250 to 300 mL/kg body weight of fecal output per day containing electrolyte concentrations similar to those seen in small intestinal fluid. This disorder is particularly life-threatening because massive diarrhea leads to rapid dehydration and electrolyte imbalance, with subsequent metabolic decompensation within a few hours.[14–16] Severe watery diarrhea persists despite bowel rest. Differential diagnosis may include congenital chloride diarrhea[17] or sodium hydrogen exchange deficiency.[18] Both are usually associated with hydramnios. Blood and stool electrolyte assessment allows the diagnosis of each of these disorders to be easily made. Conversely, clinical presentation may sometimes be very atypical, with predominant occlusive syndrome with full and distended small bowel and colon. Some newborns have been thought to present intestinal pseudo-obstruction syndrome, and some have unfortunately been operated on for an ileostomy. After ruling out the diagnosis of congenital electrolyte malabsorption diarrhea, the diagnosis of MVA/MVID has to be considered, especially if the child has consanguineous parents and/or siblings have died from severed diarrhea in early infancy. In the largest ESPGHAN survey performed by Phillips and Schmitz, clinical variants were identified in which the symptoms were of late onset, that is, the onset of diarrhea was delayed after the neonatal period, and such cases have been termed "late-onset MVA."[16] It appears that diarrhea in these cases is less severe, and although secretory granules and microvillous inclusions are present, they are distributed differently to cases of congenital MVA/MVID (see below).[16]

Histologic Presentation

Histologic analysis of small bowel biopsies shows a variable degree of villous atrophy, generally without any inflammatory infiltrate. Highly characteristic for this disorder is the accumulation of periodic acid–Schiff (PAS)-positive secretory granules within the apical cytoplasm of enterocytes (Figure 43.3-1).[19–21] The abnormal staining pattern is first noted in upper crypt epithelial cells in congenital MVA but appears later in the epithelial life cycle in late-onset MVA, first becoming evident in low villous enterocytes.[21] A third, and very rare, variant, termed "atypical MVA," has the abnormal PAS stain arising in low crypt epithelial cells.[21] Apart from the increase in secretory granules, crypt cells otherwise appear near normal on electron microscopy in

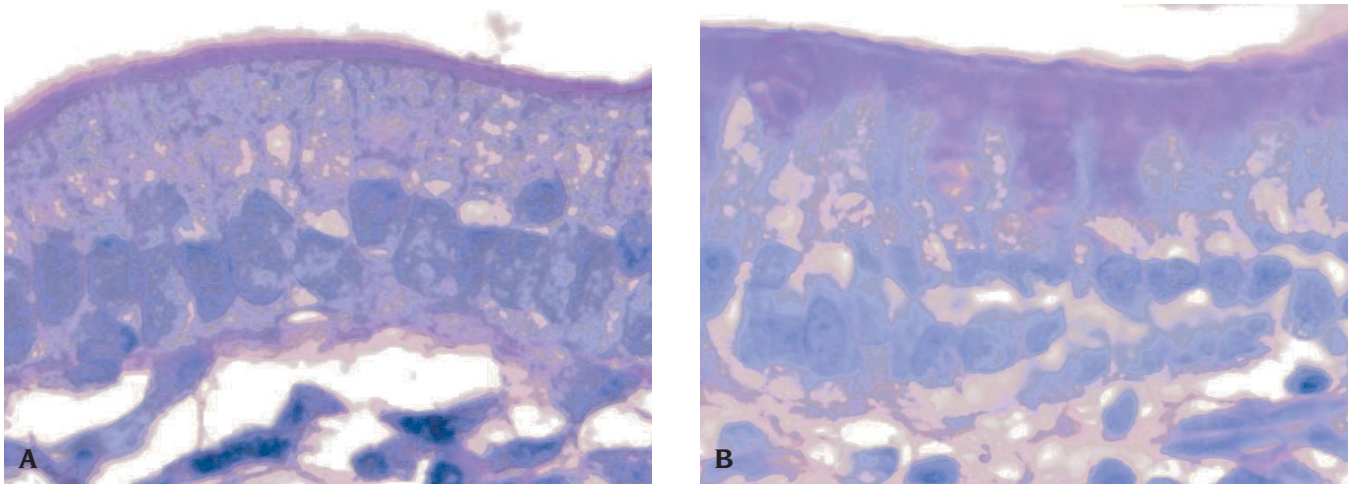

FIGURE 43.3-1 Microvillous atrophy/microvillous inclusion disease (MVA/MVID) (periodic acid–Schiff [PAS] staining; ×120 original magnification). *A*, Normal mucosa, normal PAS, brush border staining. *B*, Abnormal accumulation of PAS-positive material in the apical cytoplasm of epithelial cells in MVA/MVID.

congenital MVA/MVID, with a well-developed brush border. In contrast, in mid- to upper villous epithelial cells, there are rare or absent microvilli and an increased presence of autophagic vacuoles, along with the diagnostic presence of microvillous inclusions (Figure 43.3-2).[21] The lesion is also present in the large bowel,[8] and although it may be easier to biopsy the rectum and distal colon in early infancy, diagnostic information is not easy to discern owing to the increased presence of goblet cells.

Diagnosis can be strongly indicated by the light microscopic examination of proximal small intestinal mucosal biopsies. The thin, abnormal mucosa is not diagnostically specific on hematoxylin and eosin staining, and the description "hypoplastic" villous atrophy is incorrect because the crypts do not contain less cells than in normal mucosa, and there is a high epithelial cell turnover.[21,22] Diagnostic information can be obtained by performing PAS staining. This reveals an abnormal brush border pattern with positive staining material within the apical cytoplasm of enterocytes (see Figure 43.3-1B). It is important to realize that both secretory granules and microvillous inclusions will stain with PAS, the former producing an even apical intracytoplasmic stain, primarily in the upper crypt and low villous region, the latter giving a vacuolar and uneven pattern in older epithelial cells. The distribution of these two characteristic findings means that correct orientation of the biopsy sample is necessary for accurate evaluation.

There are reports of novel diagnostic stains that have been put forward as replacements for electron microscopy. The impetus for this comes from the consideration of the time it takes to perform transmission electron microscopy. However, it is perfectly possible to carry out rapid electron microscopy and to get an answer within 2 days of taking the biopsy. Alkaline phosphatase,[23] carcinoembryonic antigen,[24] and CD10 staining[25] have all been suggested, but the two former stains do not appear to stain secretory granules and only highlight microvillous inclusions. Indeed, it has been shown that the direct and indirect constitutive pathways in MVA/MVID are intact, and various disaccharidase and peptidase brush border enzymes are normally inserted

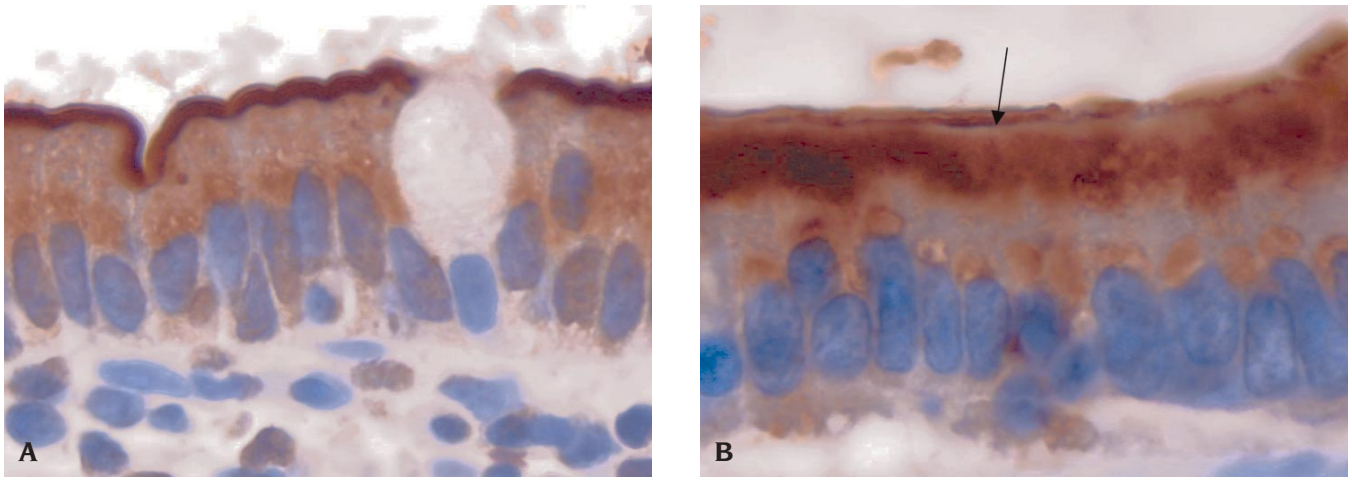

FIGURE 43.3-2 Microvillous atrophy/microvillous inclusion disease. CD10 immunostaining (×300 original magnification) in a control subject (*A*) and a patient with microvillous inclusion disease (*B*).

into the apical membrane and do not accumulate in secretory granules, although they do appear in microvillous inclusions.[26] However, CD10, a membrane-associated neutral peptidase with a linear brush border staining pattern in normal small intestine, appears to parallel PAS staining (see Figure 43.3-1B and Figure 43.3-3).[25,27]

Pathophysiology and Mode of Transmission

A defect in the membrane trafficking of immature and/or differentiating enterocytes was proposed as a potential pathogenetic mechanism of MVA/MVID,[20,26] leading, as a direct functional consequence, to complete intestinal failure. It has been speculated that the disease is associated with a disorder of the enterocyte cytoskeleton that produces an abnormal assembly of microvilli. However, morphologically normal microvilli appear in the crypt region in congenital and late-onset MVA, so it would appear logical that the microvillous changes seen in older cells are a consequence of another as yet unidentified event within the cell, perhaps linked to the accumulation of secretory granules. "Intestinal microvillous dystrophy" has been reported with the speculation that it is a hypothetical variant of MVA/MIVD.[28] However, the only reported similarity is in the abnormal microvilli, which is reported in many diseases, and MVA/MVID was excluded because there was no increase in secretory granules and no microvillous inclusions were seen. The underlying pathogenesis of MVA/MIVD is still very unclear, although a cytoskeletal myosin deficiency has been found,[29] indicating a possible molecular motor defect that could result in a trafficking abnormality. The nature of the secretory granules is not known. By using sucrase-isomaltase as a representative protein, it appears that the direct and indirect constitutive pathways are intact in MVA/MVID and that a defect in endocytosis is unlikely.[26] More recently, by investigating the glycobiologic nature of the epithelial accumulation of PAS, it is suggested that MVA/MVID involves a defect in exocytosis of the glycocalyx.[30] The absence of glycocalyx would have profound consequences on normal cell function.

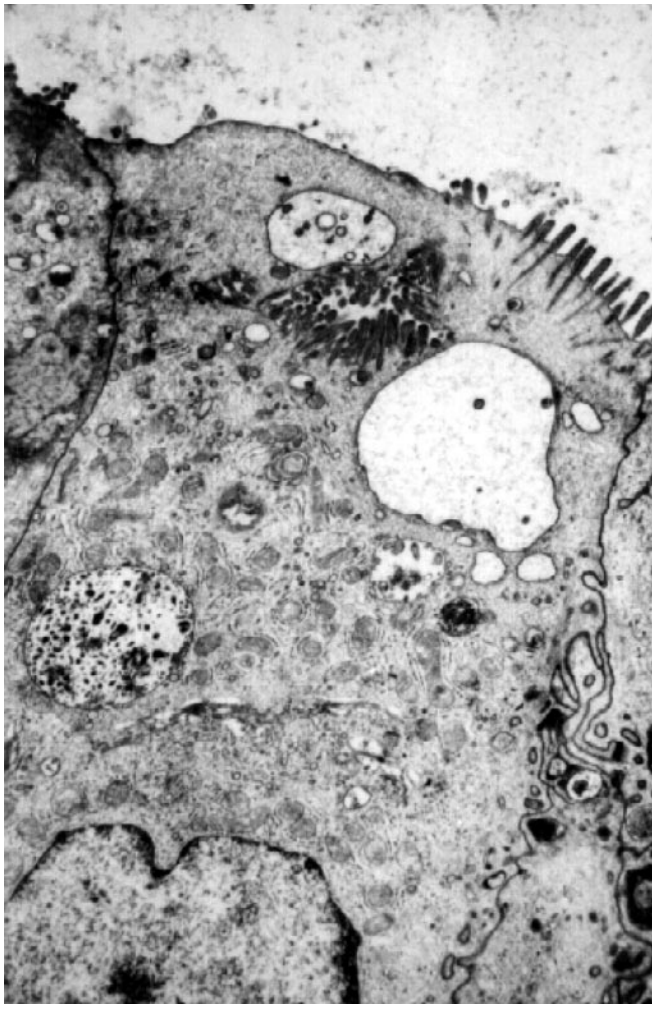

FIGURE 43.3-3 Microvillous atrophy/microvillous inclusion disease. Electron microscopy of jejunal biopsy specimen. The brush border is almost absent. The cytoplasm contains a microvillous inclusion.

Considering the number of cases with affected siblings and the frequency of consanguinity among parents with affected infants, this disease appears to be transmitted as an autosomal recessive trait.[14,16] No candidate genes for the disease have been identified to date. Affected siblings have been reported,[31] and MVID/MVA has been reported in children with autosomal dominant hypochondroplasia[32] and dihydropyriminidase deficiency.[33] The gene defect of the former disease has recently been localized on chromosome region 4p16.3[34] and the latter on 8q22[35]; thus, although they may be helpful in elucidating the genetic basis of MVA/MVID, the association may also be purely coincidental.

Long-Term Outcome

MVA/MVID is a congenital constitutive intestinal epithelial cell disorder leading, in its typical early-onset form, to definitive lifelong intestinal failure. A multicenter survey of 23 patients performed revealed an extremely reduced life expectancy in congenital MVA/MVID.[16] These patients had a 1-year survival rate of less than 25%. Most children died of septic complications, liver failure, or metabolic decompensation.

A minority of cases of MVA/MIVD may survive with a limited increased stool output and may require only partial PN.[36] Treatment with corticosteroids, colostrum, or epidermal growth factor has not been successful, but octreotide has been used with partial success in one patient.[16] In comparison with the poor initial outcome before the 1980s, PN now allows most infants and children to survive. However, complications related to inadequate PN (recurrent catheter-related sepsis, extensive thrombosis, fat overload syndrome, cholestasis) limit long-term survival. In addition, although without evidence of an associated renal disease, some of these infants and children presented with chronic electrolyte imbalance and acidosis with subsequent impaired growth. Others, because of repeated dehydration episodes associated with unchanged phosphate and calcium intake, presented with kidney calcification. Finally, even with adequate long-term PN and normal growth, most children continue to have a high and uncomfortable stool output that requires daily replacement with the daily risk of severe dehydration. Thus, intestinal

transplant became the only definitive treatment of this rare intestinal disease.

Place of Intestinal Transplant for MVA/MVID

Some cases of successful intestinal transplant for MVA/MVID have been reported following the use of a new immunosuppressive drug, tacrolimus (originally FK506).[37–40] Transplant has involved isolated intestine[37,40] or intestine combined with the liver.[38,39] In the report of these cases, there is an open discussion on whether the colon should be transplanted together with the small bowel.[37–40]

Ten consecutive patients with early-onset congenital MVA/MVID were evaluated between 1995 and 2002 at Necker-Enfants Malades Hospital (Paris) for potential small bowel transplant. Two patients died before they could be put on the waiting list, and one patient is still awaiting small bowel transplant. We performed cadaveric intestinal transplant in seven patients aged between 3 and 11 years in conjunction with the use of tacrolimus, steroids, and interleukin-2 blockers. Three isolated intestinal transplants and four liver-associated intestinal transplants were performed. Right colon transplant was performed in five cases (two isolated intestinal transplants). One patient died during transplant surgery from acute liver failure and hemodynamic shock, probably owing to a so-called reperfusion shock. The other six patients (86%) survived with a median follow-up of 3 years (range 1–8 years). Graft rejections occurred in two patients (one small bowel, one small bowel and liver) and responded favorably to methylprednisolone pulses. All patients were completely weaned from PN. The five patients with an additional colon graft were weaned off PN after a median 36 days postsurgery. In comparison, those without a colonic transplant obtained full intestinal autonomy several months after transplant. Thus, the Paris experience shows that small bowel transplant alone or in combination with liver transplant is highly successful in children with MVA/MVID, offering a longer-term perspective for patients for the first time. Additional colon grafting markedly improves outcome and quality of life after small bowel transplant in MVA/MVID. These preliminary results of intestinal transplant in this rare disease are very encouraging and demonstrate that the prognosis of MVA/MIVD has changed dramatically during the last decade.

Finally, in a child suspected of having MVA/MVID, a precise classification to one of three different variants (congenital [early onset], late onset, or atypical) should be obtained as early as possible and confirmed by an experienced pathologist according to clearly defined morphologic criteria. This is particularly important in light of the recent report of Croft and colleagues reporting on a 5-year-old girl with a late-onset form of MVA who was weaned from total PN and is thriving on a normal unrestricted diet.[41] There is some evidence to believe that this rare form of MVA has a better prognosis than the most frequent form of congenital MVA/MVID, which has a high mortality rate.[16]

Given the high success rate of small bowel transplant in MVA/MVID resulting in restored digestive autonomy, it is recommended that once the diagnosis of congenital MVA/MVID has been made and the child is in a eutrophic phase under total PN, transplant should be considered.[42–45] This approach should avoid PN-associated liver impairment. Conversely, patients with a late-onset or atypical form of MVA/MVID should not be automatically scheduled for small bowel transplant. The individual course of the disease will help to decide whether an individual child is a candidate for intestinal transplant.

INTESTINAL EPITHELIAL DYSPLASIA (TUFTING ENTEROPATHY)

In 1994, three cases of neonatal severe diarrhea with abnormal epithelial pictures were reported by Reifen and colleagues under the name of "tufting enteropathy."[46] One year later, Goulet and colleagues reported nine cases of severe neonatal diarrhea that were clearly different from MVA/MVID.[13] Further studies demonstrated that intestinal epithelial dysplasia is an epithelial disorder of the intestinal mucosa involving both small intestine and colon.[47] Intestinal epithelial dysplasia seems to be frequent in patients of Arabic, Middle Eastern, or North African origin.[13] One other characteristic of this recently described disease is its clinical and histologic heterogeneity and its association with malformation or other epithelial disease.

Clinical Expression

Typically, the patients present during the first weeks of life with severe diarrhea. Most have consanguineous parents and/or an affected sibling, some of whom have died during the first months of life with severe diarrhea of unknown origin. Most of the time, diarrhea persists in spite of bowel rest but at a lower level than in MVA/MVID patients, thus justifying attempts at continuous enteral feeding using protein hydrolysates or amino acids. Usually, continuous enteral feeding results in a worsening diarrhea; the newborn does not grow adequately and rapidly develops failure to thrive, with severe protein-energy malnutrition. The early onset of diarrhea may indicate a diagnosis of MVA/MIVD, but this is easily excluded by performing a proximal small intestinal mucosal biopsy with histologic investigations (see above). The disease is not well recognized owing to its recent description, and its clinical and histologic heterogeneity make diagnosis difficult.

Histologic Presentation

Villous atrophy is present but variable in severity. In typical intestinal epithelial dysplasia, abnormalities are localized mainly in the epithelium and include a disorganization of surface enterocytes with focal crowding, resembling tufts (Figure 43.3-4). These characteristic "tufts" of extruding epithelium, first described by Reifen and colleagues,[46] are seen toward the villus tip and may affect up to 70% of villi. The tufting process is not limited to the small intestine but involves colonic mucosa.[13] This picture can also be observed in crypt epithelium, and, in addition, crypts often have an abnormal aspect with dilatation, such as pseudocysts and abnormal regeneration with branching

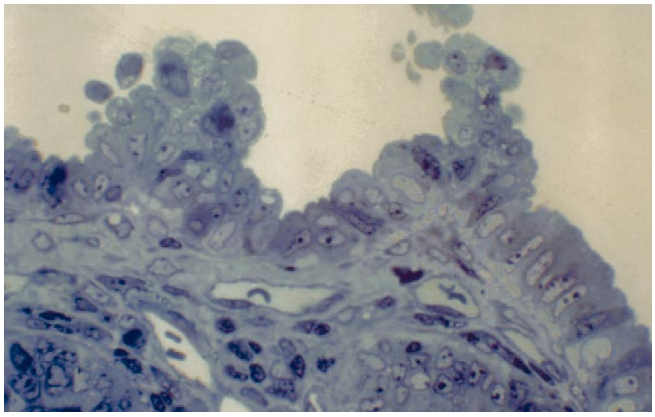

FIGURE 43.3-4 Intestinal epithelial dysplasia. Disorganization of surface epithelium showing tufts with apical rounding epithelial cells (hematoxylin and eosin; ×120 original magnification).

(Figure 43.3-5).[13] The study of basement membrane components has demonstrated an abnormal laminin and heparan sulfate proteoglycan deposition compared with biopsy specimens from patients with celiac disease or autoimmune enteropathy.[13] Relative to controls, there was faint and irregular laminin deposition at the epithelial lamina propria interface, whereas heparan sulfate proteoglycan deposits were large and lamellar, suggestive of an abnormal development of the basement membrane at the origin of the epithelial abnormalities. On the other hand, Patey and colleagues have shown an increased immunohistochemical expression of desmoglein and ultrastructural changes of desmosomes that are increased in length and number (Figure 43.3-6).[47] It is not clear if these changes are secondary or primary characteristics.

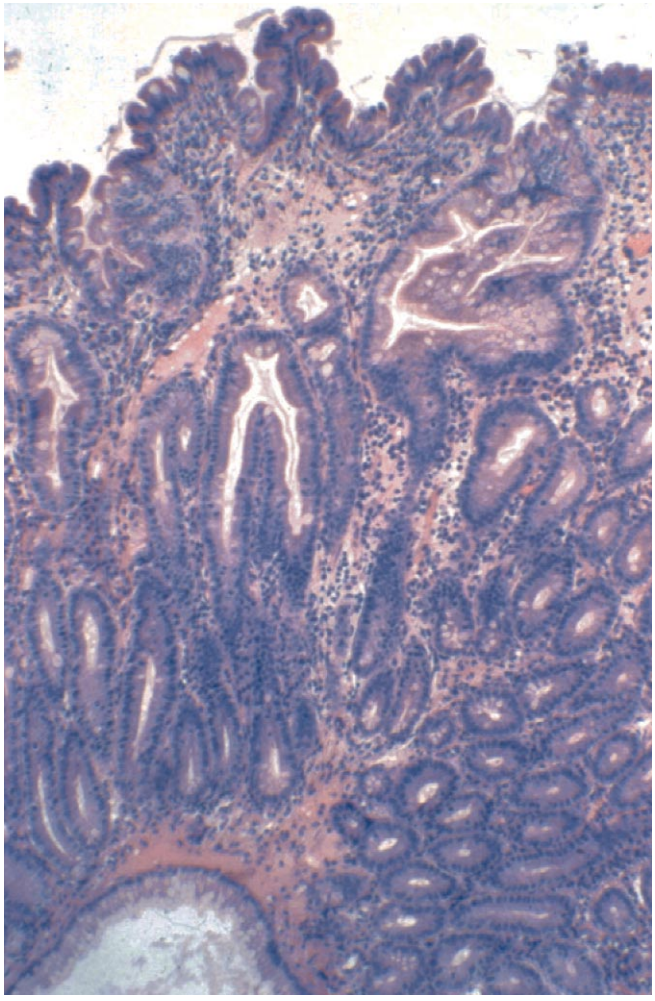

FIGURE 43.3-5 Intestinal epithelial dysplasia. Partial villous atrophy with crypt hyperplasia and/or pseudocystic crypt appearance, branching pictures, and disorganization of surface epithelium (hematoxylin and eosin; ×120 original magnification).

Difficult Diagnosis

Diagnosis of intestinal epithelial dysplasia may be difficult for several reasons. Despite the early onset of severe and permanent diarrhea and failure to demonstrate microvillous inclusion disease, the characteristic "tufts" of extruding epithelium do not appear clearly. In the initial experience, diagnosis has been made late in the illness, whereas initial biopsies performed during early life showed only nonspecific villous atrophy with or without monocellular cell infiltration of the lamina propria. Thus, only strict elimination of microvillous inclusion disease and repeated duodenal or jejunal biopsies allow diagnosis. In addition, it is rare and difficult to show any specific abnormalities of basement membrane components, integrins, or desmosomes in the mucosa in the absence tufts. The second difficulty is related to the infiltration of the lamina propria by T cells, some of which are being activated. Such infiltration suggests the hypothesis of immune-related enteropathy as previously described, particularly when tufts are missing or ignored. Defective cell adhesion toward the villus tips leads to increased intestinal permeability with subsequent severe secondary inflammation. A mouse model of dysfunctional E-cadherin clearly demonstrated that primary disorders of epithelial permeability or integrity could induce secondary T cell–mediated changes.[48] These changes were reported by Murch and colleagues in infants with epithelial dysplasia.[49] They showed that inhibition of secondary T-cell activation significantly improved enteral absorption and decreased crypt cell proliferation, although without permanent resolution of the severe diarrhea.

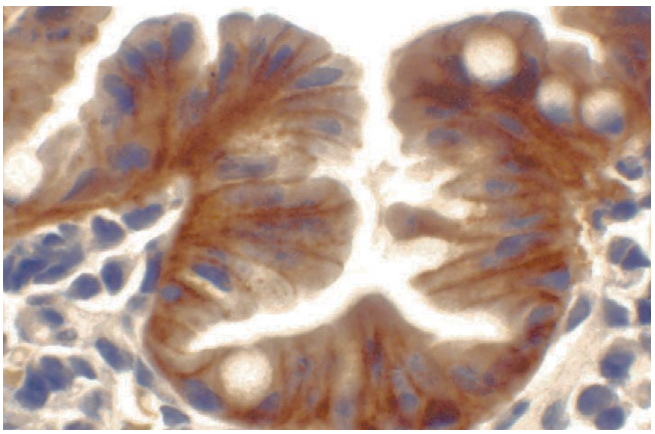

FIGURE 43.3-6 Intestinal epithelial dysplasia (desmoglein stain; ×300 original magnification).

Associated Disorders

Several cases of intestinal epithelial dysplasia have been reported as being associated with phenotypic abnormalities, for example, Dubowitz syndrome or malformative syndrome.[50,51] An association between congenital IDI and choanal atresia was recently reported in four children.[50] Djeddi and colleagues observed malformations, including rectal atresia or esophageal atresia. In addition, it became very common to detect punctiform keratitis in infants with intestinal epithelial dysplasia.[52] We recently reported an associated nonspecific punctiform keratitis in about 50% of patients with clinically and histologically recognized intestinal epithelial dysplasia. This association is important to know for diagnostic evaluation, which should include a systematic ophthalmologic examination by an experienced specialist. The fact that some children do not have such abnormalities confirms the heterogeneity of the disease.

Interestingly, Lachaux and colleagues have recently reported a case of a newborn presenting with pyloric atresia and intractable diarrhea.[53] Light microscopic examination showed extensive desquamation from the fundus to the rectum, with only a few epithelial cells remaining at the base of the crypts. Electron microscopy of the gut revealed normal desmosomes but a cleavage located between the lamina propria and the basal pole of the enterocytes. This first described disease is supposed to be related to congenital deficiency of $\alpha_6\beta_4$ integrin. This integrin is known to be defective in epidermolysis bullosa, in which gross epidermal shedding occurs, although the cutaneous expression of $\alpha_6\beta_4$ integrin appeared normal in this case of IDI. This is consistent with a mutation within an intestinal isoform of the $\alpha_6\beta_4$ integrin or a deficiency of a related and immunohistochemically cross-reactive intestinal integrin.[54,55] Rather like epidermolysis bullosa, which shares several similarities at the ultrastructural level and possibly the molecular level, there are likely to be several distinct mutations that can cause this phenotype.

Pathophysiology and Mode of Transmission

In infants with intestinal epithelial dysplasia with characteristic tufts, Goulet and colleagues reported abnormal laminin and heparan sulfate proteoglycan deposition on basement membrane compared with biopsy specimens from patients with celiac disease or autoimmune enteropathy.[13] Basement membrane molecules are involved in epithelial mesenchymal cell interactions, which are instrumental in intestinal development and differentiation.[56–59] Alterations suggestive of abnormal cell-cell and cell-matrix interactions were seen in patients with epithelial dysplasia without any evidence for abnormalities in epithelial cell polarization and proliferation.[47] Alterations included abnormal distribution of adhesion molecules $\alpha_2\beta_1$ integrin along the crypt-villous axis. The $\alpha_2\beta_1$ integrin is involved in the interaction of epithelial cells to various basement membrane components, such as laminin and collagen. There is no clear explanation for the reported increased immunohistochemical expression of desmoglein or for the ultrastructural changes affecting desmosomes, which are increased in length and number (see Figure 43.3-6).[47] Tufts correspond to groups of nonapoptotic cells that are no longer in contact with basement membrane. The increased cell-cell adhesion suggested by the modification of desmoglein distribution and the ultrastuctural changes of desmosomes in tufted cells might contribute to the inhibition of apoptosis. A mouse in which the gene encoding the transcription factor Elf3 is disrupted has morphologic features ressembling epithelial dysplasia in infants.[60] In this mouse model, there is abnormal morphogenesis of the villi while progenitor crypt cells appear normal. The enterocytes in Elf3-deficient mice produce low levels of transforming growth factor-β type 2 receptor, which induces the differentiation of immature intestinal epithelia. Currently, in human infants, the primary or secondary nature of the observed modifications remains to be determined. Both the clinical studies and the findings in experimental animal models should provide clues to the pathogenesis of these epithelial abnormalities and to the severity of this neonatal diarrhea.[60,61]

To date, the genetic origin of this disorder is suspected from the clear association of parental consanguinity and/or affected siblings. These features suggest an autosomal recessive transmission. The gene involved in this congenital inherited autosomal recessive disease remains to be found. This enteropathy, in which epithelial shedding clearly proceeds aberrantly, has been reported as a cause of IDI and may be more common than MVA/MVID, especially within the Middle East and Maltese population. The above-described associated disorders, especially punctiform keratitis, might be helpful in approaching the genetic nature of this rare and severe epithelial disease.

Outcome

This neonatal diarrhea, which resists all treatments, requires permanent PN. However, it seems that some infants have a rather milder phenotype than others.[62] Because of partial intestinal function and limited amount of stool output, some patients need only partial long-term PN with 3 to 4 times weekly infusion. However, careful monitoring should be performed to avoid progressive growth retardation. In most patients, the severity of intestinal malabsorption and diarrhea makes them totally dependent on daily long-term PN, with the subsequent risk of complications. It is thus another indication for intestinal transplant.[63–65] There is a suggestion that intestinal epithelial dysplasia may ameliorate with age,[62] but this needs further study.

SYNDROMATIC DIARRHEA

These patients present with diarrhea starting in the first 6 months of life (< 1 month in most cases) and have several features in common. They are small for gestional age and have an abnormal phenotype.[12] All have facial dysmorphism with a prominent forehead, a broad nose, and hypertelorism (Figure 43.3-7). They have a distinct abnormality of hair, tricorrhexis nodosa, in which the hair is woolly, difficult to manage, easily pulled out, and poorly pigmented even in children of Middle Eastern origin. In addition, the

FIGURE 43.3-7 Syndromatic diarrhea. Patient with an abnormal face, a prominent forehead, a broad nose, and hypertelorism.

previously reported patients had defective antibody responses despite normal serum immunoglobulin levels and defective antigen-specific skin tests despite positive proliferative responses in vitro.[12] Small bowel biopsy specimen of the patients with syndromatic diarrhea show moderate or severe villous atrophy with variable mononuclear cell infiltration of the lamina propria and absence of epithelial abnormalities. Histologically, there are no specific abnormalities. Prognosis of this type of intractable diarrhea of infancy is poor because most patients have died between the ages of 2 and 5 years, some of them with early onset of liver disease.[12] The cause of this diarrhea is unknown, and the relationship between low birth weight, dysmorphism, severe diarrhea, trichorrhexis, and immune deficiency is unclear. Among the congenital forms of hair dysplasia, tricorrhexis nodosa is very common and can be present in several pathologic conditions.[66–70]

The coexistence of morphologic, trichologic, and immunologic abnormalities with early-onset intractable diarrhea disproportionate to the mucosal architectural abnormality (consistent with a primary enterocyte abnormality) suggests either mutation within several genes, inherited together by linkage disequilibrium, or more probably interference with a higher level of control, such as a patterning gene. The characteristic hair abnormalities may allow a more focused search for candidate mutations because relatively few patterning genes have been implicated in hair development. These include suggestively lymphoid enhancer factor 1, as well as fibroblast growth factor 4, Sonic hedgehog, and bone morphogenetic protein 2.[71,72] In addition, transgenic knockout mice null for various FGH and EGH family members exhibit a range of defects in hair development.[72]

Syndromatic diarrhea represents a separate entity within the syndrome of intractable diarrhea of infancy and seems different from trichohepatoenteric syndrome. This syndrome has been described in two siblings presenting with neonatal hemochromatosis phenotype, intractable diarrhea, and hair anomalies.[66] Prenatal symptoms were intrauterine growth retardation, hydramnios, and placental hyperplasia. Clinical anomalies included hypertelorism and sparse, thin, curly hair (trichomalacia). Clinical course was marked by intractable diarrhea, with normal histologic and enzymologic studies, cholestatic jaundice, hepatomegaly appearing after 30 days, and progressive liver failure, leading to death after a few months. The only metabolic anomaly was progressive hypermethioninemia. Pathologic examination of both children showed a similar pattern of multivisceral iron deposit compatible with a diagnosis of neonatal hemochromatosis.

Finally, dysmorphologenetic aspects, hair abnormalities, and immune function should be reassessed in other cases of syndromatic diarrhea, and relationships with other disorders should be sorted out. Immune dysfunction seems to be an integral part of the disease but needs to be further characterized.[73]

OTHER DISEASES OF INTESTINAL EPITHELIUM

The classification of IDI is probably incomplete because other forms with abnormal small bowel mucosa have been described, including mitochondrial deoxyribonucleic acid (DNA) rearrangements,[74] congenital enterocyte heparan sulfate deficiency,[75] phosphomannose isomerase deficiency, and a carbohydrate-deficient glycoprotein syndrome with hepatic-intestinal presentation.[76,77] Rare diseases involving the immune system and small bowel mucosa[78] or severe intractable enterocolitis of infancy[6] also seem clearly different from the above-described epithelial diseases.

In conclusion, progress has been made within this heterogeneous group of patients in the characterization of different conditions. When confronted with the diagnosis of IDI, clinical and histologic data should be taken into account. Such an analysis may allow a broad classification, even in the absence of immunohistochemical studies. The main clinical criteria that should be considered are birth weight, familial history, date of onset and characteristics of diarrhea (watery and/or bloody, persistent despite bowel rest), the existence of extradigestive manifestations, the presence of gut and/or other autoantibodies, and the existence of phenotypic abnormalities. Protracted diarrhea of infectious or allergic origin and/or immunodeficiency has to be eliminated. MVA/MVID can be diagnosed easily by performing PAS staining and electron microscopy. Tables 43.3-1 and 43.3-2 summarize the features of distinctive disorders within the syndrome of intractable diarrhea with persistent villous atrophy. The proposed classification is provisional but indicates that there are different pathogenetic mechanisms operating in

the clinical groups of patients with IDI and may allow specific treatment to be pursued.

CHAPTER 44

ENTEROPATHY

1. *Celiac Disease*

Markku Mäki, MD, PhD
Olli Lohi, MD, PhD

Samuel Gee accurately described the classic form of childhood celiac disease, the malabsorption syndrome in infancy, in 1888.[1] Throughout the twentieth century, celiac disease has puzzled clinicians and investigators. The major breakthrough and milestone in understanding the disease came from pioneering clinical research performed by Dr. Willem Karel Dicke in the Netherlands. He discovered the harmful effect of dietary gluten in celiac disease.[2] He writes in his thesis summary that the harmful effect on patients with celiac disease is not caused by all cereals but specifically by wheat flour. Also, rye elicited or aggravated the clinical symptoms and signs, but wheat starch did not give rise to the phenomena. With construction of a peroral intestinal suction biopsy apparatus in the late 1950s, it became evident that gluten induces small intestinal villous atrophy and crypt hyperplasia. In the 1960s, it was shown that the mucosa heals on a gluten-free diet, and it became evident that gluten intolerance in celiac disease is permanent.[3] One important milestone in celiac disease clinics was the discovery of the circulating gluten-dependent autoantibodies,[4,5] the importance of which became evident only later. Celiac disease aggregation in families was a first clue to genetic susceptibility,[6] and evidence for a primary association of the disease with human leukocyte antigen (HLA)-DQ2 was shown.[7] In 1997, a new era in celiac disease clinics and research began with the discovery of transglutaminase 2 (TG-2; former tissue transglutaminase) as the autoantigen for celiac disease, the human antigen targeted by serum autoantibodies.[8]

DEFINITION OF CELIAC DISEASE

The synonyms in the literature for celiac disease are celiac sprue and gluten-sensitive enteropathy. Celiac disease is an autoimmune-like systemic disorder in genetically susceptible persons perpetuated by the daily-ingested gluten cereals wheat, rye, and barley with manifestations in the intestine and in organs outside the gut. Today it is understood that the nature of celiac disease is much more complex than simply intestinal malabsorption, which, as such, is, in fact, no longer essential for the diagnosis.

GLUTEN: THE MAJOR ENVIRONMENTAL TRIGGER

Cereals are cultivated almost all over the world and form one important component in human nutrition. Wheat, rice, and corn are spread worldwide, and rye, barley, oat, millet, and sorghum are of importance for specific regions. Figure 44.1-1 shows the taxonomic relationship of the gluten-containing cereal grains that activate celiac disease. Wheat, rye, barley, and oat are, by definition, "gluten." Of these, the first three with excellent baking properties belong to the tribe Triticeae, whereas oat belongs to a different tribe but to the same grass subfamily as wheat, rye, barley, and rice.

Intestinal inflammation and damage in celiac disease are tightly dependent on dietary exposure to prolamins present in wheat, barley, and rye. Prolamins are characterized by their high content in glutamine (35–37%) and proline (17–23%) residues. Wheat gluten consists of a complex mixture of many gliadin and glutenin polypeptides. Gliadins are monomers, whereas glutenins form large polymeric structures. Gliadins are 250– to 300–amino acid–long polypeptides, and on the basis of their amino acid sequences, they can be subdivided into α-, γ-, ω-gliadins and glutenins divided into high- (650–800

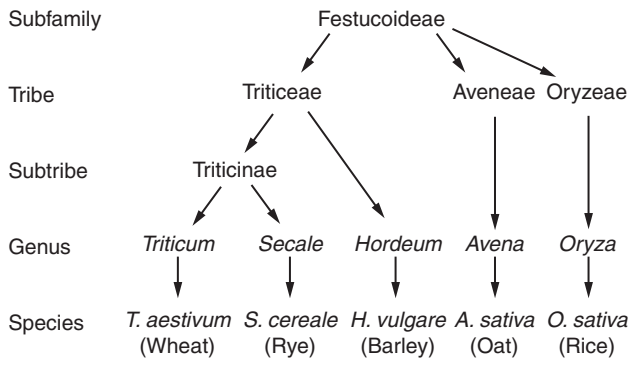

FIGURE 44.1-1 Taxonomy relationships of major cereal grains. Adapted from Kasarda DD.[9]

residues long) and low- (270–330 residues long) molecular-weight proteins. Furthermore, toxic prolamin peptide structures can be found in rye (secalins) and barley (hordeins),[9] which are similar to wheat gliadin peptides.[10] T-cell stimulatory peptides, as discussed below, are also to be found in rye and barley prolamines but not in avenins from oat.[11] However, looking at the literature in a modern, evidence-based manner, only wheat has been scientifically proven to induce disease. Regarding rye and barley, the evidence is based more on consensus, and clinical research has been scarce. Rice, corn, buckwheat, millet, and sorghum are not harmful for celiac disease patients. The case of oat, which is still under debate, is discussed separately. Also, other environmental triggers may be operative, but whatever the other "secondary hits" might be, the disease responds favorably when only one trigger is removed, the dietary gluten.

Oat and Celiac Disease

Even if oat is defined as gluten, its toxicity in celiac disease was readdressed in the early 1990s.[12] When the literature was re-evaluated, it was clear that earlier evidence was not thorough. Some studies were interpreted to prove that oat is harmful[13,14]; some stated that oat can be consumed by celiac disease patients without detrimental effects.[15–17] The reliability of these studies could be questioned because the evidence was based on a few patients, 1 to 12 studied cases, and none of the studies were controlled. In one study only, small intestinal biopsies had been performed.[17] In the study by Janatuinen and colleagues, oat proved to have no detrimental effect on nutritional status, laboratory values, or small intestinal mucosa in celiac disease patients in remission at 6 months, nor did it prevent the intestinal mucosa of newly diagnosed patients from healing after 1 year of treatment.[12] These results were later confirmed in other studies.[18–21] It has also been suggested that including oat can help celiac disease patients follow a strict gluten-free diet.[22] Dermatitis herpetiformis patients, who are thought to be very sensitive to gluten, do also seem to tolerate oat.[23,24] In the United States, Hoffenberg and colleagues first showed oat to be nonharmful for children with celiac disease.[25] In a recent 1-year randomized double-blind study comprising 93 children, a moderate amount of oat in a gluten-free diet did not prevent clinical or small intestinal mucosal healing or a humoral immunologic response.[26] Cereal toxicity studies using in vitro organ culture also point in the direction of nonharmfulness.[27,28] However, very recently, a patient intolerant to oat was identified.[29] It seems evident that, in rare cases, there are celiac disease patients who are intolerant to oat. They should be identified, and their diet should be designed not to contain oat.

GENETIC FACTORS

Celiac disease is a multifactorial disease in which, in addition to environmental triggers, inherited factors confer susceptibility. A clear observable clue to genetic susceptibility is the tendency of the disease to run in families.[6] The disease prevalence among the first-degree relatives of a proband has varied from 1 to 18%, often, as a rule, at about 10%.[30] The low-prevalence figures may be due to different screening strategies or the tendency of the disease to develop late, meaning that it is found in individuals who once had been excluded for the disease.[31,32] Celiac disease is also found in healthy relatives of multiple case families.[33,34]

The concordance and discordance rates of monozygotic and dizygotic twin pairs are often compared to define the balance between environmental and genetic factors of a disease. In celiac disease in a large twin study, Greco and coworkers found the concordance rate of monozygotic twins to be 86% compared with 20% in dizygotic twins.[35] This indicates that genes play a very important role. The literature is also knowledgeable of reported discordance in monozygotic twins, in whom concordance has developed later.[36] One should also remember that monozygotic twins are genetically not identical. The differences come from point mutations, skewed X-chromosomal inactivation, nondisjunctions, and gene rearrangements of immunoglobulin and T-cell receptors. Recently, it was clearly shown that one identical twin may have celiac disease, whereas the other suffers from dermatitis herpetiformis.[36]

The major histocompatibility complex (MHC) on chromosome 6 short arm (Figure 44.1-2) comprises a gene cluster including the HLA class II genes. The HLA genes are highly variable and polymorphic, which forms the basis for the immune system to recognize foreign and self-antigens, processed and presented by antigen-presenting cells. Certain HLA alleles are found to be associated with diseases, either in a protective or a predisposing manner, and many of these diseases are of an autoimmune nature. Celiac disease is strongly associated with the HLA class II extended haplotype DR3-DQ2 or DR5/7-DQ2. The DQ2 molecule, an α/β heterodimer, is located on the surfaces of cells involved in immune responses and is encoded by the alleles *DQA1*0501* and *DQB1*02* (in *cis*, in which both risk alleles are located in the same chromosome in linkage with DR3, and in *trans*, in which the individual is heterozygote for DR5 and DR7) (see Figure 44.1-2). Approximately 90% of the celiac disease patients carry the DQ2 molecule, and 10% of the patients are positive for DQ8 (DR4 haplotype), in which the α/β heterodimer is encoded by the genes *DQA1*0301* and *DQB1*0302*.[7,37,38] A large European multicenter study gave further evidence of the strong association to the risk alleles described above: from 1,008 celiac disease patients, 61 were identified to be negative for both DQ2 and DQ8. Fifty-seven of these encoded half of the DQ2 heterodimer. Only 4 were found to be negative for all known risk alleles.[39] Individuals not carrying any of the risk genes have a very low probability of developing celiac disease. Clinicians may take advantage of this knowledge, and a negative test for both DQ2 and DQ8 speaks against celiac disease.[40] On the other hand, even if most celiac disease patients carry the risk alleles, it must be borne in mind that in whites, 15 to 20% of the general population are DQ2 positive and another 20% are DQ8 positive. Owing to the extremely low DR3 gene frequencies in countries such as China and Japan and in black African countries, the probability of diagnosing celiac disease is very low.

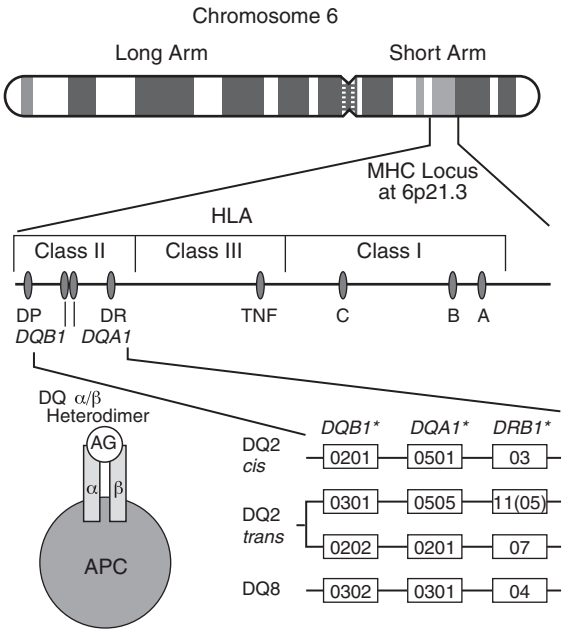

FIGURE 44.1-2 Human major histocompatibility complex (MHC) location in chromosome 6 short arm. In this locus, the key genetic risk factors for celiac disease and dermatitis herpetiformis, the human leukocyte antigen (HLA) class II genes *DQA1*05* and *DQB1*02* encoding the DQ2 α/β heterodimer molecule, are located. Individuals who have DR3 (the gene *DRB1*03*) almost always, owing to linkage disequilibrium, carry also the DQ alleles *DQA1*0501* and *DQB1*0201* in the *cis* position, that is, on the same chromosome. The genes encoding the DQ2 molecule may also be on different chromosomes, in *trans* position, *DQA1*05* in linkage with DR5 (*DRB1*11*) and *DQB1*02* in linkage with DR7 (*DRB1*07*). The genes encoding the DQ8 α/β heterodimer are located in the DR4 haplotype. The HLA class II molecules are situated on antigen-presenting cells (APC), and they have a groove where the antigen (AG) peptides are presented to T helper cells.

Disease concordance between HLA identical siblings is much lower than that in monozygotic twins, being approximately only 30%.[41] HLA genes are important but not sufficient to predispose them to celiac disease. Therefore, it is probable that other genes outside the HLA region are involved in celiac disease susceptibility. Recently, autosomal genomic screenings have provided evidence of linkage of several non-HLA loci to celiac disease.[42,43] There is now strong evidence of linkage at two non-HLA regions, chromosomes 5q31-33[44] and 19p13.1.[45] The linkage to a certain chromosome region does not, however, indicate which genes might be involved. One of the future targets for celiac disease research is to identify these genes and study their role in the disease.

PATHOGENESIS

Several major hypotheses regarding the nature of the primary host defect in celiac disease have been proposed during the past decades, namely, the missing enzyme theory, the immunologic hypothesis, the membrane glycoprotein defect, and the mucosal permeability defect. When the pathogenetic mechanisms are known, it may turn out that all of the above-mentioned and some so far unknown mechanisms are operative. Today there is evidence that celiac disease is a T cell–mediated chronic inflammatory bowel disorder with an autoimmune component, also with extraintestinal manifestations. There are three prominent features of celiac disease: (1) its remission is highly dependent on a strict gluten-exclusion diet; (2) it requires a unique genetic background for antigen presentation—expression of the HLA type II molecules DQ2 or DQ8; and (3) patients have specific circulating autoantibodies to the ubiquitous TG-2.[8] What is remarkable is the connection between these three characteristics: TG-2–deamidated (see below) gluten peptides presented in the context of DQ2 or DQ8 molecules stimulate proliferation of T cells derived from celiac patients and secretion of inflammatory cytokines, particularly interferon-γ, the expression of which is increased in active celiac disease. Parallel to this, B cells receive signals and, by an unknown mechanism, turn against the self, TG-2, and start producing autoantibodies. The role of TG-2 autoantibodies in the pathogenesis of celiac disease is unclear and controversial, although they have been shown to inhibit the differentiation of T84 crypt-like cells in a three-dimensional tissue culture model.[46] Interestingly, these autoantibodies can be found deposited in the subepithelial region of normal-appearing intestinal biopsies, targeting TG-2 even before the infiltration of T cells into lamina propria or the onset of evident celiac disease or even before the antibodies are measureable in the sera of patients.[47]

The DQ2 and DQ8 molecules are responsible for presenting celiac disease–related gluten peptides to T cells in the small intestine. When biopsies from treated celiac disease patients are challenged in vitro with gluten, the result is a strong stimulation of $CD4^+$ lamina propria T cells.[48] These T cells express α/β T-cell receptor, and they can be isolated and cultivated. Importantly, the T cells recognize only gluten peptides presented by DQ2 or DQ8 molecules.[49] The groove of HLA-DQ2 and -DQ8 molecules contains positively charged basic amino acid residues in several anchor positions and, therefore, predicts a preference for negative charges at critical positions of the bound peptides. However, gluten proteins are rich in proline and glutamine and contain few negatively charged residues. This obvious puzzle can be explained by the post-translational modification of glutamine residues in gluten by TG-2 enzyme.[50] TG-2 is a Ca^{2+}-dependent enzyme that modifies a whole range of proteins by crosslinking, transamidating, or deamidating specific polypeptide-bound glutamines.[51] It has been shown that TG-2 can deamidate gluten peptides in situ and that the lesion-derived T cells predominantly recognize deamidated gluten peptides, that is, peptides in which certain glutamine residues have been converted to negatively charged glutamic acids. Deamidation increases

the binding affinity of gliadin peptides for DQ2 and DQ8.[52] Detailed characterization of these peptides has demonstrated that there is no single pathogenic motif but instead many DQ2- and DQ8-restricted epitopes. The current estimate is that there are at least 50 T cell–activating epitopes present in gluten. T-cell populations that have several distinct gluten specificities can be derived from a single patient. On the other hand, there is a hierarchy of the epitopes in that some epitopes are recognized by T cells from almost all patients, whereas others have reactivity only in a minority of celiac disease patients.[53] One remarkable feature of T cell–stimulating gluten regions is the high content of proline residues. It is evident that prolines play a key role in determining the structure, immunogenicity, and proteolytic resistance of immunodominant gluten peptides. Experiments have shown that treating α_2-gliadin with a physiologic repertoire of digestive enzymes leads to the survival of 33-mer peptide fragment (Figure 44.1-3).[54] The 33-mer fragment has turned out to be an excellent substrate of TG-2, and it has been shown to be able to activate T-cell clones derived from celiac disease patients. It contains a cluster of partially overlapping T cell–stimulating epitopes (oligomerized epitopes). This kind of repetitive nature of epitopes enhances their T-cell activation potential. Intriguingly, degradation and loss of the antigenicity of 33-mer peptide could be induced by the addition of bacterial prolyl endopeptidase. This finding has opened up the possibility that specific prolyl endopeptidases could be used to detoxify this and potentially other proline-rich, digestion-resistant gluten peptides.

In active celiac disease, the level of TG-2 expression is increased: TG-2 is expressed at the epithelial brush border and extracellularly in the subepithelial region.[8,50] The pH in the proximal small intestine is about 6.6. This should enable the deamidation of gluten peptides in the luminal side of small intestine because it has been demonstrated that the propensity for deamidation compared with transamidation is markedly increased when the pH is below 7.3.[55] Another possibility is that TG-2 is endocytosed and active during the early stages of the endocytic process, when the pH is slightly acidic. Thus, gluten peptides could undergo TG-2–mediated deamidation during the endocytosis and before the peptides bind to the DQ2 or DQ8 molecules in the endosomes of antigen-presenting cells.

A crucial question in understanding the pathomechanisms of celiac disease is why only gluten, of the many food proteins, brings about such a harmful immune response. The increased level of TG-2 expression in the mucosa of celiac patients seems to be related to inflammation. Infection and inflammation, in turn, might breach the epithelial barrier of intestine and lead to harmful influx of gluten peptides into the lamina propria. The higher concentration of gluten peptides in the lamina propria and the abundant TG-2 would promote the formation of deamidated peptides. In experimental animal models, oral administration of antigens induces systemic hyporesponsiveness, defined as oral tolerance.[56] Although it is not clear if oral tolerance operates in humans by this definition, it is obvious that the immune system of the gut tries to ensure that immune responses to food proteins are not mounted normally. Therefore, it can be envisaged that tolerance to gluten in celiac disease is either not established or is broken in early childhood. The absence of intestinal T-cell responses to gluten in nonceliacs and the preferential recognition of deamidated gluten peptides suggest that there is, in the beginning, tolerance to unmodified gluten fragments. Accordingly, deamidation and the altered affinity of modified peptides for DQ2 and DQ8 would be the key event leading to the disruption of tolerance in celiac disease patients. Another possibility is that gluten could function as an adjuvant factor in eliciting T-cell responses, or short gluten peptides might reach the underlying lamina propria of the gut at higher concentrations than do other food protein peptides.

Recently, a novel aspect of the pathogenesis of celiac disease has been described. By using in vitro organ cultures, Maiuri and colleagues demonstrated that intestinal immune reactions in celiac disease are partly driven by the (less specific) innate immune system, which provides a quick, so-called pattern recognition response to stimuli such as viral and bacterial proteins.[57] Maiuri and colleagues' data propose that certain gluten peptides elicit an early innate immune response (the toxic peptide[10,58]; see Figure 44.1-3), whereas immunodominant peptides[59] drive much slower adaptive immunity (which is dependent on HLA presentation, T-cell recognition, and T-cell expansion), and that in the pathogenesis of celiac disease, there is an interplay between these mechanisms.

CLINICAL DISEASE

Malabsorption Syndrome

Characteristically, celiac disease manifests during infancy and before school age. In the classic form of childhood celiac disease, symptoms and signs of malabsorption become obvious within some months of starting a gluten-

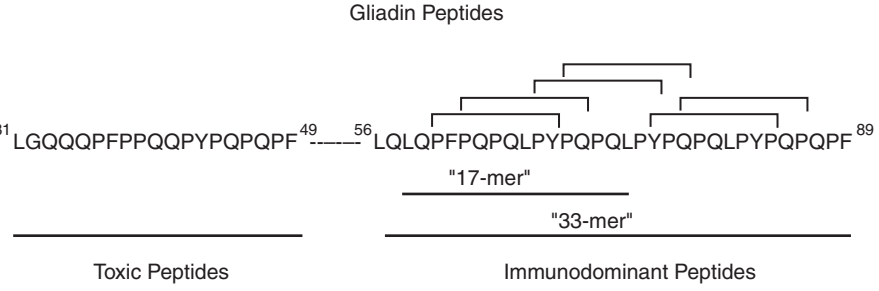

FIGURE 44.1-3 Amino acid sequences of part of domain I of A gliadin showing three proline- (P) and glutamine- (Q) rich peptides known to be either toxic or immunogenic for celiac disease (explained in the text). Within the immunodominant peptides, especially the 33-mer, several T-cell epitopes can be identified (oligomerized epitopes).

containing diet. The child has chronic diarrhea or loose stools and vomiting, and the abdomen is distended (Table 44.1-1 and Figure 44.1-4). Typically, the child presents with failure to thrive, and proximal muscle wasting may be seen. These symptoms are those of classic celiac disease (see Figure 44.1-4). Young infants with a malabsorption syndrome and prolonged diarrhea, as presenting in the 1960s,[60–63] may be hypotonic and have other symptoms of severe enteropathy, for example, dehydration, hypoproteinemia, hypokalemia, hypoprothrombinemia, and hypocalcemia. Rickets may be a presenting symptom even in one-fourth of the children diagnosed for celiac disease.[64] In some communities, the delay in diagnosis might be due to the presence of other diseases clinically resembling celiac disease.[64] Table 44.1-2 lists disease conditions that may be interpreted as celiac disease also at a small intestinal mucosal level.

Presenting signs of malabsorption in celiac disease in older children may be short stature,[65–68] delayed puberty,[67] iron deficiency anemia,[67,69,70] and osteoporosis.[71] The older the child is, the more diffuse are the symptoms, and gastrointestinal symptoms may be totally missing.

Changing Clinical Features

Nowadays, celiac disease presenting with a malabsorption syndrome is an exception, not the rule, and a changing symptom pattern has been experienced in most countries.[72] During the early 1980s, it was reported that childhood celiac disease was disappearing,[73–75] but this seemed not to be true. Rather, clinicians were experiencing a changing pattern of disease presentation with milder symptomatology and an increase in the age at diagnosis (Figure 44.1.-5).[67,76] Later evidence has verified this to have been a general trend throughout Europe.[77]

One exception existed: Sweden. Ivarsson and colleagues described a countrywide epidemic of a chronic malabsorptive syndrome in infancy during a 10-year period from 1985 to 1995.[78] The annual incidence rate increased fourfold in children less than 2 years of age, when, at the same time, such cases disappeared in a neighboring country, Finland.[67,79] Before the epidemic in 1983, the recommendations for gluten introduction were changed from 4 months to 6 months of age. Also, in 1983, the amount of gluten in the industrially produced weaning food gruels and porridges in Sweden was doubled on average. The only difference between these two countries was the amount of gluten ingested by infants. Healthy infants in Sweden ingested two to three times more wheat protein than did infants in Finland. They also consumed 50% more than infants did in 1978, which was before the onset of increase in incidence.[79] Finnish infants again received more barley and oat. An important message here is that

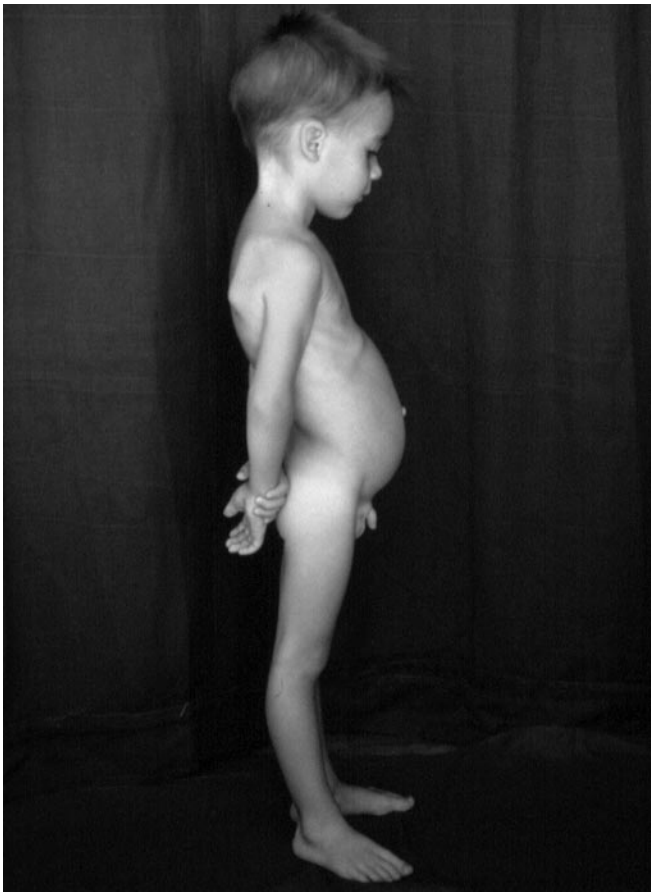

FIGURE 44.1-4 A 4-year old boy with newly diagnosed celiac disease presenting with loose stools and recurrent abdominal pain. He also had growth retardation and muscle weakness. A distended abdomen is seen. Photograph courtesy of Dr. Ilma Korponay-Szabo, Heim Pál Children's Hospital, Budapest, Hungary.

TABLE 44.1-1 DATA ON 53 CONSECUTIVE PATIENTS SUFFERING FROM CELIAC DISEASE AT ADMISSION TO THE CHILDREN'S HOSPITAL, UNIVERSITY OF HELSINKI, DURING THE 1960S

General data	
Number of patients	53
Age at onset of the symptoms (mo)	7.7
Gluten in the diet before the onset of symptoms (mo)	4.3
Age on admission (mo)	10.2
Symptoms	
Diarrhea or altered stools	87%
Vomiting	74%
Failure to gain weight	98%
Signs	
Weight below the 2.5th percentile	70%
Distended abdomen	64%

new authority directives or other changes within the community may change the disease panorama completely even during a short time period.

Case Finding

The observation that celiac disease exists in a completely asymptomatic form was obtained from gluten challenge[63,80] and family studies.[6,30] Today it is clear that celiac disease with typical gastrointestinal symptoms represents only the tip of the iceberg (Figure 44.1-6).[81,82] In clinically silent celiac disease, a manifest mucosal lesion, which is gluten dependent, can be found on biopsy. The mucosal lesion responds favorably to a gluten-free diet. The reliable serologic screening tools, as discussed below, allow us today to detect such cases. On the other hand, one may also argue that clinically silent celiac disease, as such, is just an undiagnosed condition.

Celiac disease can be found in children with traditional symptoms and signs but in a very mild form (Table 44.1-3).[63] Abdominal discomfort, loose stools, flatulence

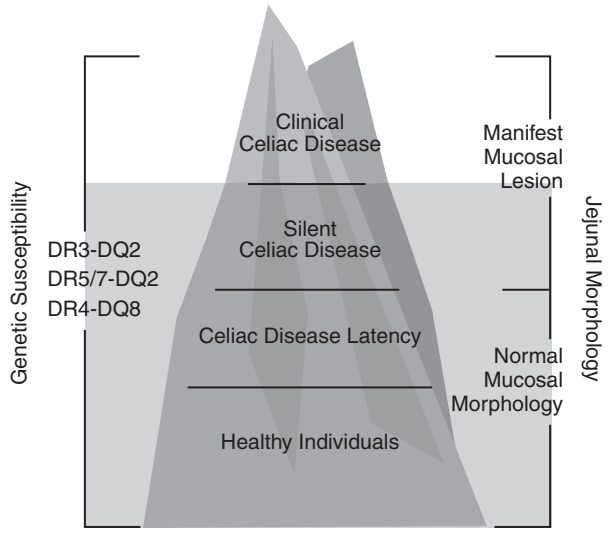

FIGURE 44.1-6 The iceberg of celiac disease. Adapted with permission from Mäki M and Collin P.[82]

TABLE 44.1-3 DIAGNOSTIC APPROACH IN FINDING CELIAC DISEASE IN INDIVIDUALS WITHOUT CLEAR SYMPTOMS SUGGESTING JEJUNAL MUCOSAL ATROPHY

Policy
High index of suspicion of celiac disease
Liberal use of serologic screening tests
Case finding in patient groups
Minor abdominal symptoms (abdominal discomfort, loose stools, recurrent abdominal pain, lactose intolerance)
Growth failure, delayed puberty, iron deficiency anemia, rickets
Other chronic or celiac disease related diseases (type 1 diabetes, thyroid disease, selective IgA deficiency)
Skin disorders, suspected dermatitis herpetiformis
Celiac-type, permanent tooth enamel defects
Joint symptoms as arthralgia, arthritis
Liver diseases
Some neurologic diseases
Down syndrome, Turner syndrome
Healthy first-degree relatives of celiac patients

problems, recurrent abdominal pain, and diagnosed lactose intolerance are conditions in which celiac disease should be sought. Arthritis and arthralgia may also be presenting symptoms in celiac disease.[83] As mentioned earlier, short stature, delayed puberty, and isolated nutritional deficiencies are already signs of malabsorption, even in cases with no gastrointestinal symptoms.

In addition to finding clinically silent celiac disease in healthy first-degree relatives of celiac disease patients,[6,30–34] the disease is highly prevalent in type 1 diabetes mellitus (2–5%),[84,85] in individuals with selective immunoglobulin A (IgA) deficiency (10%),[86] and in Down syndrome (10%).[87,88]

It is widely accepted that dermatitis herpetiformis is gluten induced, has the same genetic background as celiac disease,[36,38] and is a classic example of the extraintestinal manifestation of the disease.[89] Other linked disorders include permanent-tooth enamel defects,[90] central and peripheral nervous system involvement,[91,92] liver involvement,[93,94] and even autoimmune diseases in general.[95] A risk for a malignant complication of untreated celiac disease seems not to be as high as previously thought.[96]

DIAGNOSTIC CRITERIA

The gold standard for clinical diagnosis is the initially manifested small intestinal mucosal lesion, villous atrophy, together with crypt hyperplasia (Figure 41.1-7). Another characteristic is an increased density of intraepithelial lymphocytes.[97] Heavy cellular infiltrativity is not always present in untreated celiac disease. The European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN; formerly ESPGAN) set the criteria for the diagnosis in 1970.[98] It was stated that a patient with absent or almost absent villi who shows definite improvement on a gluten-free diet cannot be designated as having celiac disease before he has been proved to normalize on a dietary treatment, not only clinically but also histologically, and subsequently to relapse after reintroduction of gluten. This

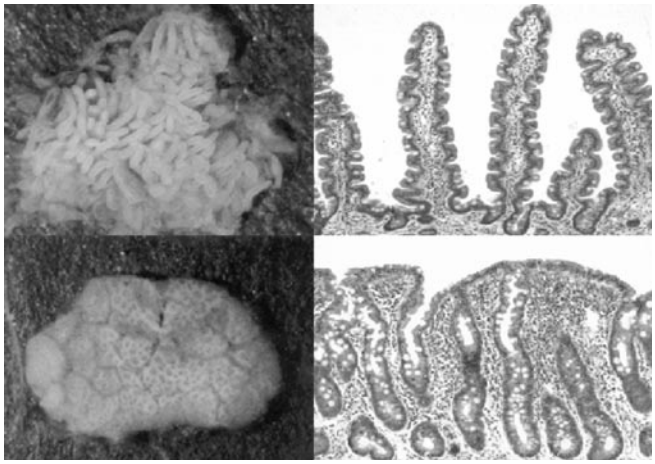

FIGURE 44.1-7 Dissection microscopic (*left*) (×50 original magnification) and histologic sections (*right*) (hematoxylin and eosin; ×280 original magnification) of small intestinal mucosal biopsy specimen with normal mucosal morphology with high villi (*upper*) and celiac disease (*lower*) (subtotal villous atrophy with crypt hyperplasia).

implies that three small intestinal biopsies should be performed. Also, a "2-year rule" was developed. It implicated that on gluten challenge, there should be a recurrence of the mucosal lesion within 2 years of gluten reintroduction. These strict criteria were later revised. However, the cornerstone remained the same, that is, in the initial biopsy, flat small intestinal mucosa should be found.[99] Neither repeated biopsy nor gluten challenge was considered mandatory in cases with full clinical remission after withdrawal of gluten from the diet. However, in uncertain cases, the old criteria may still be used, particularly when other diseases clinically complicate or resemble celiac disease (see Table 41.1-3).

Today clinicians may use new tools, serology (endomysial or TG-2 autoantibodies), and HLA-DQ typing. Positivity for the autoantibodies is an accurate indication of manifest small intestinal mucosal lesion (see below). On the other hand, negativity for the alleles encoding DQ2 and DQ8 speaks strongly against celiac disease.[40] In developing countries, the TG-2 autoantibody positivity is also highly indicative of celiac disease.[8,100] On a population-based level, the endomysial and TG-2 autoantibody positivity goes hand in hand with celiac disease–specific HLA-DQ markers.[101]

New Diagnostic Criteria Warranted

In celiac disease, small intestinal mucosal damage develops gradually, from normal morphology through inflammation to the so-called flat lesion (subtotal villous atrophy with crypt hyperplasia) (see Figure 41.1-7). This development is depicted in Figure 41.1-8, indicating the gradual process of mucosal deterioration, which may take years or even decades.[30–32,102–106] This means that when a child, an adult, or an elderly person on a gluten-containing diet has been shown to have a normal small intestinal mucosal morphology, even with no cellular inflammation, the disease is not excluded by conventional histology. The mucosa may deteriorate later.[107,108] A further demand on new criteria is obvious because patients suspected of having the disease, with correct HLA-DQ types but with only minor mucosal lesions and with an increased density of γ/δ-positive intraepithelial lymphocytes, were shown to have a gluten-dependent disease and osteopenia.[109] Oral tolerance to gluten in celiac disease may be broken in some individuals only after decades. This may be due to the amount of gluten in the diet but also because other environmental factors may act as "second hits." When gluten is introduced in the infant's diet, the ingested amounts vary. Later, daily food may contain gluten from 1 gram to up to 15 to 30 g. With this "normal" diet, the mucosal lesion may manifest at any age. Celiac disease with only low-grade inflammation should be distinguished from other diseases (see Table 44.1-2). It can be foreseen that biopsy will not be the gold standard in the diagnosis of celiac disease in the future when the diagnostic criteria will be widened toward "celiac trait" or "genetic gluten intolerance."

When performing gluten challenge studies with "normal" food, it has become evident that the individual tolerance to gluten is variable (see Figure 41.1-8). Most individuals react with a mucosal lesion within 3 months to 2 years on gluten ingestion, but it may take even longer,

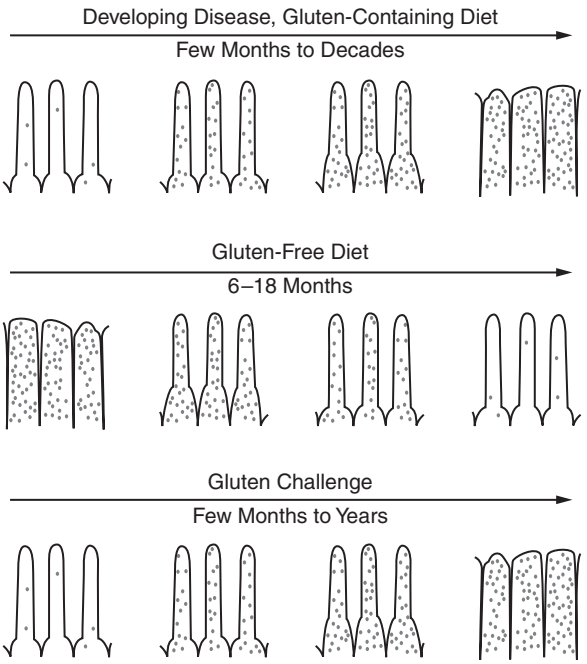

FIGURE 44.1-8 Schematic behavior of celiac disease small intestinal mucosa. *Upper row:* After starting a gluten-containing diet in infancy, the mucosa may deteriorate within a few months to that typical for celiac disease, villous atrophy with crypt hyperplasia. On the other hand, oral tolerance toward gluten may be kept for decades; the mucosa may be normal on morphology or show only a low-grade inflammation before deterioration. *Middle row:* The mucosa heals in 1 year on a gluten-free diet. *Lower row:* During gluten challenge, the mucosa may deteriorate within a few months, but it may also take years. Gluten intolerance in celiac disease is permanent, and a recurrence of the lesion will occur.

up to 14 years, before the mucosa relapses. In a Finnish series of gluten challenge performed in 29 adolescents and young adults with previously confirmed and treated celiac disease, 4 girls did not relapse within 2 years, one relapse occurred after 7 years, and another relapse manifested with dermatitis herpetiformis after 14 years of gluten ingestion.[80] In the latter case, the small bowel mucosal morphology remained normal.

SCREENING AND EPIDEMIOLOGY

Oral glucose tolerance tests, fecal fat excretion, D-xylose excretion tests, hematologic investigations, and radiologic examination of the small bowel failed to distinguish patients with suspected malabsorption from those with or without mucosal atrophy and, thus, frequently gave misleading results.[110] Intestinal permeability tests are not widely used as screening methods. However, autoantibodies have been shown to be highly predictive for untreated celiac disease. When there is a suspicion of celiac disease or the antibodies are positive, small intestinal biopsy should be the first diagnostic procedure. Often serum autoantibody tests direct the patient to the invasive diagnostic test.

In the United States, the disease is rare when the criteria for diagnosis rely on classic symptoms such as diarrhea and short stature.[111] By broadening the clinical indication, however, antibody screening seems to indicate that the prevalence in the United States is similar to that in Europe.[112] This is confirmed in recent large-scale screening programs.[113] Screening programs within childhood populations indicate that celiac disease is heavily underdiagnosed, and serologic testing using endomysial and TG-2 autoantibodies has the potential to detect otherwise undiagnosed disease in even more than 1 in 100 individuals (Table 44.1-4).[101,114–120] However, it should be remembered that subclinical cases of celiac disease will not be detected by screening only selected groups of at-risk patients.[81,101] Early detection of the disease and subsequent dietary elimination of gluten might be an appropriate method for preventing complications later in life. Today, however, we use mainly directed case finding screening. Figure 41.1-9 gives an example of the value of the use of antibody screening in one hospital: during 15 years, new cases per year have increased over 10-fold. Currently, population-based screening programs are used only in research.

SEROLOGIC SCREENING TOOLS

Serum gluten and milk antibody tests, performed with immunodiffusion techniques, were already promising in an early series of celiac disease patients.[62,63] As reviewed by Mäki, various methods have been developed to determine gliadin antibodies in serum: immunofluorescence, enzyme-linked immunosorbent assay (ELISA), diffusion-in-gel ELISA, solid-phase radioimmunoassay, and strip ELISA.[121] These antibodies have frequently been found in patients with untreated celiac disease, but the sensitivities and specificities of the tests have been unsatisfactory.

The currently used autoantibody tests have been in use since 1971,[121] and by measuring the IgA class R1-type reticulin antibodies, sensitivities and specificities became high, close to 100%.[122] The endomysial autoantibody test, with human umbilical cord tissue as a substrate, was widely used and was standardized and ring-tested to detect untreated celiac disease.[123] Following the identification of tissue transglutaminase as the target in rodent and primate tissues for celiac disease–specific autoantibodies, a non–observer-dependent ELISA method was developed and was used to detect the antibodies.[8,124–128] In contrast to gliadin antibodies, the serum endomysial and TG-2 autoantibodies are genetically determined and correlate strongly with the celiac-type HLA genetics.[30,33,101]

TREATMENT

In celiac disease, a lifelong gluten-free diet is the only effective treatment. Wheat-, rye-, and barley-based products should be avoided. Even if oat, by definition, is "gluten," its prolamin avenin seems not to be disease inducing. In Finland, the United Kingdom, and other northern European countries, industrially purified wheat starch–based gluten-free flours have been accepted as part of the gluten-free diet for over 40 years. A minority of patients in Finland have been prescribed a natural gluten-free diet. On the other hand, in many countries, a zero limit is demanded, thus not allowing the use of purified wheat starch–based flours. On

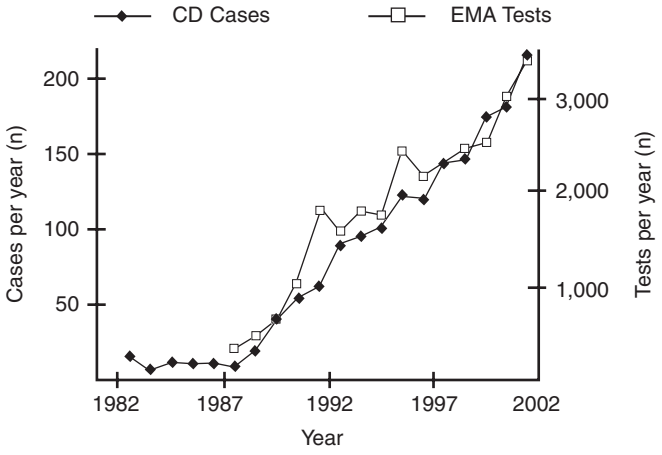

FIGURE 44.1-9 Significant increase of new celiac disease (CD) cases per year is obvious after starting the endomysial antibody (EMA) testing in 1987 in the Heim Pál Children's Hospital, Budapest, Hungary. Courtesy of Dr. Ilma Korponay-Szabo.

a long-term gluten-free diet including wheat starch–based gluten-free flours, no increased mortality, malignancies, or morbidity in the celiac disease patients over the population in general were observed.[129] On the prescribed diet, the mucosa heals and stays morphometrically normal over 10 years of flour ingestion.[130] Recently, it was concluded from a controlled study that wheat starch containing gluten-free flour products were acceptable in the gluten-free diet. No differences were observed in clinical responses; small bowel mucosal morphology; intraepithelial T-cell densities; mucosal HLA-DR expression; serum endomysial, TG-2, or gliadin antibody levels; quality of life measurements; or bone mineral densities when compared with the group on a diet that was gluten free by nature.[131]

The daily intake of gluten by the patients can be measured. The gluten levels in the products can be determined using the new R5 ELISA method, thus allowing an estimate of even trace amounts of gluten in the gluten-free diet.[132] It should be remembered that natural gluten-free products may contain gluten because international trade tolerates about 5% (50,000 ppm) extraneous grain in a cereal. On the other hand, if compliance to any given gluten-free diet is poor, the patient may ingest daily several grams of gluten.[133]

FUTURE INSIGHTS

Our increasing knowledge of the molecular and cellular details of events leading to celiac disease should benefit patients. The knowledge of the harmful gluten epitopes should facilitate our ability to genetically modify these epitopes in grains without losing their baking properties. The large number of T-cell epitopes and the complexity of wheat genetics complicate manipulation of wheat to remove toxic peptides. An alternative strategy might be to inhibit the deamidation process by developing TG-2–specific inhibitors.[134,135] However, the inhibitors should be designed to inhibit only the deamidation activity of TG-2, not the other enzymatic activities or structural properties of TG-2. It is noteworthy that celiac disease patient IgA antibodies inhibited differentiation of T84 crypt-like cells to enterocytes, and specifically designed inhibitors might do the same, that is, provoke crypt hyperplasia and villous atrophy. One approach could be to use enzyme-supplement therapy (eg, bacterial prolyl endopeptidase) to destruct the proteolytically resistant proline-rich fragments of gluten proteins.[54] This approach is attractive and practical because the protease could be ingested along with a diet containing gluten. However, the enzyme should be present in large amounts, and it should work very efficiently in the correct place (upper part of small intestine) to prevent efficiently undigested peptides from activating T cells. Interference with the stimulation of $CD4^+$ gluten-specific T cells, their eradication, or silencing could be another effective way to control the disease. Alternatively, blocking the peptide-binding sites of DQ2 and DQ8 HLA molecules could prevent the presentation of disease-inducing gluten fragments. One more strategy is blockade of signals derived from the cytokine interleukin-15 (part of innate immunity). We should not forget, however, that a gluten-exclusion diet is a safe treatment, although it is not convenient or easy to comply with. New therapeutic approaches must outweigh the current gluten-free therapy with regard to costs and safety.

2. Food-Allergic Enteropathy

Franco Torrente, MD
Simon H. Murch, BSc, PhD, FRCP, FRCPCH

The best described mucosal manifestation of food allergy is food-allergic (sensitive) enteropathy, in which an immunologically mediated abnormality of the small intestinal mucosa occurs. The features of this enteropathy may include excess lymphocyte infiltration, epithelial abnormality, or architectural disturbance. This may often impair absorption and less commonly causes a frank malabsorption syndrome. Such enteropathy continues while the food remains in the diet and remits on an exclusion diet but recurs on food challenge. In most current cases, formal evidence of such an allergic reaction to challenge, based on sequential biopsies, is not performed in children with clinical intolerance to dietary proteins. Diagnosis is thus based on histologic features at initial biopsy and clinical response to antigen exclusion and challenge. The consequences of enteropathy include abdominal distention, loose stools, micronutrient deficiency, and sometimes protein-losing enteropathy leading to edema. In contrast to celiac disease, these enteropathies are usually restricted to early life, and later challenge with the protein is usually tolerated. The disorder is best described for cow's milk, and cow's milk–sensitive enteropathy (CMSE) has been recognized for over two decades.[1]

RECOGNITION OF FOOD-SENSITIVE ENTEROPATHIES

The existence of food-sensitive enteropathies was initially controversial and established only after the development of the pediatric biopsy capsule. The disorders were finally confirmed by the same diagnostic techniques introduced for celiac disease, based on sequential small intestinal biopsies at diagnosis, after food elimination, and again after challenge. Small intestinal mucosal abnormalities were first suggested to occur in response to cow's milk protein by Lamy and colleagues in 1963.[2] These observations were supported by other reports of abnormal small intestinal mucosa in young children who manifested delayed clinical reactions to cow's milk and improved clinically after cow's milk exclusion.[3,4] The first formal study of the histologic response to cow's milk challenge in CMSE came from Kuitunen and colleagues,[5] who showed that symptom-free cow's milk–allergic children with normal prechallenge biopsies reacted to milk challenge by recurrence of symptoms and development of histologic small intestinal abnormality. Walker-Smith and colleagues confirmed the existence of CMSE by serial small intestinal biopsies related to dietary milk intake in five infants.[6] The mucosal lesion at the time of first biopsy was of variable severity, in part related to the length of time the patients had already been on a milk-free diet. In all children, there was improvement in morphology after a milk-free diet and in most a return to normal. In all, there was a significant deterioration after a further milk challenge. However, the mucosal lesion was markedly variable in its severity, ranging from a partly flat mucosa to a mild degree of partial villous atrophy. Disaccharidase activity rose on a milk-free diet and fell after a positive milk challenge,[6] whereas intraepithelial lymphocytes increased on challenge.[7] Comparison of biopsies taken at the duodenojejunal junction with those taken a further 15 cm distally showed that proximal abnormalities induced by milk challenge in CMSE were greater than those in the distal small intestine.[8] The lesion is thus likely to be less extensive than in celiac disease, but there is significant interpatient variability.

Abnormalities of the small intestinal mucosa have been reported in children with intolerance to a variety of other protein, including soy, wheat, oats, eggs, rice, and fish.[9–11] In some cases, these reports were corroborated by serial biopsies during challenge, but the gradual acceptance of the existence of food-sensitive enteropathy has made serial diagnostic biopsies unusual.

CLINICAL FEATURES OF FOOD-ALLERGIC ENTEROPATHY

Classic Food-Sensitive Enteropathy

The most common syndrome is CMSE. Its classic presentation is with chronic diarrhea and failure to thrive, often beginning after an episode of gastroenteritis in a formula-fed infant and recovering only after cow's milk is excluded from the diet.[1,12] Other clinical features include abdominal distention, perianal erythema, or napkin rash owing to malabsorbed sugars and dermatographia. Associated clinical features may include colic, gastroesophageal reflux, rectal bleeding, or eczema. Up to 40% of infants with classic CMSE also sensitize to soy, often after a "honeymoon period" of about 2 weeks, when it appears to be tolerated. The great majority, however, settle on extensively hydrolyzed formulas. Classic CMSE is usually a self-limiting condition, with most children tolerating reintroduction at the age of 2 to 3 years.[1,12,13] However, some children may have persistent low-grade symptoms for much longer.[14,15] There is sometimes a history of additional immediate reactions to food antigens, such as rash, urticaria, angioedema, or even anaphylaxis. However, many children suffer

enteropathy without immediate reactions, and it is important to recognize that food-allergic enteropathy can occur in the absence of any systemic signs of food allergy. Thus, skinprick tests may be negative, and specific immunoglobulin E (IgE) is undetectable.[1,12,16,17] Review of the infant's weight record often shows a period of good weight gain prior to the onset of symptoms, followed by downward drift against the percentiles until antigen exclusion is adequate. In terms of mechanism (discussed later), this presentation represents the transient loss of initially established oral tolerance.

Breast Milk Sensitization and Multiple Food Allergy

In contrast to this classic presentation, there are increasing reports of very early life sensitization in exclusively breastfed infants. Symptoms can begin very early in life, sometimes within the first 2 weeks.[16,18] In these infants, cow's milk is usually one of several antigens that induce symptoms, and many affected infants are intolerant of multiple foods. These infants have a different pattern of weight gain compared with classic CMSE in that failure to thrive is seen in only about 25%, who usually show poor weight gain from birth.[19,20] For the infants who have inherited high IgE or predisposition to immediate reactions, diagnosis is usually more straightforward because the clinical history usually indicates the causative antigen(s), and skinprick tests are usually positive.[1,16] In contrast, those without immediate responses, particularly if weight gain is good, may present great diagnostic difficulty and may not be recognized as suffering from food allergies. Endoscopic evidence of duodenal and/or ileal lymphoid hyperplasia appears to be characteristic.[21–24]

For these infants, it appears that oral tolerance mechanisms are not primarily established[17,25]; thus, sensitization occurs to trace amounts of multiple antigens eaten by their mother and passing into breast milk. The clinical picture is often dominated by dysmotility, with delayed gastric emptying and gastroesophageal reflux contributing to a severe colic-like presentation with irritability.[16] Many infants have associated eczema, and napkin rash occurs owing to malabsorbed dietary sugars.[16] The histologic findings are less striking than for classic CMSE, and this can be a condition that causes great diagnostic difficulty.

FOOD PROTEIN–INDUCED ENTEROCOLITIS AND COW'S MILK COLITIS

The food protein–induced enterocolitis syndrome (FPIES) is a particularly severe and sometimes life-threatening form of mucosal food hypersensitivity.[26,27] It is most commonly associated with cow's milk or soy ingestion but has recently been reported to be induced by a variety of foods usually thought to be of low antigenicity, including rice, oat, barley, vegetables, and poultry.[11] It is also common for such symptoms to occur in exclusively breastfed infants, triggered by milk protein in the mother's diet.[28] Negative skinprick tests do not exclude this diagnosis, and the majority of cases are, in fact, negative.[29] The infant usually presents with severe vomiting and diarrhea and may become dehydrated and shocked, requiring emergency admission to hospital.[11] Some demonstrate melena and passage of mucus per rectum. The withdrawal of milk or soy from the diet induces remission, but early challenge often induces a systemic reaction with peripheral neutrophilia, in addition to vomiting and loose stools. The condition may develop after the earlier diagnosis of cow's milk colitis, in which colonic features such as melena, diarrhea, and passage of mucus occur without the systemic manifestations, apart from thrombocytosis.[1] Inadvertent milk or soy challenge after a period of exclusion diet may then precipitate the full-blown FPIES response. Skinprick testing is usually negative, and the diagnosis may have to be based on the response to antigen exclusion and challenge. Many affected infants may respond in this manner to multiple antigens, with tolerance re-established around 2 to 3 years for FPIES[11] and rather earlier for cow's milk colitis.[1]

If colonoscopy is performed, the colitic changes are usually milder than with classic inflammatory bowel disease, and the macroscopic findings are dominated by loss of the vascular pattern, prominent lymphoid follicles with a rim of perifollicular erythema (red halo sign), and an easily traumatized mucosa.[1] Histologic changes include mononuclear cell infiltration, mucosal eosinophilia with evidence of degranulation, and the presence of lymphoid follicles in the majority of colonic biopsies. If the ileum is visualized, lymphoid hyperplasia is usually seen. This condition may also occur in older children and be unrecognized as attributable to milk allergy, leading, on occasion, to mistaken laparotomy in the investigation of rectal bleeding.[30] A trial of cow's milk exclusion is thus recommended in all children with a history of unexplained rectal bleeding.

HISTOLOGIC FEATURES OF FOOD PROTEIN ENTEROPATHIES

Early reports of the classic CMSE lesion suggested that the mucosa was flat and largely similar to that in celiac disease.[5] With improvements in the composition of infant milk formulas, this became very rare, and mucosal damage is usually now much less striking and of patchy distribution (Figure 44.2-1).[1,31] At initial diagnosis, there may be areas demonstrating mild villous atrophy, with some hyperplasia of the crypts. In exceptional cases, there may be a flat mucosa, and the lesion is typically distinguished from celiac disease by the thin mucosa and patchy distribution.[32,33] Typical histologic findings are shown in Figures 44.2-1 and 44.2-2. If the diagnosis is being considered, at least two biopsy specimens are helpful for diagnosis. Dissecting microscopic examination in the endoscopy room is helpful in detecting a patchy lesion. There may be some increase in intraepithelial lymphocyte numbers, but this is often focal and less than in celiac disease.[7] Crypt cell proliferation is only modestly increased in CMSE, to an extent less than in celiac disease.[34]

Quantitative morphometric studies during serial diagnostic milk challenges[32] confirmed no increase of mucosal thickness in comparison with control biopsies but identi-

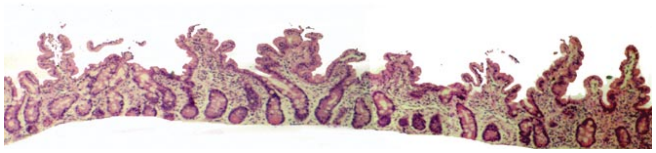

FIGURE 44.2-1 Low-power view of a small intestinal biopsy (fourth part of the duodenum) in a child with cow's milk–sensitive enteropathy. The lesion is patchy, showing areas with preserved villus architecture and a crypt-to-villus ratio greater than 2, and others with villus blunting and crypt lengthening. Such patchiness is characteristic of food-sensitive enteropathy and suggests the need for taking more than one biopsy for histologic assessment. The handling of biopsies is important, and orientation under dissecting microscopy with card mounting may be helpul in optimizing biopsy orientation.

fied an increase in intraepithelial eosinophils on milk challenge. Improvements in infant formulas have led to a change in the mucosal appearances of CMSE so that celiac-like villous atrophy is now very rare in the developed world. Morphometry of recent cases of CMSE confirms a less severe lesion than archival biopsies from the 1980s (Table 44.2-1).[16] This causes some histopathologic difficulty because there is no international consensus in reporting of subtle lesions such as villous blunting or mild mucosal eosinophilia.

One unexplained finding that may be diagnostically helpful is the accumulation of fat within the epithelium, as is also seen in postenteritis syndrome.[35] Within the lamina propria, there is often a patchy increase in the density of lymphocytes, and increased eosinophil accumulation may be seen (see Figures 44.2-2 and 44.2-3). In original descriptions, classic CMSE appeared to disappear by the age of 2 years, and milk challenge was then frequently successful.[1,12,13] However, there is now evidence that some children do not grow out of CMSE in early childhood, and an abnormal mucosa may be seen in later childhood. Kokkonen and colleagues characterized persistent CMSE in school-age children in comparison with celiac disease and control children.[14,15] Typical findings in children with CMSE were endoscopically visible lymphonodular hyperplasia of the duodenal bulb and lymphoid follicles without villous atrophy in biopsy samples.[21–23] The patients with definite CMSE showed significantly increased densities of intraepithelial T cells, particularly γδ T cells.[22] Previous studies had demonstrated variability in γδ intraepithelial lymphocyte numbers in CMSE, from a high celiac-like density to normal,[36] suggesting that this would not be a reliable marker for CMSE. The consequences of the infiltration of activated T cells in enteropathy include impairment of enterocyte absorptive mechanisms, such as decreased expression of lactase and other hydrolases, and an additional impairment of the small intestinal drive to pancreatic enzyme secretion. Thus, fecal elastase concentrations may be reduced in active disease.[37,38]

SPECIFIC FOODS CAUSING ENTEROPATHY SYNDROMES

Cow's Milk

Unlike cow's milk, human milk does not contain β-lactoglobulin, and this protein was initially implicated in the development of CMSE.[1,12,13] There is more recent evidence that allergic responses to casein may also occur and that certain epitopes may be particularly important. For systemic cow's milk allergies, IgE reaction to linear

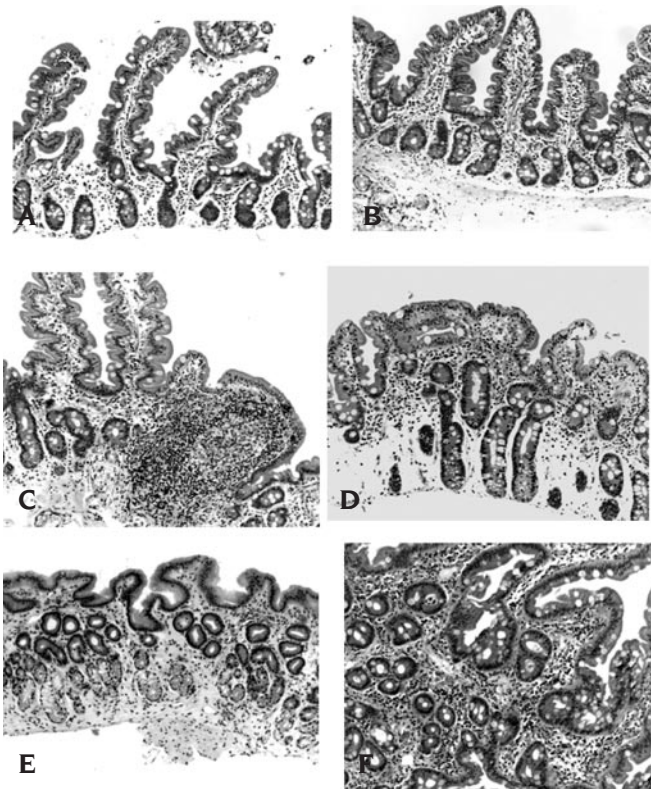

FIGURE 44.2-2 Subtle findings in food-sensitive enteropathy. *A* and *B* show biopsies within normal histologic limits from children with no eventual gastrointestinal diagnosis. *C* shows a prominent lymphoid follicle with an active germinal center in a child with cow's milk–sensitive enteropathy (CMSE). Despite the recognizable villus architecture, there is evidence of some crypt lengthening. Prominent lymphoid tissue within the duodenum and terminal ileum is a recently recognized association of childhood food allergy.[21–24] In contrast, *D* shows the major disturbance of small intestinal architecture characteristic of celiac disease, which presents little diagnostic difficulty compared with CMSE. *E* shows villus shortening in a case of cow's milk– and soy-sensitive enteropathy. The prominence of Brunner glands, however, suggests that the biopsy may have been taken in the first or second part of the duodenum, which may overemphasize villus shortening. Correct technique is to take biopsies in the fourth part of the duodenum or jejunum. *F*, Although the biopsy is cross-cut, there is a clear increase in the density of mononuclear cells within the duodenum in this case of CMSE.

TABLE 44.2-1 MORPHOMETRIC EXAMINATION OF SMALL INTESTINAL BIOPSIES IN FOOD-SENSITIVE ENTEROPATHY, COMPARING CLASSIC CMSE WITH MULTIPLE FOOD ALLERGY

PATIENT GROUP	VILLUS HEIGHT (μm)	CRYPT DEPTH (μm)	MEAN CRYPT-TO-VILLUS RATIO
Normal controls (n = 47)	345	164	2.1
Multiple food allergy (n = 45)	282	188	1.4
Classic CMSE (n = 46)	210	190	1.2
Celiac disease (n = 17)	30	400	0.0

Data from Latcham F et al.[16]
CMSE = cow's milk–sensitive enteropathy.

sequences in casein, rather than α-lactalbumin or β-lactoglobulin, are predictive of long-lasting milk allergy. Those children whose IgE bind specific sequences of α_{S1}-casein, α_{S2}-casein, and κ-casein are less likely to outgrow their allergy.[39,40] Overall, the prognosis of the child with CMSE appears good, and the great majority outgrow their sensitization by age 3 years,[13,41] although other allergies may subsequently develop in about half of the cases.

Soy

Soy-based formulas have been used for many years as a substitute for cow's milk formulas in milk-sensitized infants, although this has been controversial. Recent recommendations from the American Academy of Pediatrics (AAP) Committee on Nutrition[42] differ from those from the European Society for Pediatric Allergology and Clinical Immunology (ESPACI) and the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN)[43] with respect to soy use. Soy-based formulae are as antigenic as cow's milk formulas[44] and cause a similar spectrum of allergic responses, including enteropathy.[1,11] A 30 kD protein in soy may induce cross-reactivity to casein in cow's milk,[45] potentially explaining why so many cow's milk–allergic children also develop soy intolerance or enteropathy. The antigenicity of soy-derived products varies substantially with the method of preparation, and children may react to some soy products but not others.[46] This may be important to consider if challenge testing is performed with a soy preparation to which the child does not react, but symptoms suggestive of soy enteropathy continue. Skinprick testing is a poor predictor of subsequent clinical reactions to soy,[47] but skin patch testing shows promise in identifying soy-sensitized children.[48]

Hydrolysates

It is important to recognize that some children can show reactions to the trace cow's milk protein present in hydrolysate formulas and thus show incomplete resolution of symptoms unless moved to an amino acid–based formula.[16,49–52] The clinical features tend to be less florid than induced by the unprocessed protein; thus, there is often some improvement in symptoms on commencing the hydrolysate. Ongoing reaction to hydrolysates may therefore be missed if the diagnosis is not considered.

Wheat Gluten

A particularly important form of food-sensitive enteropathy occurs to wheat gluten in celiac disease. The enteropathy is quite distinct to other food-sensitive enteropathies such as CMSE and is discussed separately in Chapter 44.1, "Celiac Disease."

Multiple Food Allergy

Increasing numbers of infants and children are becoming sensitized to multiple foods, making either immediate or delayed reactions or a combination. Many sensitize despite exclusive breastfeeding. Diets involving the elimination of single foods are usually ineffective, and many affected infants are intolerant of hydrolysates and require amino acid formulas.[16,49–52] This provides a particularly challenging clinical scenario and requires experienced specialist input. The antigens most likely to provoke symptoms in the multiply food-allergic child include cow's milk, soy, wheat, egg, peanuts, tree nuts, and fish, but a variety of other food antigens have been implicated.[16,29,53] If the multiply allergic

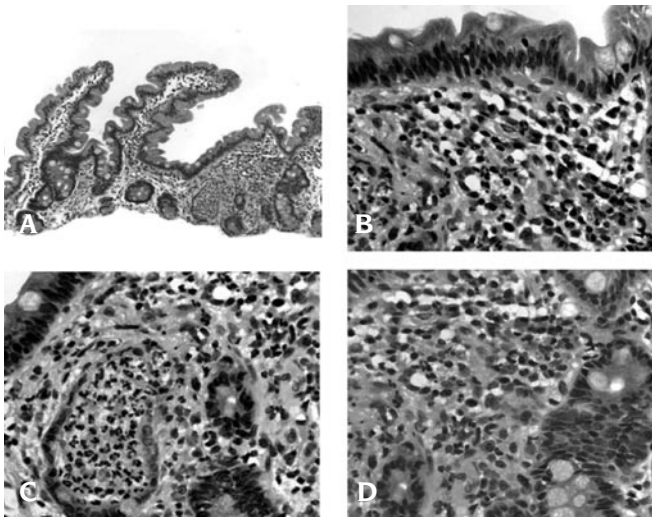

FIGURE 44.2-3 Eosinophil infiltrate within the mucosa in a case of food protein–induced enterocolitis. The low-power view in *A* shows preserved villus architecture in the duodenum, with a single crypt abscess. Higher-power views in *B* and *C* show the intense eosinophil infiltrate within the lamina propria. *C* demonstrates that the crypt abscess seen in *A* is, in fact, eosinophilic. *D* shows a sigmoid colonic biopsy from the same child, which also shows mucosal eosinophilia. This child required an amino acid formula because he was intolerant of hydrolysates.

infant remains even partially breastfed, the dietary exclusions that the mother must make may have a very negative effect, and it is often better to discontinue breastfeeding in favor of an amino acid formula if she has to exclude more than two major foodstuffs.[54] A cow's milk– and soy-free diet is just about at the level of tolerance of all but the most fanatically committed adult, and the further exclusion of egg or wheat provides not only additional complexity but a real risk of nutritional adequacy for a lactating mother.[54]

One important clinical issue in the management of the child with multiple food allergy is the maintenance of a nutritionally adequate diet, and close liaison with an experienced dietitian is mandatory. The consequences of mucosal T-cell activation in food-sensitive enteropathy include reduction in brush border disaccharidase expression,[55] leading to impaired carbohydrate absorption, and a secondary reduction in pancreatic enzyme release,[37,38] which may also contribute to malabsorption. In some cases, improvement in weight gain can be achieved by the temporary addition of pancreatic enzyme supplements. It is important to exclude cystic fibrosis in cases in which elastase is found to be low because both conditions can coexist. Many children with multiple food allergy do maintain normal growth and weight gain[20]; thus, the diagnosis may not be suspected if the child makes delayed non–IgE-mediated reactions only.[16,20] Unlike classic CMSE, it is unusual for an affected child to regain tolerance for cow's milk by the age of 2 years.[16,20]

IMMUNOPATHOLOGY

T-Cell Responses

Immunohistochemical studies during serial challenges in CMSE have identified changes induced by milk, including increased intraepithelial CD8 cells and activation of lamina propria CD4 cells, with increased human leukocyte antigen (HLA)-DR expression on surface epithelium (Figure 44.2-4).[10] The intraepithelial lymphocyte population appears to be in a state of activation and shows enhanced expression of the cytotoxic marker TIA-1.[56] Analysis of mucosal lymphocytes in CMSE or multiple food allergy confirms excess T-cell activation, with either a T helper (Th)1–dominated or a mixed Th1/Th2 response.[12,25,57–60] Thus, Th1 responses are not reduced overall within the mucosa or Th2 responses significantly increased, in contrast to findings reported in peripheral blood lymphocytes from milk-allergic infants[61] or in cloned milk-reactive T cells isolated from the duodenal mucosa.[62] Enzyme-linked immunospot analysis of children with classic CMSE showed increased interferon(IFN)-γ– and interleukin (IL)-4–producing cells, with unchanged IL-5 and reduced IL-10 in comparison with controls.[57] Th1 responses are also maintained within the Peyer patch lymphocyte population.[63] A study using reverse-transcriptase polymerase chain reaction in Finnish children with food-allergic enteropathy also identified increased IFN-γ messenger ribonucleic acid (mRNA), but with no increase in IL-4.[58] Flow cytometric analysis of intraepithelial and lamina propria lymphocytes from children with multiple food allergy did not show an increase in IL-2–, IL-4–, or IFN-γ–producing cells but showed a marked reduction in lymphocytes producing the regulatory cytokine transforming growth factor-β (TGF-β), which is also seen by immunohistochemistry and in situ hybridization.[60] Thus, although classic CMSE shows a broadly Th1-skewed mucosal lesion, the multiple food-allergic lesion may be immunologically distinct and characterized by reduced expression of the regulatory cytokine centrally associated with oral tolerance. Reduction of TGF-β expression has been seen in two further studies of milk-reactive duodenal T-cell clones from milk-allergic children[62] and of the duodenal mucosa in food protein enterocolitis syndrome.[64] This is discussed in the section on oral tolerance.

Tumor necrosis factor-α (TNF-α) production is stimulated within the mucosa by milk challenge of allergic patients,[65,66] which is again distinct from responses seen in circulating T cells from allergic children[67] but may reflect its release from mucosal mast cells. Increased TNF-α responses are also seen, in association with enhanced Th2 responses in food protein–induced enterocolitis.[68]

Mast Cells and Eosinophil Responses

One frequent association of mucosal food-allergic responses is the infiltration of both eosinophils and mast cells, both of which produce a number of proinflammatory, vasoactive, and neuroactive mediators (see Figure 44.2-3). These cells have been implicated in antigen-induced dysmotility, and their products may disturb enteric neural function.[69] In response to ingested allergens, mast cell tryptase and eosinophil cationic protein are released into the lumen and may be detected in stools.[66,70,71] In a study comparing mucosal responses in milk-intolerant infants with those in milk-tolerant infants with small intestinal enteropathy, Chung and colleagues showed that milk intolerance was associated with increased mucosal expression of eosinophil major basic protein together with up-regulation

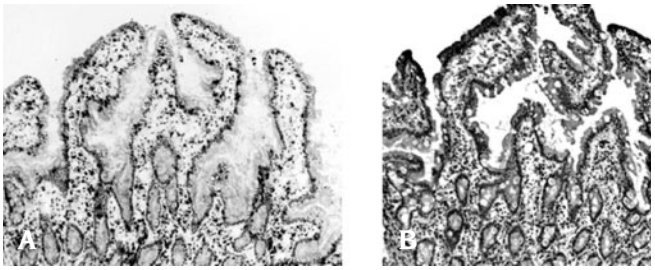

FIGURE 44.2-4 Immunohistochemical staining of frozen sections from a child with multiple food allergy. *A* and *B* are serial sections through the same villi, with *A* stained for CD3+ T cells and *B* stained for human leukocyte antigen (HLA)-DR. Positively stained cells are brown, and unreactive cells show blue counterstaining only. *A* shows a modest increase in the density of intraepithelial lymphocytes but otherwise normal T-cell density. *B* shows HLA-DR–positive epithelium at the villus tip but not in crypt epithelium. Because a major determinant of epithelial HLA-DR expression is the T helper (Th)1 cytokine interferon-γ, this positive staining is consistent with several reports of preserved Th1 responses in mucosal food allergic responses.[57–60] This contrasts with Th2 dominance of circulating lymphocytes in milk allergy.[61]

of vascular cell adhesion molecule 1.[72] In this study, the degree of villous atrophy correlated with the extent of deposition of major basic protein.

There are important differences in the time course of responses mediated by mast cells and eosinophils, despite their rather similar products. Mast cell mediators are stored preformed within intracellular granules and released rapidly through degranulation after cross-linking of surface IgE molecules. This does not require synthesis of new protein and thus ensures that mast cells play a predominant role in immediate mucosal responses. For eosinophils, there is a contrasting lag period because they need to be recruited into the tissues. Eosinophils are thus more likely to play a role in delayed responses to antigen. The three forms of response to cow's milk in sensitized infants identified by Hill and colleagues[73] of immediate, intermediate, and delayed reactions thus correlate temporally with mast cell–, eosinophil-, and T cell–mediated responses, respectively.[73]

PATHOGENESIS OF FOOD-SENSITIVE ENTEROPATHY

Control of T-Cell Responses

The intestine contains more T cells than any other organ in the body, and there are distinct roles for intraepithelial and lamina propria lymphocytes (see Figure 44.2-4). An important role of T cells in inducing the tissue remodeling characteristic of crypt hyperplastic villous atrophy in small intestinal enteropathy was made explicit by organ culture studies of human fetal intestine by MacDonald and coworkers.[74,75] Immediate hypersensitive responses in animals associated with mast cell degranulation or polymorph infiltration without T-cell activation do not cause crypt hyperplasia.

T cells within the mucosa are normally maintained in a state of tolerance, for reasons discussed in this chapter.[76] One requirement is the maintenance of a tight epithelial barrier to prevent passage of intact macromolecules to the lamina propria. The role of the epithelium in antigen presentation and cytokine production has been recognized,[77–80] and an important epithelial contribution to tolerance was suggested by Sanderson and colleagues on the basis that costimulatory ligands for T-cell activation were not expressed.[79] Recent data suggest that intestinal epithelium may directly induce a regulatory phenotype in CD8 cells.[81] It has been estimated that only peptides shorter than 11 amino acids may penetrate the epithelial barrier in health.[82] One reason for initial sensitization may be the bypassing of the normal pathways for immune tolerance through epithelial leakiness, usually owing to acute gastroenteritis.[1,25] Early studies by Gruskay and Cook showed excess egg albumin absorption in infants with acute gastroenteritis,[83] and experimental studies during viral gastroenteritis in piglets confirmed excess absorption of dietary antigens.[84] Subsequent studies of paracellular permeability in children with gastroenteritis confirmed that this is a time when antigens may penetrate in abnormal amounts.[85,86] The immune response to the penetrating antigen may then contribute to maintaining epithelial hyperpermeability and increased antigen entry.[87] Thus, a positive food challenge may induce further excess paracellular permeability.[88] The cytokines that are particularly implicated in increasing paracellular permeability in the intestine are TNF-α and IFN-γ.[65,89,90] There is an intriguing overlap of function with the cytokines central in oral tolerance, TGF-β and IL-10, because both of these cytokines inhibit IFN-γ–induced permeability,[91,92] whereas IFN-γ itself specifically blocks TGF-β signaling.[93] Thus, it appears possible that the relative local concentrations of IFN-γ and TGF-β or IL-10 may be one factor that determines when immune tolerance is regained to sensitizing antigens.

Oral Tolerance

There has been much advance in the understanding of oral tolerance mechanisms. Relevant factors include the dose of ingested antigen because low doses invoke different responses to high doses.[17,25,94,95] Bulk dietary antigen is likely to be presented by epithelium without costimulatory ligands,[79] which may induce lymphocyte anergy[79,80] by processes little understood in childhood. Murine studies suggest that specific targeting of ingested antigen occurs to late endosomes within the enterocyte and that this may be an important component of the antigen presentation process in oral tolerance.[96] There are as yet no confirmatory studies in humans. A complex state appears to be induced in lymphocytes by food administration, with an increase in both pro- and antiapoptotic factors and downregulation of T-cell receptor function.[97] A different mechanism for low doses of antigen follows its uptake by the M cells that overlie Peyer patches. The antigen induces suppressor lymphocyte formation within the Peyer patch, particularly Th3 T cells that produce TGF-β.[17,25,94,95,98] Other important regulatory T-cell populations include IL-10–producing T regulator 1 (Tr1) cells and CD4+CD25+ cells.[25,80,95] The master regulator molecule that is critical in the generation of regulatory lymphocytes is the transcription factor Foxp3,[99] and mutation in this molecule induces a severe multifocal inflammatory disease characterized by enteropathy of autoimmune basis in human infants (IPEX syndrome [immune dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance]).[100] Thus, Foxp3 may be a molecule that is of critical importance in maintaining oral and systemic tolerance. Several regulatory cells may be important in preventing food-sensitive enteropathy. In older patients, a population of multiply exposed CD4+CD25+ cells inhibit milk responses.[101] However, most of the circulating CD4+CD25+ in adults express the skin-homing marker cutaneous lymphocyte antigen (CLA) but not the gut-homing β_7 integrin, whereas cord blood CD25+CD4+ cells express neither marker.[102] Cord blood CD4+CD25+ cells show ineffective regulatory properties[103]; thus, neonatal animals show impaired low-dose oral tolerance.[104] Oral tolerance mechanisms in general do not appear to be fully intact at birth but develop postnatally, in response to the luminal flora. There is expression of a specific group of Toll receptors on CD4+CD25+ regulatory T cells, and their response to bacterial lipopolysaccharide is one of increased suppressive effect.[105]

The early infectious exposures of the young infant may be as important as the food antigens experienced in generating oral tolerance and preventing allergy and enteropathy.[25] TGF-β rather than IL-10 appears to be the important cytokine in preventing the development of infant food allergy. TGF-β responses but not IL-10 responses to cow's milk were impaired among cord blood mononuclear cells in the children of allergic mothers.[106] This lack of TGF-β response is seen within the mucosa of infants with CMSE and other food-related enteropathies.[60,64] The early-life generation of TGF-β1–producing Th3 cells is an area of great importance for future study of food-allergic sensitization. Infectious exposures are certainly one such factor, and blockade of innate immune responses to the enteric flora induced food-sensitive enteropathy in a notable murine model.[107] It is intriguing that duodenal TGF-β–producing cells are present at a much higher density in healthy rural African than in UK infants.[108]

On a worldwide basis, it is possible that food-sensitive enteropathy may contribute to malnutrition in young children within the tropics. Although repeated infectious challenge and caloric insufficiency are centrally implicated in the development of tropical enteropathy and the clinical syndrome of protein-energy malnutrition, there is also evidence that affected children may become intolerant of cow's milk or soy and improve on exclusion diets.[109–111] Because paracellular permeability is a major determinant of subsequent mortality in tropical infants[112] and the progression to marasmus is characterized by the increasing dominance of IFN-γ and TNF-α over IL-10 and TGF-β in the mucosa,[108] it is possible that acquired loss of oral tolerance may contribute to the high mortality from malnutrition among developing world infants. Food protein–induced enteropathy may thus be a condition of truly global importance.

B-Cell Responses

The role of mucosal IgA in the maintenance of a tolerant response to dietary antigens is probably great. The uptake of mucosal IgA by epithelium, and its transport into the lumen, is probably a key event in regulating the presentation of dietary proteins to the mucosal immune system. Food-allergic responses and low-grade enteropathy are common among adults with constitutive IgA deficiency.[113] A condition of transient IgA deficiency in infants prone to allergy was suggested by Taylor and Soothill and their colleagues as a cause of increased antigen entry and allergic sensitization.[114,115] At the whole population level, low IgA is, indeed, more predictive of overall allergic sensitization than high IgE.[116] The development of mucosal IgA responses appears to relate to an increase in the mucosal density of IgA2-producing plasma cells because IgA1 cell density is relatively stable after birth in most infants,[117] although around 10% of studied infants showed delayed maturation of all IgA responses.[118] Factors regulating IgA2 development are still poorly understood, but reduced mucosal IgA responses predispose the patient to the development of CMSE after gastroenteritis.[119] However, IgA production appears to be increased overall within the mucosa in active CMSE as a consequence of inflammation.[120] Because the cytokine responsible for the shift of B-cell isotype to IgA is TGF-β, this molecule appears to play a pivotal role in both T- and B-cell responses to dietary antigen.[25] The evidence that mucosal TGF-β production is low in infants with food-sensitive enteropathy[60,64] suggests that the mechanisms by which TGF-β is induced may be a central question in understanding the pathogenesis of food-sensitive enteropathy.

It is clear that normal infants without enteropathy may produce circulating antibodies to cow's milk proteins.[1,12,13,41] There have been few reports suggesting a pathogenic role for circulating IgG antibodies against dietary components, and the detection of IgG to cow's milk or gliadin is notoriously nonspecific. However, there have been reports suggesting the possibility of immune complex formation and complement activation in milk allergy[121] and the potential induction of antibody-dependent cell-mediated cytotoxicity to β-lactoglobulin–coated cells in CMSE,[122] although it has still not been established whether these phenomena contribute to the development of the CMSE lesion.

Transient IgE responses to foods are seen in normal children and are of doubtful relevance.[123] High-level IgE responses are usually pathologic but more important in systemic food allergies than in enteropathy. Production of IgE is favored by the dominance of Th2 cytokines, particularly IL-4 and IL-13.[124] The receptors for both cytokines share a common α chain (IL-4Rα), and increased signaling through this receptor is associated with increased atopy.[125] Blockade of either IL-4Rα or its downstream intracellular signaling molecule Stat-6 (signal transducer and activator of transcription 6) may inhibit IgE-mediated allergic reactions.[126,127] IgE may be produced within the mucosa, even in the absence of a systemic IgE response, and may be delivered into the gut lumen by a mechanism distinct from IgA transport (Figure 44.2-5).[128,129] There is up-regulation of expression of the IgE receptor CD23 on the enterocytes in active CMSE in infants, although little is known about the functional responses to mucosal IgE production by the small intestinal epithelium.[130] It is thus possible that mucosal IgE responses may be elicited by dietary antigen, even if skinprick tests are negative and circulating specific IgE is undetectable.[131]

Mast Cell and Eosinophil Responses

As mentioned above, it is common to see focal increase of eosinophils within the mucosal lesion of food-sensitive enteropathy. There has been an important recent advance in determining the mechanisms of eosinophil recruitment, and studies by Hogan and colleagues and others have clarified the central role of two mediators, IL-5 and eotaxin (Figure 44.2-6).[132–135] Studies using mutant mice, with targeted deletion of these genes, have identified separate roles for both molecules in the antigen-driven recruitment of eosinophils to the intestinal mucosa. Mice sensitized to ovalbumin and then challenged with oral administration of ovalbumin-coated beads made an allergen-specific Th2 response, characterized by increased circulating IgE and IgG1 with mucosal eosinophilia.[132] However, mice defi-

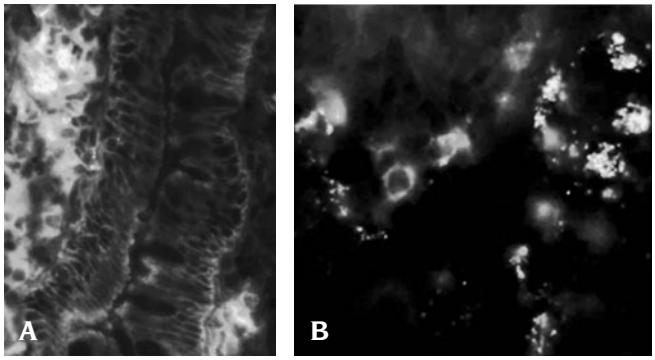

FIGURE 44.2-5 Immunofluorescence for IgA and IgE in a case of cow's milk–sensitive enteropathy. *A* shows details from two adjacent villi, with the epithelium and luminal glycocalyx outlined by IgA, whereas strongly staining IgA plasma cells are seen in the adjacent lamina propria. *B* shows two types of IgE-positive cells: round plasma cells with large unstained nuclei and homogeneously staining periphery and intensely staining mast cells showing the characteristic granular deposition. There is evidence of some mast cell degranulation, with non–cell-associated deposition of IgE. This child had a normal total IgE, undetectable milk-specific IgE, and negative skinprick tests, demonstrating the compartmentalization of IgE responses that can occur within the intestine.[25,70,128–130]

cient in IL-5 had reduced circulating eosinophils, whereas those deficient in eotaxin could not recruit eosinophils to the mucosa, although they showed evidence of systemic sensitization with both IgE and IgG1 responses.

A particular role for eosinophil recruitment in the disturbance of gut motility frequently seen in food allergies was provided by the same group in similar studies of gastric eosinophil recruitment.[133] Using ovalbumin-coated beads, it was possible to confirm that antigen induced delayed gastric emptying in sensitized animals and that this was dependent on antigen-specific recruitment of mucosal eosinophils. Further studies using these animals have identified the esophagus as a particular target for eosinophil recruitment, both by dietary antigen and by less predictable stimuli such as inhaled aeroallergens[134] or increased systemic IL-5 release.[135]

Human relevance of these murine findings is suggested by evidence of increased expression of IL-5 mRNA within the small bowel mucosa after challenge of food-allergic patients but not in atopic or nonallergic controls.[136] Circulating T cells from food-allergic children produce IL-5 on food challenge, whereas those from tolerant children do not.[67,137] Eotaxin expression is increased in the esophageal basal epithelium in infants with gastroesophageal reflux secondary to CMSE compared with those with a primary mechanical reflux.[138] These studies suggest that IL-5 and eotaxin are two potential targets for specific immunotherapy in food-allergic enteropathy.

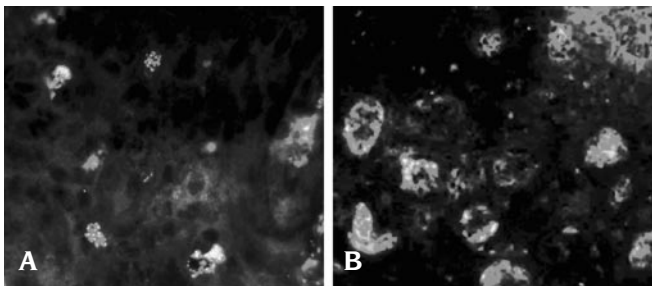

FIGURE 44.2-6 The major mediators of eosinophil recruitment in food-allergic enteropathy.[132–136,138] *A* is a high-power view showing interleukin (IL)-5 immunoreactive cells with intense granular IL-5 expression. Both mast cells and eosinophils were shown to be IL-5 positive on double staining. *B* shows intense eotaxin expression within crypt epithelium, with weaker staining on the surface epithelium in the top-right.

DIAGNOSTIC STRATEGIES FOR FOOD-ALLERGIC ENTEROPATHY

Food Challenge Testing

The core requirement for diagnosis of food allergy is response to an elimination diet with recurrence of symptoms on challenge.[139,140] Other diagnostic tests may support the diagnosis but are secondary to this. In the circumstance of allergy to a single food, complete exclusion should induce relief of all symptoms and restore normal growth if this was impaired. For a secure diagnosis, the second requirement is a recurrence of symptoms on challenge with the food antigen. In some cases, however, parents may refuse challenge if their child has improved dramatically and diagnostic tests such as skinprick tests were positive. Insurance companies often require positive food challenges for confirmation of diagnosis.

In addition to the initial diagnostic challenge, later challenges may be performed when it is reasonably likely that tolerance has been regained. This is usually after the age of 2 years, and tolerance may be regained later than this in children with multiple food allergies. The ESPGHAN recommendations for investigation of possible food-sensitive enteropathy included the need for small bowel biopsy in cases of failure to thrive or diarrhea but stated that blinded challenge was not always necessary in younger children.[141] In cases of multiple food allergies, response to elimination of just one or two antigens will be incomplete, and it may be quicker to move initially to a very restricted diet, which can subsequently be broadened. It may be difficult to persuade some parents to broaden the diet if there has been a very clear clinical response or if they have received advice from some alternative practitioners or Internet sites. In cases of exclusively non–IgE-mediated allergy, it may become very difficult to obtain a clear picture of the true level of sensitization.[16,29] The associated minor immunodeficiency may increase the chance of viral infection during prolonged food challenges.[16,115,116] It is thus important not to perform food challenges while a child is systemically unwell. For multiply sensitized children, it can be logistically difficult to perform lengthy blinded challenges.

Open food challenges are performed either in the outpatient clinic or in a day ward, depending on the severity and type of reaction expected.[29,142] It is usual to perform a graded challenge in cases of immediate reaction, beginning with single drops and moving to increasing amounts, with a period of several minutes between stages. It is mandatory to have adequate medical supervision and appropriate

resuscitation facilities in cases of immediate reaction. In cases with a history of anaphylaxis, an intravenous line should be inserted.

For the child who makes delayed reactions only, as in classic CMSE, challenges have to be extended over several days and are usually completed at home. In a recent large study of 370 challenges in 242 children, 5 children demonstrated mild reactions immediately after intake, but only on the second day at home and not at initial administration.[143] These reactions were subsequently confirmed by the skinprick test and double-blind placebo-controlled food challenge (DBPCFC). Hill and colleagues identified early reactions to milk (within 1 hour), intermediate reactions (up to 1 day), and very late reactions (up to 3 days).[49,73] For the very late reactions, the cumulative intake of milk was high—up to 120 mL. There are reports of even later responses to cow's milk challenge, with gastrointestinal, respiratory, or cutaneous responses beginning a week after challenge.[144] Thus, the interpretation of food challenges is by no means always straightforward, particularly in the case of non–IgE-mediated delayed symptoms. Whereas some cases of food-sensitive enteropathy have associated immediate reactions, many do not. There is a difficult balance between missing true late responses and colluding in the overdiagnosis of food allergy.

The "gold standard" challenge test is the DBPCFC. This is much easier for immediate reactions than delayed ones and can be quite cumbersome if several antigens need to be tested over a prolonged period. However, it does provide a degree of certainty that other challenges do not.[1,29,140,142] For immediate allergies, DBPCFCs are highly specific and of high prognostic value, with a suggested false-positive rate below 1% and a false-negative rate below 5%.[140] No universally accepted protocol exists,[140] but suspected allergens or placebo are given in a hidden form, either in liquid or inside a capsule, over a period of around 2 hours. The child should not have been given the antigen for at least 2 weeks and should be well and not receiving antihistamines. For cases of food-sensitive enteropathy, it may be necessary to exceed the total 10 g usually administered and to continue the challenge for at least 3 to 4 days.

Skinprick Testing

Skinprick tests are much less useful in straightforward food-sensitive enteropathy than in immediate allergies.[16,142] These tests are performed by placing a drop of the potential antigen on the skin and introducing it into the skin with a lancet. Both positive and negative controls are used (histamine and saline, respectively), and the results are read at 15 to 20 minutes. Sensitizing antigens cross-link surface IgE on cutaneous mast cells and induce mast cell degranulation. The size of wheal elicited may be of prognostic value. Although a wheal of greater than 3 mm is usually regarded as positive, in young infants, the histamine response is smaller because there are fewer cutaneous mast cells.[47] For immediate reactions, larger skinprick wheals (> 8 mm) may predict positive food challenges.[145,146]

The atopy patch test may potentially offer a better insight into food-sensitive enteropathies because the cellular mechanisms of this skin reaction are more similar to those in enteropathy. In the atopy patch test, the antigen in question is maintained for 48 hours against the skin in a sealed patch before being removed, and the skin response is studied after a further 24 hours.[48] A positive test is characterized by erythema and induration at this stage. The test appears to be mediated by a specific T-cell response to dietary antigen,[147] in contrast to the simple mast cell responses in the skinprick test.

The combination of patch testing with skinprick testing or specific IgE serology may detect food-sensitized children who were negative on classic testing.[148,149] Despite an apparently high sensitivity for delayed responses of up to 89%,[48,148–150] the atopy patch test has not yet become widely used and remains under evaluation. There are still few data on the relevance of patch testing in food-sensitive enteropathy, in contrast to eczema. It cannot be assumed that these two delayed hypersensitivity reactions will have identical skin patch testing results because the T cells that infiltrate the skin during the test are likely to express skin-homing markers such as CLA, whereas those involved in CMSE are likely to express the gut-homing integrin $\alpha_4\beta_7$ and not CLA. There are also possible logistic difficulties because reading of the test requires a second assessment after 3 days, and there is the possibility of artefactual induction of local erythema while unsupervised in cases of factitious illness.

Specific IgE Testing

Testing of specific IgE production to individual foods can be helpful, providing results complementary to skinprick testing. For immediate allergies, the information provided can be clinically predictive, although they are less useful in straightforward enteropathies. Positive predictive values of 95% were found for egg, milk, peanut, and fish reactions, at different thresholds.[151] The tests are reported on a semiquantitative scale of 0 to 6, with a likelihood of immediate reaction at level 3 or more. Higher titers of specific IgE for milk, casein, or β-lactoglobulin increase the likelihood of long-lasting sensitization.[152]

Study of epitope sequences bound by food-specific IgE may give prognostic information. Binding to linear peptide sequences within the egg antigen ovomucoid was associated with long-lasting allergy, whereas binding to discontinuous sequences (only bound by IgE because of protein folding) was seen in those who outgrew allergies.[39] Thus, some children will react to raw but not cooked egg, where the tertiary sequence has been disrupted. Similarly, IgE reaction to linear sequences in α_{S1}-casein, α_{S2}-casein, and κ-casein appears to be predictive of long-lasting milk allergy.[39,40] In future, epitope sequencing may identify infants at risk of long-lasting food allergies and thus potentially likely to benefit from immunotherapy.

In Vitro testing

Lymphocyte function tests are still useful only in research rather than diagnosis, and in vitro stimulation tests have not proved as useful as once hoped. Analysis of cytokine production patterns in response to food antigens may provide one future approach, particularly if surface mark-

ers characteristic of either sensitized or tolerant cells can be identified. Peripheral blood lymphocytes from food-allergic children produce a Th2 response to antigen, dominated by IL-4, IL-5, and IL-13, whereas the response from healthy controls is more Th1 skewed, dominated by IFN-γ.[137] Mucosal T cells show a different pattern of reactivity, without the Th2 dominance. A promising technique involves tagging peripheral blood mononuclear cells with carboxyfluorescein succinimidyl ester, which allows recognition by flow cytometry of antigen-specific T-cell responses.[67] This confirmed that peripheral T-cell responses to peanuts in children with peanut allergy are indeed skewed toward Th2 in contrast to findings of a Th1-dominated response in healthy controls or those who had outgrown their allergies.[67] The authors report similar skewing in milk and egg allergy, suggesting a common mechanism in IgE-mediated food allergies. Thus, it is the host immune response, rather than specific effects of food antigens, that determines whether allergy is induced. As mentioned above, the mucosal pattern in food-sensitive enteropathy is less straightforward and is characterized by preserved Th1 responses but decreased Th3-type regulatory responses.[57,60,64]

MANAGEMENT OF FOOD-SENSITIVE ENTEROPATHY

Primary Prevention

It remains controversial whether food-sensitive enteropathy and other food allergies can be prevented by stringent avoidance of allergies in early life.[153] Two position statements by the AAP[42] and the ESPACI with ESPGHAN [43] differ in some important respects. Neither considered food-sensitive enteropathy alone but rather the broader topic of overall food allergies. Both statements suggest that primary prevention should be limited to high-risk infants only and recommend use of hypoallergenic formulas, usually extensively hydrolyzed, rather than soy milk for bottle-fed high-risk infants. The degree of risk is defined on family history grounds, the AAP statement requiring two first-degree relatives with atopic disease and the ESPACI/ESPGHAN statement only one. Neither recommend maternal exclusion diets during pregnancy, whereas both recommend exclusive breastfeeding but for slightly different periods (AAP 6 months, ESPACI/ESPGHAN 4–6 months). The AAP, but not ESPACI/ESPGHAN, recommends exclusion of peanuts and nuts during lactation. The AAP also recommends much later introduction of cow's milk and eggs than the European statement.

A large study from the German Infant Nutrition Intervention study group randomly assigned 2,252 at-risk infants at birth to receive one of four blinded formulas (cow's milk based, partially hydrolyzed whey, extensively hydrolyzed whey, or extensively hydrolyzed casein).[154] The primary end point at 1 year was the presence of one or more of atopic dermatitis, gastrointestinal food allergy, or urticaria. The study had a high attrition rate owing to exclusive breastfeeding in 865 cases and noncompliance or dropping out in 442 cases. Study of the 945 remaining infants showed a protective effect of extensively hydrolyzed casein compared with unmodified cow's milk (9% vs 16% had allergies). Atopic dermatitis was reduced in infants fed extensively hydrolyzed casein or partially hydrolyzed whey formulas.[154]

Treatment of Established Food-Sensitive Enteropathy

For treatment of established food allergies overall, both the AAP[42] and ESPACI/ESPGHAN[43] statements recommend complete exclusion of the causative antigen. For the treatment of the milk-sensitized infant, both recommend an extensively hydrolyzed but not a partially hydrolyzed formula. The AAP guidelines but not the ESPACI/ESPGHAN guidelines also recommend soy as an alternative, whereas both recommend an amino acid formula for the infant who is intolerant of hydrolysates. Neither recommend the use of unmodified goat's or sheep's milk. For the infant who sensitizes while breastfed, both statements support maternal exclusion of the relevant antigen, whereas the AAP further recommends weaning to an extensively hydrolyzed formula or soy milk. With respect to probable food-sensitive enteropathy, both recommend extensively hydrolyzed or amino acid formulas. Thus, in cases of diagnosed or probable CMSE, soy milk feeds are not recommended as an alternative.[42,43]

FUTURE POSSIBILITIES FOR FOOD-SENSITIVE ENTEROPATHY

As mentioned above, there is evidence that the normal flora plays a role in the induction of tolorogenic lymphocytes and the establishment of oral tolerance.[155] Indeed, oral tolerance cannot be established normally in germ-free mice without a gut flora.[156] Handling of the newborn infant was shown in a study of the 1970 UK national birth cohort to affect the incidence of allergic disease in young adulthood.[157] The early gut colonization of allergic infants differs from those without allergies.[158] Thus, one major question is whether the "clean child hypothesis"[159] may apply at the level of the normal gastrointestinal flora and whether the major changes in early colonization in the last half-century[25,160] have played a role in the increasing incidence of allergies and the novel forms of food allergy such as breast milk sensitization. Because interaction between gut bacteria in early infancy and innate immune cells may determine whether a response sufficient to induce tolerance occurs, probiotic organisms represent a potentially important form of immunomodulator, particularly in infancy. However, much work remains to be done to determine the ideal dosage, timing, and type of probiotic.[160]

The potential role for probiotics in prevention of food allergies in susceptible infants is thus likely to be based on the role of luminal bacteria in inducing a tolerant lymphocyte response.[25,60] Genetic variation in receptors for bacterial products, such as Toll-like receptors and NOD proteins, is known to occur and is very likely to be related to allergic sensitizations,[161] particularly because Toll receptors are

also expressed on mast cells.[162] Thus, the early results using probiotics neonatally, suggesting that non–IgE-mediated allergies in particular may be reduced by *Lactobacillus GG* or *Escherichia coli*, are of particular relevance for the future.[163–165] The use of probiotics at birth may be more effective because it may allow stable long-term colonization, which does not occur if probiotics are administered after the first 6 months of life.[166]

An alternative approach to whole probiotic organisms is to attempt to induce tolerance with bacterial products. A suspension made from killed *Mycobacterium vaccae* reduced airway eosinophilia in murine asthma by inducing a TGF-β– and IL-10–dependent regulatory T-cell response that was allergen specific.[167] More safety data need to be accumulated and placebo-controlled trials completed, but such approaches appear promising for the future.

In the treatment of established food-sensitive enteropathy, there may be potential benefit from supplementing dietary ω-3 fatty acids, and a murine model of ovalbumin-induced enteropathy was attenuated by reducing intake of ω-6 fatty acids or by supplementing ω-3 intake.[168] There are also murine data to suggest that the induction of regulatory lymphocytes necessary for oral tolerance may be enhanced by administration of vitamin D receptor ligands such as 1,25-dihydroxyvitamin D_3.[169]

Other potentially novel therapies for food allergies include immunotherapy, which depends on gradually increasing the dose of antigen until a Th1 response is made.[170] Future targets include small peptide vaccines, foods with altered protein sequences, deoxyribonucleic acid (DNA) immunization, and IgE-blocking agents. The small peptide vaccines are based on synthesizing 10 to 20 amino acid portions of a known allergen, which are able to block IgE binding sites but are too short to cross-link IgE and trigger mast cell degranulation.[170] Mutations in food proteins may also prevent T-cell or mast cell responses, which are so far best studied for the major peanut proteins Ara h1-3, whose T-cell and IgE binding domains have been established and mutated.[171]

There are potentially important monoclonal antibodies that may play a role in attenuating severe food allergies. Although anti–IL-5 therapy appears to be a logical choice in eosinophil-mediated enteropathy, clinical trials in asthma have been disappointing, with a reduction in peripheral eosinophilia in asthma without an effect on bronchoconstriction.[172] In addition to IL-5 monoclonals, eotaxin blocking therapy would appear to be a logical choice for eosinophilic enteropathy in cases in which food exclusion alone is insufficient. There have also been promising results with anti-IgE monoclonal therapy in peanut allergy,[173] which is of more relevance at this stage to anaphylaxis than enteropathy.

One future challenge may be the induction of food-allergic responses, including enteropathy by genetically modified foods. In one notable case, the Brazil nut 2S albumin protein was introduced transgenically into soy to increase the protein content of cattle food. This protein turned out to be a previously unsuspected Brazil nut allergen, and the transgenic soy induced reactions in Brazil nut–allergic patients.[174] Many potentially allergic molecules are large, heavily glycosylated, and resistant to digestion.[175] It has been suggested that novel proteins should be tested by immunoassay against sera from allergic patients.[176] However, this may not detect the epitopes more likely to cause small intestinal enteropathy, and it is possible that in vitro organ culture may provide a better guide to the responses within the specialized microenvironment of the intestine that may lead to an enteropathic response to novel antigens.[131]

3. *Autoimmune Enteropathy*

Frank M. Ruemmele, MD, PhD
Nicole Brousse, MD, PhD
Olivier Goulet, MD, PhD

Over the past few years, major advances in the understanding of the pathophysiology of intractable diarrhea of infancy (IDI) were made, allowing a new conceptual view of this heterogeneous group of different diseases. The term "intractable diarrhea of infancy with persistent villous atrophy" is based on the clinical observation of a diarrhea starting within the first 2 years of life, which is abundant (> 100 mL/kg/d) and persists despite bowel rest, along with a flat intestinal mucosa. Diarrhea rapidly becomes life threatening, and long-term total parenteral nutrition (TPN) is required. A clearly distinct presentation of IDI is in the form of autoimmune enteropathy (AIE). The first report of AIE in the literature goes back to 1978.[1] McCarthy and colleagues reported on an adolescent boy with immunoglobulin (Ig)A deficiency who showed a severe enteropathy with total villous atrophy and circulating gut autoantibodies.[1] The term AIE was introduced by Unsworth and Walker-Smith for severe persistent diarrhea in the absence of immune deficiency but associated with autoimmune disorders.[2] One characteristic of AIE is the presence of specific complement-fixing circulating antibodies directed against small intestinal and colonic epithelial cells.[3] A historic keystone in the description of protracted, immune-mediated diarrhea is the report of Powell and colleagues, who observed in the same family over three generations 17 boys with various autoimmune disorders. Eight of them died of severe protracted diarrhea.[4] This and other observations clearly suggest an X-linked mode of transmission.[2,5–10] However, some rare cases of girls presenting with AIE have been reported.[11–13] Meanwhile, there are several reports on immune-mediated profuse diarrhea occurring within the first few months of life, often preceded or accompanied by insulin-dependent diabetes mellitus or other endocrinopathies, indicating a systemic rather than an isolated gastrointestinal disease.[8–10]

Based on recent advances on the genetics, pathophysiology, and clinical presentation, AIE can be classified into three different types: the classic form of AIE, type 1, which is identical to the so-called IPEX syndrome (immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome), type 2 (without extraintestinal manifestations), and type 3 (in girls). AIE has to be clearly distinguished from profuse diarrhea occurring in different forms of immunodeficiency syndromes.

IPEX SYNDROME (AIE TYPE 1)

IPEX is a rare disorder, and clinical experience is based on a limited number of cases. To date, no estimates of incidence have been proposed. The main clinical characteristic of IPEX is the combination of early-onset type 1 diabetes mellitus, severe immune-mediated enteropathy, and eczema-like dermatitis (see below). IPEX is usually fatal during early infancy. Recently, with the characterization of specific mutations in the *FOXP3* gene, a first clue to the understanding of this X-linked disorder was found.[14,15]

Pathophysiology

First insight into the pathophysiology of IPEX came from scurfy mice, which are a naturally occurring X-linked mutant presenting with symptoms very similar to human IPEX, that is, massive lymphoproliferation, scaly skin, diarrhea, intestinal bleeding, anemia, thrombocytopenia, and hypogonadism.[16–18] Symptoms occur only in hemizygous mutant males; female carriers are asymptomatic. In scurfy, CD4+CD8– T cells are chronically activated and play a key role in the development of the disease.[19,20] These cells are characterized by an up-regulation of the cell surface antigens CD69, CD25, CD80, and CD86, a marked hyperresponsiveness to activation via the T-cell receptor (TCR), and a decreased requirement for costimulation through CD28. In scurfy, high levels of cytokines, such as interleukin (IL)-2, -4, -5, and -10 and tumor necrosis factor (TNF)α, were produced by these cells.[19,20] The gene mutated in scurfy mice was recently identified (*FOXP3*) and cloned on the X chromosome.[16,21] It encodes a 48 kD protein of the forkhead (FKH)/winged helix transcription factor family, named scurfin.[21] This protein is expressed at low levels in CD4+ T cells, with a more abundant expression in the CD4+/CD25+ T-cell subgroup. The structure of the protein suggests that it has deoxyribonucleic acid (DNA) binding activity. Schubert and colleagues recently showed that scurfin acts as a repressor of transcription and regulator of T-cell activation.[22] Intact scurfin represses transcription of a reporter containing a multimeric FKH binding site. Such FKH binding sites were identified adjacent to nuclear factor of activated T cells (NFAT), regulatory sites in the promotors of IL-2, or granulocyte-macrophage colony-stimulating factor enhancer. This observation indicates that intact scurfy is capable of

directly repressing NFAT-mediated transcription of the IL-2 gene in CD4+ T cells upon activation.[22] The exact molecular mechanisms leading to scurfy are not yet fully understood. However, there is experimental evidence that the biologic activity of scurfin depends on a functional FKH domain. In scurfy mice, a 2 bp insertion results in a premature stop codon leading to a loss in the C-terminal domain.[21] The loss of function of scurfin may result in abnormal (nonsuppressed) T-cell reactivity, leading to an uncontrolled inflammatory reaction.

Genetic Background

The overwhelming clinical similarities between scurfy mice and patients led to an exhaustive genetic analysis in IPEX families. Genetic mapping in these families allowed identification of the human IPEX locus to chromosome Xp11.23-q13.3.[23–25] The gene was named *FOXP3* (or *JM2*), and its protein product was named scurfin.[23] As discussed, scurfin is implicated in the regulation and suppression of T-cell activation.[22] Wildin and colleagues recently reported that in 10 of 11 screened IPEX syndrome families, mutations were found within the coding region, potentially leading to a scurfin protein product with loss of function.[26] In the eleventh family, a mutation in the 3′ untranslated region of *FOXP3* was observed. Several IPEX mutations were within the winged helix domain of scurfin, altering its DNA binding capacity.[14] In two patients with typical clinical symptoms of IPEX, no mutations were found within the coding regions of *FOXP3*,[14,15] suggesting that regulatory or conditional mutations may occur outside *FOXP3*, such as described by Bennett and colleagues in the polyadenylation signal following the final coding exon of *FOXP3*.[27] This may result in a decreased *FOXP3* messenger ribonucleic acid (RNA) expression, probably owing to nonspecific degradation of the aberrant RNA. In addition, it is possible that other forms of IPEX (AIE with extraintestinal manifestations) may also occur in boys. The molecular mechanisms of IPEX without mutations in *FOXP3* remain to be elucidated. Females are obligate carriers of these IPEX mutations without any clinical symptoms.[28] None of the mutations described in IPEX patients were observed in 240 nondisease, ethnically diverse individuals, excluding the possibility of gene polymorphisms unrelated to IPEX.[14]

Clinical Presentation

IPEX can be considered a classic, full presentation of AIE (Table 44.3-1). The major clinical symptoms are the association of a severe enteropathy with insulin-dependent diabetes mellitus along with eczema, hematologic abnormalities, and, eventually, other endocrinopathies.[26,29–31] In many cases, the onset of diabetes is prior to the first intestinal symptoms. Levy-Lahad and Wildin suggested that diabetes is the result of a complete inflammatory destruction of pancreatic islet cells.[32] Equilibration of diabetes with insulin in these patients is sometimes rather difficult.

The onset of diarrhea is often within the first 3 months of life; however, later onset was occasionally described.[6,33,34] Characteristically, diarrhea is of a secretory nature with stool sodium > 100 mEq/L, and it persists despite bowel rest. In our experience, stool volumes are approximately 150 mL/kg/d, with sometimes mucus or blood discharge. Patients usually develop a protein-losing enteropathy with a markedly increased clearance of α_1-antitrypsin and hypoalbuminemia. Severe clinical expression is most often a sign of a poor prognosis. Electrolyte imbalances are secondary to diarrhea. Electrolyte correction and stabilization of IPEX patients can initially be achieved only by bowel rest and TPN.

Another clinical feature of IPEX is eczema (atopic dermatitis), which is often severe in presentation. Eczema is most often diffuse, involving the entire skin, and may show follicular dermatitis. It was recently reported that eczema is present in about two-thirds of patients.[26] Further symptoms, such as thyroiditis, hematologic abnormalities (Coombs-positive anemia, neutropenia,[34] and thrombocytopenia), and diffuse lymphadenopathy, are markedly less frequent.[26,34] Thyroiditis most often presents in the form of hypothyroidism, requiring substitutive treatment. In our personal experience, hypothyroidism occurred in 2 of 13 AIE patients followed at Necker-Enfants Malades Hospital. Renal involvement, in the form of glomerulonephritis, tubulopathy, or nephrotic syndrome, was also described in a subset of IPEX patients.[9,35,36] In our patients, two cases presented with biopsy-proven membranous glomerulonephritis.

Other organ systems that are occasionally involved are the liver, ranging from normal liver function to acute or chronic hepatitis,[4,7,10,37] and the lung. In three patients, diffuse pulmonary interstitial lymphoid infiltrates were noted at autopsy.[3,7,38]

Endoscopy

Upper and lower endoscopies are mandatory when AIE is suspected. The entire gastrointestinal tract, from the stomach to the rectum, can be involved. In most cases, there is a marked discrepancy between macroscopic, endoscopic, and histologic findings. Macroscopically, the mucosa of the stomach, duodenum, jejunum, and ileum shows only mild abnormalities, that is, a variable degree of enhanced mucosal granularity along with erythema and sometimes erosions. Normally, no ulcerations are observed. Macroscopic signs of small bowel mucosal atrophy are rather discrete. Colonic lesions are more pronounced, that is, loss of the normal vascular pattern owing to inflammatory edema, along with erythema, potentially involving the entire colonic mucosa. In addition, a marked granular aspect of the mucosa is regularly observed. These findings are most

TABLE 44.3-1 CLINICAL MANIFESTATIONS OF IPEX

Diarrhea

Lymphadenopathy

IPEX = immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome.

often homogeneous along the entire colon and not distributed in a patchy manner with normal mucosa interposed. However, rectosigmoidal sparing can occur. Similarly, as in the upper gastrointestinal tract, no ulcerations are observed in the colon.

Histology

Obligate histologic findings in IPEX are the combination of villous atrophy (moderate to severe) and a massive mucosal mononuclear cell infiltration (Figure 44.3-1). This infiltrate consists predominantly of T lymphocytes and is a main feature of AIE, helping to distinguish this entity from other cases of IDI related to constitutive, inherited defects of enterocytes.[38] In most cases, severe to total villous atrophy is associated with crypt hyperplasia. Total villous atrophy on duodenal biopsies can initially mislead the physician to suspect celiac disease. However, in celiac disease, villous atrophy is associated with a striking increase in the number of intraepithelial lymphocytes.[39] In contrast, T-cell infiltration in immune-mediated enteropathy predominates in the lamina propria, with no or only a moderate increase of intraepithelial lymphocytes.[40] Whereas in celiac disease, a marked increase in T lymphocytes expressing the TCR of the δ type was observed,[41] in AIE, TCR expression is restricted to the α/β+ subset. In some patients, villous atrophy is associated with epithelial cell death and crypt abscess formation (see Figure 44.3-1B). Recent studies indicate that enterocyte cell death occurs via apoptosis, probably induced by activated, cytotoxic lymphocytes. The number of goblet cells is also reduced, and, in some cases, goblet cells are almost absent.[40,42]

Mononuclear cell infiltration within the lamina propria includes mainly CD4+ T lymphocytes and macrophages, with numerous cells expressing CD25. Human leukocyte antigen (HLA)-DR expression is markedly increased on crypt epithelium.[38] These inflammatory changes are largely observed in small bowel mucosa, but they can also be seen in other parts of the digestive tract, such as the stomach or colon.[37] All along the entire intestinal tract, the same type of lesions can be observed, including epithelial cell apoptosis, crypt abscess formation, and mononuclear cell infiltration of the lamina propria. Extensive digestive involvement is usually associated with a poor outcome.

Laboratory Findings

Peripheral blood lymphocyte counts are normal, as are the T- and B-cell subsets in almost all patients (Table 44.3-2). In addition, the CD4-to-CD8 ratio was also reported to be normal, except in one observation with a slightly increased CD4 count.[10] T-cell proliferation assays (mitogens, antigens) are within the low normal range or completely normal in the vast majority of patients. Humoral immunity is normal, with normal vaccination titers and normal immunoglobulin levels for IgG, IgM, and IgA. In clear contrast, IgE levels are often dramatically raised and can be considered as one diagnostic criterion of IPEX. In addition, persistent or periodic eosinophilia is also frequent, reflecting an atopic-allergic background. In fact, skin tests for immediate hypersensitivity are often pathologic in IPEX.[24,38]

Autoantibodies of the antienterocyte or anticolonocyte type are present in the vast majority of IPEX patients; however, in some patients, the search for autoantibodies was

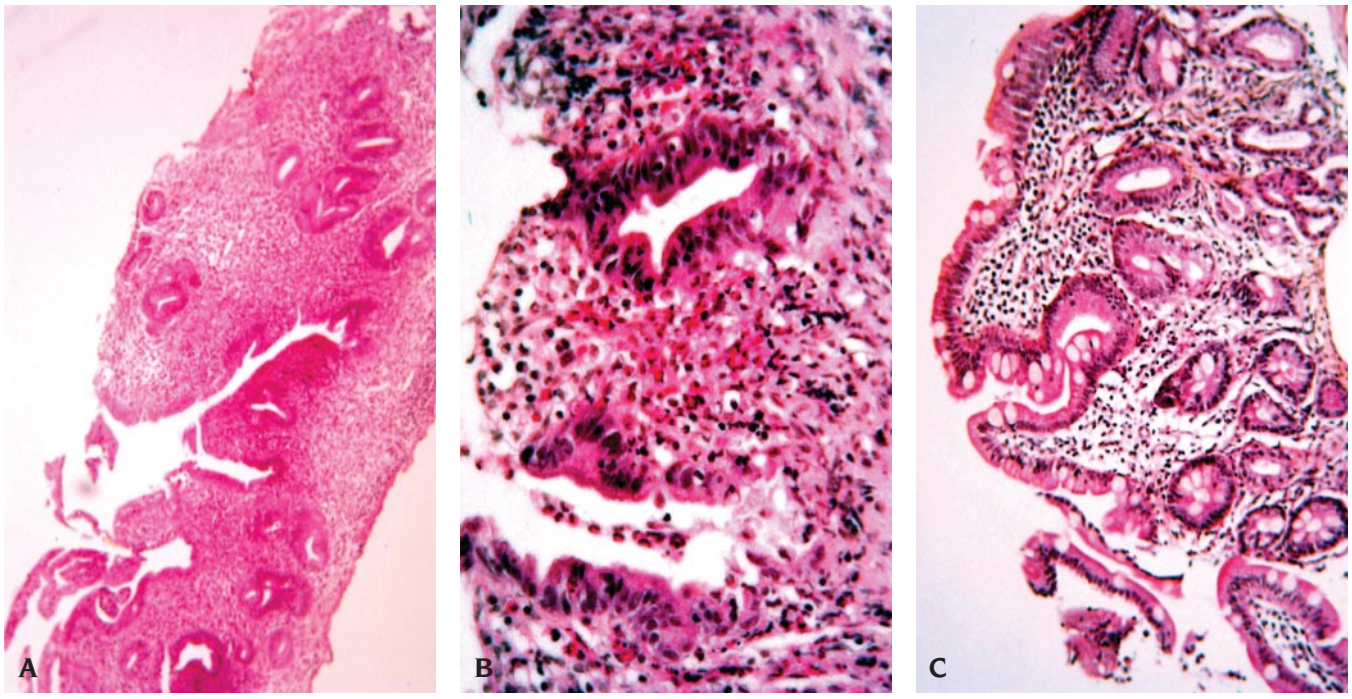

FIGURE 44.3-1 Duodenal biopsy of a patient with autoimmune enteropathy type 2 showing the dense mononuclear infiltrate of the lamina propria. Note the marked villous atrophy and dedifferentiation of the intestinal epithelial cells. *A* and *B*, At the time of diagnosis (before treatment). *C*, After 4 weeks of treatment with tacrolimus, methylprednisolone, and azathioprine, the inflammatory infiltrate is markedly reduced, and a normal intestinal architecture is visible (hematoxylin and eosin; ×10 original magnification).

TABLE 44.3-2 LABORATORY FINDINGS IN IPEX

BIOLOGIC PARAMETERS	FINDING IN IPEX
White blood cells	Normal; sometimes eosinophilia
CD4-to-CD8 ratio	Normal or CD4+ slightly increased
IgG, IgA, IgM	Normal
IgE	High–extremly high
Antienterocyte antibodies	Present (IgG type, sometimes IgA or IgM)
Anticolonocytes antibodies	Present (IgG type, sometimes IgA or IgM)
Anti–goblet cell antibodies	Present or absent
Anti-AIE-75 antibodies	Present or absent
Anti-GAD	Present or absent
Anti-SMA	Present or absent
Anti-DNA	Present or absent
Albumin	Always (markedly) decreased
Liver enzymes	Can be increased
α_1-Antitrypsin clearance	Pathologic

AIE = autoimmune enteropathy; DNA = deoxyribonucleic acid; GAD = glutamic acid decarboxylase; Ig = immunoglobulin; IPEX = immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome; SMA = smooth muscle antibodies.

negative.[9,34,43] On the other hand, antienterocyte antibodies at very low titers were also observed in other inflammatory gut conditions, such as Crohn's disease, ulcerative colitis, or cow's milk allergy.[9] In the context of IDI, the presence of antienterocyte (human duodenum, jejunum) and/or anticolonocyte antibodies of the IgG type are thus highly suggestive of AIE. Antienterocyte antibodies of the IgA or IgM type were also described in a subgroup of patients.[9] High titers and the complement-fixing ability of antienterocyte antibodies indicate a poor prognosis. Indirect immunofluorescence studies showed that these autoantibodies are directed against components of the cytoplasm of mature enterocytes, with an increasing intensity toward the villus tip (Figure 44.3-2). Positive staining of the intestinal brush border membrane can also be observed. A pathogenetic role in the onset of intestinal inflammation—as suspected in the past—is rather unlikely.[2,3,6,44,45] The occurrence of antienterocyte/anticolonocyte antibodies is rather an epiphenomenon of intestinal inflammation. A precise kinetic study performed in one patient showed that autoantibodies occurred after the onset of intestinal lesions.[44] Anti–goblet cell antibodies are also encountered in AIE patients.[42] Another highly specific antibody often detected in IPEX patients is directed against a novel gut- and kidney-specific 75 kD antigen, named AIE-75.[35,46] This antigen shares over 99% identity with NY-Co-38, a colon cancer–related autoantigen.[47] Other circulating autoantibodies observed in IPEX are antibodies against gastric parietal cells, pancreatic islets, insulin, glutamic acid decarboxylase, and anti–smooth muscle, antiendoplasmic reticulum, antireticulin, antigliadin, antiadrenal, anti-antinuclear antibodies, and anti-DNA antibodies. Finally, antithyroglobulin or antimicrosomal antibodies can be seen without the clinical symptoms of hypothyroidism.[3,4,13,43–45,48–50]

No particular or pathognomonic laboratory abnormality is observed in IPEX. Clinical laboratory tests are within the normal range, apart from signs of diabetes mellitus, protein-losing enteropathy, hypothyroidism, and, eventually, cytopenia. Electrolyte disturbances are secondary to secretory diarrhea and hypoproteinemia, and decreased albumin levels indicate the degree of protein-losing enteropathy. Abnormal biochemical liver tests (increased transaminase activity and cholestatic markers) were reported[4,7,37]; however, this can also be secondary to TPN.

Highly elevated stool levels for TNF-α or calprotectin, as markers of intestinal mucosal inflammation, are regularly encountered in IPEX patients (personal unpublished data, 2004). With the induction of remission, these inflammatory fecal markers return to normal. A reliable marker for the degree of protein-losing enteropathy in AIE is an increased clearance of α_1-antitrypsin in the stool. Indeed, whereas, normally, this clearance in the stool is less than 20 mL/d, in our IPEX patients, α_1-antitrypsin clearance was pathologically elevated.

AIE TYPE 2: WITHOUT EXTRAINTESTINAL MANIFESTATIONS

A few patients were described in whom the disease was exclusively limited to the gastrointestinal tract in the form of secretory diarrhea with positive circulating antienterocyte/anticolonocyte antibodies and positive anti-AIE-75 antibodies. In these patients, no extraintestinal manifestations were reported.[6,37] A priori, *FOXP3* mutations are not a characteristic of these patients. However, in the past, mutational analyses of the *FOXP3* gene were not performed; therefore, it is unclear if these children do not present with a minor or monosymptomatic form of IPEX. On the other hand, other mutations in regulatory genes controlling T-cell functions on the level of the intestinal mucosa are very likely. It would be interesting to study if the long-term follow-up of these patients reveals the occurrence of extraintestinal symptoms. In our personal experience, three boys presented with an isolated intestinal manifestation of AIE without any notion of endocrinopathy, hematologic abnormalities, or renal involvement. *FOXP3* mutations were negative in all patients. However, all three patients had a

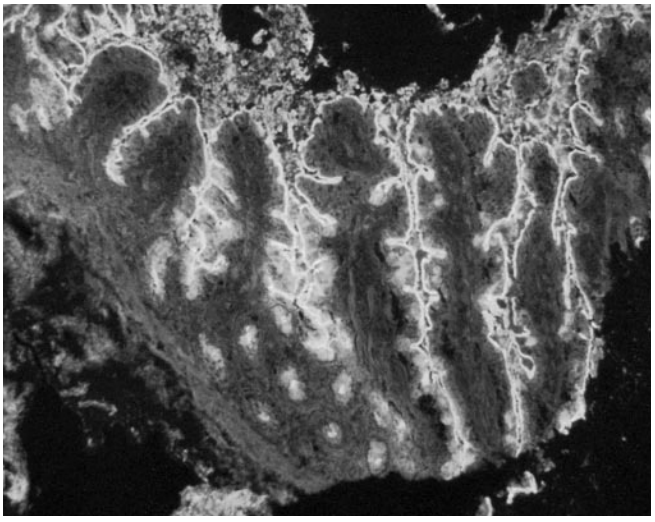

FIGURE 44.3-2 Immunofluorescence staining pattern of circulating antienterocyte antibodies, which are directed against the brush border membrane of intestinal epithelial cells.

marked eczema-like dermatitis. In this patient group, the clinical presentation of secretory diarrhea within the first few months of life and endoscopic and histologic findings were not different from typical IPEX patients (see above). In particular, the histologic picture of a marked mononuclear cell infiltration of the intestinal lamina propria, along with villous atrophy and epithelial cell apoptosis, was identical to that described in IPEX. The diagnosis of AIE type 2 is made by the presence of antienterocyte and/or anticolonocyte antibodies, along with positive anti-AIE-75 antibodies. Antienterocyte/anticolonocyte antibodies fix against intracytoplasmic compounds of mature enterocytes and, in some cases, against intestinal brush border membrane compounds (as discussed above). Future genetic analyses in these patients have to be performed to clarify if these patients carry a specific gene defect, presumably also implicated in the regulation of T-cell activation, which is different from *FOXP3*.

AIE TYPE 3: IN GIRLS

The observation of rare cases of AIE in girls[6,11–13] suggests that there might be a different non–X-linked mode of the disease. In most cases, these girls present with extraintestinal autoimmune manifestations, such as thyroiditis or diabetes. In the report by Mirakian and colleagues, one girl presented with Still disease, diabetes mellitus, and AIE with positive antienterocyte antibodies.[6] Bousvaros and colleagues described one girl showing typical symptoms of autoantibody-positive AIE associated with diabetes mellitus, indicating a strong autoimmune background.[11]

DIFFERENTIAL DIAGNOSIS

As discussed, AIE and IPEX have to be clearly distinguished from other forms of diffuse diarrhea occurring in the context of primary or secondary immunodeficiencies. Therefore, cellular and humoral immune functions have to be characterized during the initial diagnostic workup of patients in whom IPEX is suspected. In addition, some syndromatic disorders have some overlap with IPEX; for instance, Wiskott-Aldrich syndrome, which is characterized by eczema, thrombocytopenia, and autoimmunity, can also present with a variable degree of enteropathy.[51] This disorder is clearly different from IPEX in that CD8+ counts are low, and signs of a combined immune defect with recurrent bacterial infections are detectable. The search for mutations in the *WAS* gene further helps to distinguish these disorders.[52] The so-called APECED syndrome, an acronym for autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy,[53,54] can occasionally resemble IPEX. Children with APECED syndrome develop diarrhea with malabsorption along with diabetes and/or hypothyroidism. However, in contrast to IPEX, symptoms occur later in life. APECED syndrome is inherited on an autosomal recessive basis, with a known mutation in the *AIRE* gene.[53,54] Furthermore, Omenn syndrome is characterized by erythrodermia with T-cell infiltration, lymphadenopathy, diarrhea with failure to thrive, and raised IgE with eosinophilia.[55] This syndrome can be easily distinguished from IPEX in that B-cell counts are low or even zero, and T-cell proliferation responses are poor. Diabetes is not associated with Omenn syndrome, which is characterized by mutations in the *RAG1* or *RAG2* genes.[55,56]

TREATMENT AND OUTCOME

Mortality was reported to be extremely high in patients with IPEX.[57] All patients are initially dependent on parenteral nutrition. Management by TPN can be additionally complicated in patients presenting with diabetes. In the past, different treatment strategies were attempted; however, to date, only two approaches proved to be successful: immunosuppressive medication or bone marrow transplant (BMT). Immunosuppression is quite difficult because various reports clearly indicate that the response to only one immunosuppressive drug alone is rather disappointing.[4,43–45] Over the past few years, some experience was gained in treating AIE patients with steroids alone or in combination with azathioprine, cyclosporine A (CSA), or tacrolimus.[10,11,25,58–60] Other approaches include the use of immunoglobulins, antilymphocytic immunoglobulins, or cyclophosphamide, which were all rather inefficient.[61] Recently, Vanderhoof and Young reported the successful use of anti-TNF antibodies in the treatment of a patient with AIE.[62] However, on three injections, the treatment was stopped, and high-dose steroid medication was again required to maintain remission. Therefore, no information on the long-term beneficial effect of anti-TNF treatment exists. Using immunosuppressive medication, a first series of patients was treated with CSA, but only in some of them with some benefit.[58] One patient of the series by Powell and colleagues is still alive and doing well on chronic CSA medication.[4] However, many patients responded only partially or not at all to CSA. In fact, T cells from scurfy mice are highly resistant to CSA suppression, indicating that agents inhibiting TCR signaling may be of limited benefit.[21] With the introduction of tacrolimus, some advances in the care of AIE patients were made, significantly improving the outcome of AIE.[11,24,59,60] Chronic immunosuppression was effective in some patients but ineffective in others. In our experience, remission can be most often induced by the combination of methylprednisolone and tacrolimus. As indicated in Table 44.3-3, initially, steroid pulses (25 mg/kg) were applied on 3 consecutive days, followed by 2 mg/kg/d, concomitant with tacrolimus. The doses of tacrolimus are adjusted to achieve and maintain blood levels between 8 and 12 ng/mL. To maintain remis-

TREATMENT	MODALITIES
Bowel rest and TPN	Until remission
Corticosteroids	3 pulses, eventually repeated
Tacrolimus	Blood levels 8–12 ng/mL
Azathioprine	2 mg/kg/d

TPN = total parenteral nutrition.

sion, we use a triple therapy approach, combining tacrolimus, prednisolone, and azathioprine. If the response to the first steroid pulse is insufficient, a second pulse is tried. The outcome measure of immunosuppressive treatment and ultimate medical aim is to stop secretory diarrhea, allowing the child to be subsequently weaned from TPN and to start normal oral or enteral nutrition. However, chronic immunosuppression may also increase the risk for viral, bacterial, fungal, or opportunistic infections, such as *Pneumocystis carinii* pneumonia. Therefore, we put our patients on trimethoprim-sulfonamide prophylaxis. A close follow-up of IPEX and AIE patients is required to avoid or at least minimize complications related to long-term immunosuppressive medication.

In our series, the induction of remission using this triple immunosuppression (methyprednisolone, tacrolimus, and azathioprine) was successful in 7 of 8 consecutive patients. In the past (before tacrolimus was available), however, all patients treated with CSA failed to come into remission and subsequently died. In the case of nonresponse to immunosuppressive drugs, including tacrolimus, we now consider these patients as candidates for HLA-identical allogenic BMT. The first successful BMT was performed in our center on a 4-month-old boy who failed to respond to tacrolimus.[30] The donor was his HLA-identical 18-year-old sister. BMT was followed by a complete remission over 2.5 years. It is important to underline that the conditioning regimen itself already controlled the disease, further confirming that IPEX is a T cell–mediated disease.[20,57] After BMT, not only the enteropathy remained in remission, but also the diabetes and eczema were clinically silent. Insulin therapy could be stopped 7 days after BMT, and parenteral nutrition was reduced 4 weeks after BMT and stopped within 6 months. Unfortunately, 29 months after BMT, the child died of a rapidly progressive hemophagocytotic syndrome, which remained completely unexplained. Meanwhile, two other boys received BMT as the ultimate treatment option for IPEX.[26] In both cases, BMT was initially successful; however, lethal, infectious complications occurred 3 and 5 months post-BMT, respectively. These three cases indicate that BMT is potentially successful in otherwise treatment-resistant IPEX. However, this treatment remains quite difficult. Therefore, further experience with BMT has to be gained by particularly experienced teams before it could be recommended as rescue therapy for AIE. On the other hand, with the increasing understanding of the pathophysiology of IPEX, there is hope that in the near future, new immunosuppressive strategies will be available to treat this T cell–mediated autoimmune disorder.

CHAPTER 45

INTESTINAL TUMORS

1. *Intestinal Polyps and Polyposis*

Jean-François Mougenot, MD
Sylviane Olschwang, MD, PhD
Michel Peuchmaur, MD, PhD

Polyps refer to any mass projecting into the lumen of the gastrointestinal tract. However, when one refers to intestinal polyps, one usually thinks of an epithelial lesion. Histologically, epithelial polyps may be divided into two major groups: neoplastic and non-neoplastic. Neoplastic polyps include benign adenomas and malignant carcinomas. Non-neoplastic types include hamartomas as juvenile polyps, hyperplastic polyps, and inflammatory polyps. However, the term "polyp" encompasses many gastrointestinal lesions (Table 45.1-1) as submucosal lesions that also may impart a polypoid appearance to the overlying mucosa.

Occasionally, polyps in children may occur in the context of a genetic gastrointestinal polyposis disorder characterized by the presence of multiple polyps throughout the gastrointestinal tract, their histopathology, their heritability within a family, and an increase in the lifetime risk of cancer in the gastrointestinal tract and other organs. Two major categories of polyposis are recognized: adenomatous polyposis syndrome and hamartomatous polyposis syndromes (Table 45.1-2).

Ganglioneuroma

COLONIC POLYPS

Juvenile Polyps

Solitary polyps of the large intestine are common during childhood, usually presenting with painless rectal bleeding. These lesions, known as juvenile polyps, are benign and carry no long-term risk of neoplasia.

Frequency. Juvenile polyps, single or multiple (< 3), are the most frequent type of gastrointestinal polypoid lesion encountered in pediatric practice (97% of colonic polyps in our personal registry).[1] However, the true incidence of polyps in childhood remains unknown.[2] Most often, juvenile polyps are diagnosed in the first decade of life. The peak incidence occurs between 2 and 6 years of life.[1,3–5] Polyps are rare in the first year of life and much less common in children older than 10 years of age. In all studies, a male preponderance is noted.[1,5] All ethnic groups can be affected.[1]

Pathology. The various appellations given to juvenile polyps reflect some of the areas of uncertainty about the current understanding of the pathogenesis of these lesions:

TABLE 45.1-2 CLASSIFICATION OF POLYPOSIS SYNDROMES

Adenomatous polyposis syndromes
Familial adenomatous polyposis
Gardner syndrome
Turcot syndrome
Hamartomatous polyposis syndromes
Juvenile polyposis
Bannayan-Riley-Ruvalcaba syndrome
Cowden disease
Peutz-Jeghers syndrome
Mixed polyposis syndrome
Hyperplastic polyposis

juvenile retention polyp, juvenile inflammatory polyp, and juvenile hamartomatous polyp.

Grossly, juvenile polyps usually have a smooth, bright red, friable surface that bleeds easily when traumatized. Initially sessile, 90% of juvenile polyps appear pedunculated, spherical, and mushroom-like and are attached to the colonic mucosa with a narrow stalk (Figure 45.1-1). These lesions measure 1 to 2 cm in average diameter—rarely, 2 to 4 cm. The length of the stalk varies from 0.5 to 1.5 cm. The base of insertion is always broader than the distal extremity. The stalk has the same color as the colonic mucosa. The colonic chicken skin mucosa, characterized by a pale yellow, speckled pattern of the colonic mucosa, resulting from lipid accumulation in lamina propria macrophages, is observed only on larger juvenile polyps in the rectosigmoid colon, most concentrated at the base of the stalk and extending to the surrounding mucosa.[6] A cut section of polyps demonstrates numerous large cystic spaces of variable size, filled with a grayish or yellowish mucus surrounded by reddish stroma—hence the term "retention" polyp.

Microscopically, juvenile polyps have a characteristic Swiss cheese appearance created by dilated mucinous lakes widely separated by abundant stroma (Figure 45.1-2). The lamina propria is infiltrated by numerous inflammatory cells, consisting of neutrophils, eosinophils, lymphocytes, plasma cells, and histiocytes with, in some cases, lymphoid follicles. In contrast to the hamartomatous polyps of Peutz-Jeghers syndrome (PJS), smooth muscle cells are not present in the stroma.[7] However, bands of smooth muscle associated with mucosal blood vessels, serrated or stellate glands with epithelial infolding, and osseous metaplasia are occasionally seen. A single layer of cytologically bland, cuboidal to columnar, mucus-secreting epithelium lines the glands. Paneth cells are present but sparse. Some glands, filled with mucus, become cystically dilated. Epithelial cells demonstrate no atypia. Focal ulceration and hemorrhage may be seen.

Etiology. The etiology of the common juvenile polyp is unknown. If the usual mutations found in preneoplastic or neoplastic lesions are not found,[8] gene mutations implicated in juvenile polyposis (see "Hamartomatous Polyposis Syndromes") have been identified in solitary juvenile polyps but not in the somatic cells of patients.

Clinical Features. Intermittent painless rectal bleeding is the most common presentation. Rectal bleeding occurs during defecation. Major rectal bleeding responsible for acute anemia is a rare event, likely the result of autoamputation of pedunculated polyps. However, iron deficiency anemia is found in as many as one-third of cases.[9] Rectal bleeding is recurrent, present for over 3 months in 55% of cases.[1] Additional manifestations are unusual, including colicky abdominal pain, diarrhea with mucus, autoamputation with spontaneous extrusion, prolapse of rectal polyp, and prolapse of rectum.[9,10] Colocolic intussusception rarely occurs.[11]

Diagnosis. By anorectal examination, lower rectal polyps are felt as firm, moderately mobile, pedunculated masses.

Colonoscopy is the procedure of choice for diagnosis of colorectal polyps of all sizes. It allows resection of most polyps.[1,5,12,13] Endoscopic evaluation of the colon requires cleansing. The most effective preparations appear to be polyethylene glycol (PEG) electrolyte lavage solution, PEG alone, and Fleet Phosphosoda oral laxative.[14] Although juvenile polyps may be distributed throughout the colorectum, they have a distal predominance within the rectosigmoid (70%).[1,5,15] They are more often single (73%) than multiple.[1,5] Because juvenile polyps are often found in the rectosigmoid but also in the proximal colon, in front of recurrent painless rectal bleeding, and without anoperineal lesions, the preferred method for diagnosis and treatment is pancolonoscopy under anesthesia followed by snare polypectomy. Finding a polyp in the rectum does not relieve the endoscopist from the responsibility of pancolonoscopy to identify and remove additional lesions.

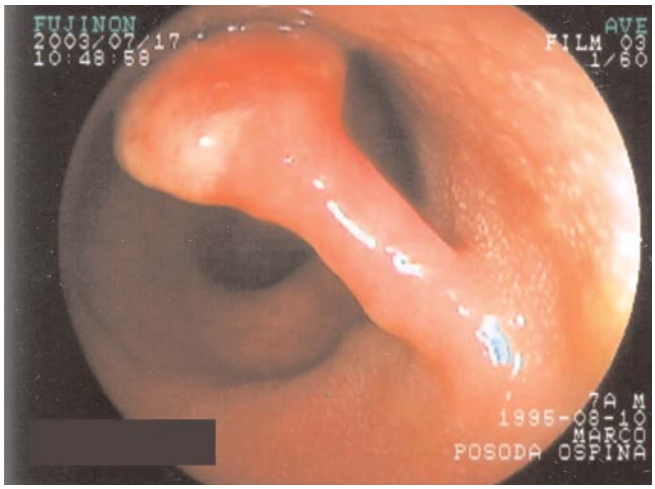

FIGURE 45.1-1 Pedunculated solitary juvenile polyp with a smooth, bright red, friable surface.

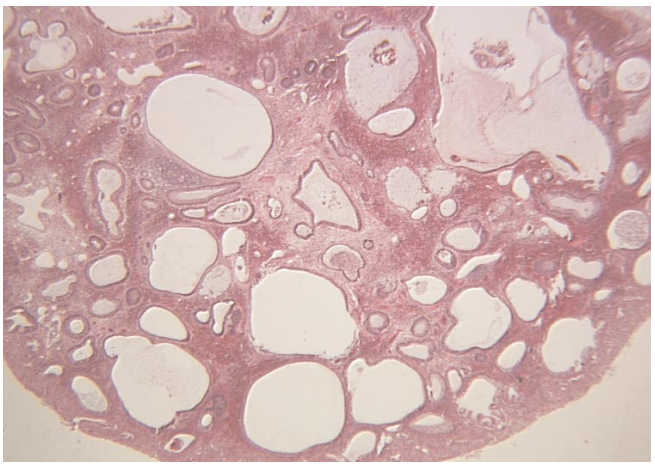

FIGURE 45.1-2 Juvenile polyp. Light microscopy: Swiss cheese appearance created by dilated mucinous lakes widely separated by abundant stroma. Lamina propria infiltrated by numerous inflammatory cells. Single layer of cytologically bland, cuboidal to columnar, mucus-secreting epithelium lines the glands. (Hematoxylin and eosin; ×75 original magnification.)

Treatment. Polypectomy is performed in a medicosurgical environment under anesthesia. Cold forceps resection is feasible only for tiny (1–2 mm) colorectal polyps. Removal with hot biopsy forceps can be used for polyps less than or equal to 4 mm in size.[16] However, the hot biopsy forceps technique anecdotally has been associated with an unexpected high rate of perforation and delayed postpolypectomy hemorrhage. Moreover, the use of hot biopsy forceps in the right colon is five times more likely to result in complication than their use in the left colon.[17] So, the monopolar hot biopsy forceps has severe risks and has no indication in this context. An alternative is to guillotine small polyps using a snare without an electric current. Tiny snares have greatly facilitated the use of snares for removal of small sessile polyps.[18] Polyps 5 mm or larger in size should generally be removed using monopolar snare cautery. Application of detachable snare loops (Endoloop, Olympus, Tokyo, Japan) to a very large stalk (> 10 mm) of pedunculated polyps has reduced the risk of delayed hemorrhage.[19] Immediate hemorrhage from pedunculated polyps can be managed by grasping the residual polyp stalk and holding it with a snare or by application of either a detachable snare or metallic clips (Endoclips, Olympus).[20] To stop more severe bleeding, an argon plasma coagulator may be useful. A 1:10,000 solution of epinephrine can be injected into the bleeding site to promote hemostasis. Postpolypectomy perforation (Table 45.1-3) occurs more frequently in children than in adults.[1,12,13,21] More than 200 procedures are reported for an endoscopist to be technically competent, and a higher complication rate appears to occur in an examiner's first 500 procedures.[14] Resected polyps or multiple polyp fragments are collected for histopathologic examination by suction into a trap if they are small or by using a Roth or a tripod basket, and, if unsuccessful, soon after colonoscopy by colorectal enema.[5] Although the risk of development of malignancy in a solitary polyp is very small, such polyps should be removed, even when discovered incidentally. It is important to emphasize that polyp histology cannot be predicted by gross appearance alone. Forceps biopsies performed through the endoscope only have a yield of correct histologic diagnosis in 75% of patients.[22]

In general, juvenile polyps do not tend to recur. However, in two large pediatric retrospective series, recurrence was observed in 4 to 7%.[1,5] The risk of malignant change for a solitary juvenile polyp is almost negligible. There are only eight cases of patients developing neoplasia in the literature.[23] In addition, a review of 82 patients with a solitary juvenile polyp showed no increased risk for colorectal cancer or of dying as result of the polyp.[24] So, if a polyp is found to be solitary after full colonoscopy and if there is no relevant family history, endoscopic polypectomy is sufficient treatment. Parents must be aware that juvenile polyps may be the first feature of juvenile polyposis. If fresh symptoms arise, the child should be reinvestigated. However, when there is a positive family history or when multiple juvenile polyps are found, the possibility of juvenile polyposis syndrome (JPS) is raised. Multiple juvenile polyps are associated with a risk of colon neoplasia,[23,25] but the precise number that statistically increases cancer risk is unknown. Three or more juvenile polyps or any number of polyps occurring in the context of a family of juvenile polyposis or colon cancer have been proposed as a criterion for a risk of colon cancer.[23]

Hyperplastic Polyps

Hyperplastic polyps rarely occur in children: 3% in our personal series of single and multiple polyps.[1] They appear as single or multiple dewdrop mucosal elevations with a smooth convex surface, arising on the mucosal crest, usually less than 5 mm, and mainly in the rectosigmoid. These small lesions are asymptomatic. When a small polyp (< 5 mm) is encountered during flexible sigmoidoscopy, it should be biopsied to ascertain whether it represents a true hyperplastic polyp or an adenoma.

Microscopically, the colonic crypts are elongated. The epithelial cells assume a characteristic papillary configuration. Absorptive and goblet cells are well differentiated. True hyperplastic polyps do not have intrinsic malignant potential. A hyperplastic polyp is not, by itself, an indication for further colonoscopy or follow-up in childhood.[26]

Polyps that display both hyperplastic and adenomatous features have been very rarely observed in childhood. When this type of polyp exhibits larger-size, prominent architectural distortion, nuclear atypia, and increased mitoses, the lesion is considered more adenomatous than hyperplastic and is termed a "serrated adenoma" (Figure 45.1-3). In such a case, the follow-up must be the same as that for adenomas.

Isolated Adenomas

Whereas in adult patients, the relationship between adenomatous polyps and adenocarcinomas has been extensively studied, isolated adenomas are extremely rare in pediatric practice. Knox, as reported in Mougenot and colleagues[2] and Rodesch and Cadranel,[5] did not observe such adenomas in patients younger than 15 years. One to three cases have been reported in a series of, respectively, 50, 77, and 129 consecutive patients with polyps.[1,2]

Pathology. Adenomas are neoplastic epithelial polyps. All adenomas feature dysplastic aspects, that is, cellular atypia, increased mitotic activity, and nuclear hyperchromatism owing to abnormal cellular differentiation and renewal. The dysplasia can be graded as low (Figure 45.1-4) or high grade (Figure 45.1-5). In high-grade dysplasia, the nuclear abnormalities are marked, and the

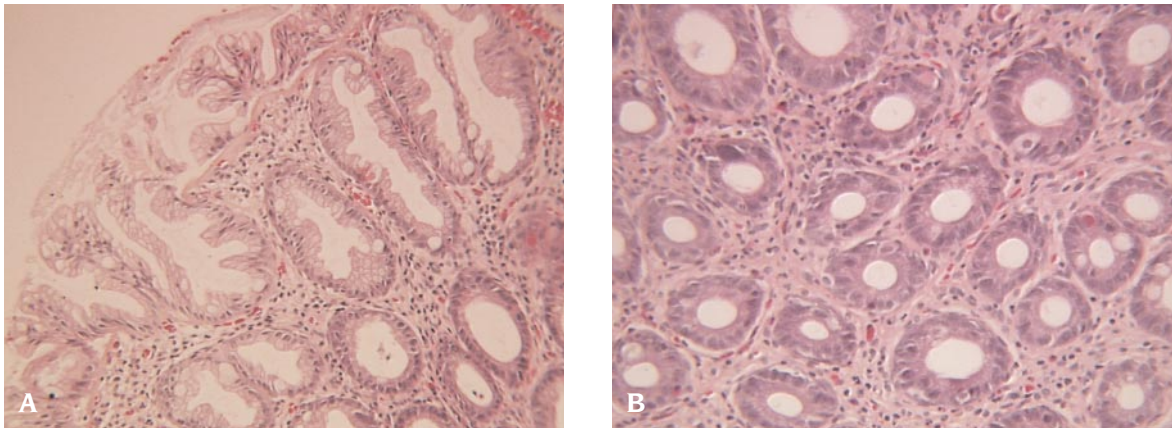

FIGURE 45.1-3 Low-power photomicrograph of a serrated adenoma showing a saw-toothed surface and stellate luminal profiles (*A*). However, the nuclei are mildly pseudostratified (*B*). (Hematoxylin and eosin; ×250 original magnifications.)

nuclei are stratified with nucleoli and uneven coarse chromatin. When cells appear overtly malignant but confined within the basement membrane, the lesion can be designated as carcinoma in situ. In practice, the term "high-grade dysplasia" encompasses severe dysplasia and carcinoma in situ. If the malignant cells extend beyond the basement membrane into the lamina propria, the diagnosis of intramucosal carcinoma must be used. In the colon, lymphatics extend only in the submucosa, which explains the absence of a risk of metastasis associated with high-grade dysplasia or intramucosal carcinoma. Invasive adenocarcinoma is defined by extension of malignant cells through the muscularis mucosa into the submucosa.

Two overall glandular patterns are separated: tubular with an organized glandular pattern (Figure 45.1-6) and villous with a frond-like pattern that is more likely present in large adenomas and is associated with a greater risk of high-grade dysplasia and invasive cancer, independent of polyp size. Adenomas demonstrating more than 75% tubular elements are called tubular adenomas. Those demonstrating more than 75% villous elements are called villous adenomas, and those with less than 75% of each are designated tubulovillous adenomas.

Adenomas originate through the process of gene mutation. Sporadic adenomas begin most commonly with somatic mutations in both alleles of the adenomatous polyposis coli gene (see "Familial Adenomatous Polyposis"). Subsequent accumulation of additional mutations results in the development of cancer. Most adenomas do not develop sufficient mutations to generate into cancer. Development of cancer requires an average time of 7 to 10 years.

Endoscopy. Only dye spraying (0.5% indigo carmine solution) in combination with high-resolution endoscopy offers the opportunity to distinguish adenomas from hyperplastic polyps in real time. Hyperplastic polyps demonstrate the normal honeycomb or evenly dotted pattern of the background colonic mucosa. All other patterns on the surface of the polyp favor an adenomatous histology. A cribriform pattern is commonly evident in adenomas when visualized with high-resolution endoscopes, even without chromoscopy.[27]

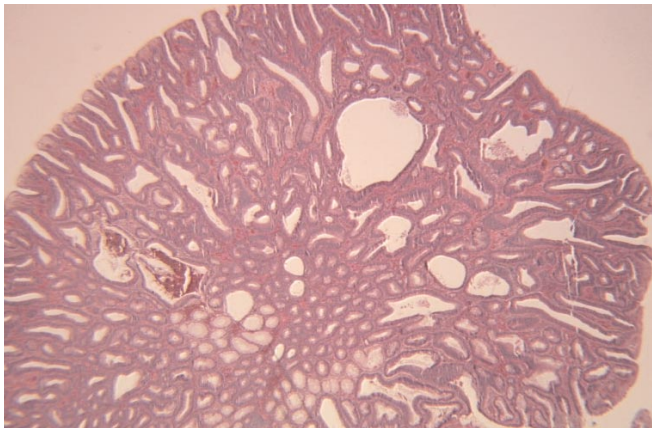

FIGURE 45.1-6 Low-magnification micrograph of a typical colonic tubular adenoma. (Hematoxylin and eosin; ×75 original magnifications.)

Pediatric Management. If an adenoma histopathologic diagnosis is made for an isolated or small number of polyps in a child or an adolescent, the following recommendations should be considered: (1) looking for a history of familial adenomatous polyposis (FAP), although a family history may be absent in sporadic forms of this disease; (2) searching for a history of familial colorectal cancer; and (3) employing postpolypectomy surveillance colonoscopy as proposed for adults by the Agency for Health Care Policy and Research Consortium (Table 45.1-4).[28]

Polyps and Ureterosigmoidostomy

After ureterosigmoidostomy, adenomas and colorectal cancer near, or distal to, the stoma have been observed in at least 29% of patients. The delay varies from 2 to 38 years after surgery: 20 years for the development of adenoma and 28 years for arising colorectal cancer.[29,30] Juvenile polyps also have been seen at sites of previous surgery, including ureterosigmoidostomy.[31] A colonoscopy follow-up at regular intervals is indicated in such cases.

Inflammatory Polyps

Inflammatory polyps arise during the healing phase of severe colitis, following full-thickness ulceration. These polyps, which have no intrinsic neoplastic potential, may mimic a neoplastic mass in diseased colon, ulcerative colitis, and Crohn colitis and chronic schistosomiasis in endemic countries.[32] Because patients with these diseases are at increased risk for developing colon cancer, careful examination of these lesions has to be considered.[33]

POLYPOSIS SYNDROMES

Recently, major progress has been made in understanding the molecular pathogenesis of polyposis syndromes. (Table 45.1–5).[34–39] A gastrointestinal polyp results from a defect in the highly regulated counterbalance of cellular growth promotion and cellular growth inhibition. This may be the result of either aberrant gain of function in a growth-promoting protein (oncogene, most often activated) or loss of function in a growth-inhibiting protein (tumor suppressor gene, most often inactivated). In the genetic gastrointestinal polyposis syndromes, a germline inactivating mutation of a tumor suppressor gene is the crucial event. Loss of normal growth regulation results from an eventual somatic mutation of the normal allele. Progression of the polyp to gastrointestinal cancer requires further acquisition of additional genetic defects.

Inherited Adenomatous Polyposis Syndromes

The inherited adenomatous polyposis syndromes are characterized by (1) the development of a large number of adenomas in the colorectum and (2) extracolonic features (ie, gastroduodenal polyps; benign soft tissue tumors; osteomas of the mandible, skull, and long bones; and congenital hypertrophy of the retinal pigmented epithelium [CHRPE]. FAP is the most common polyposis syndrome in children. It is also known as familial polyposis for patients without extracolonic manifestations or Gardner syndrome for patients with extracolonic manifestations.[40] Identification of the adenomatous polyposis coli (*APC*) gene as the gene mutated in the germline deoxyribonucleic acid (DNA) of patients affected by FAP has been a major development in understanding the pathogenesis of colorectal cancer[34–36,41] and has allowed proper classification of Gardner syndrome,[40] attenuated FAP, and some cases of Turcot syndrome as variants of classic FAP coli (Mendelian Inheritance in Man [MIM] 175100).

Familial Adenomatous Polyposis. FAP is characterized by the progressive development of hundreds to thousands of adenomatous polyps in the large intestine (Figure 45.1-7).[7,42–44] The disease begins in younger patients with a small number of tiny polyps less than 5 mm (Figure 45.1-8).[2] Half of FAP gene carriers will have polyps at colonoscopy by approximately age 15 years. The number of polyps increases progressively, with all of the colonic length being covered by countless adenomas. In all cases, the vast majority of polyps are less than 10 mm (Figure 45.1-9).

At histologic examination, all varieties of adenomatous polyps may be seen, including tubular, tubulovillous, and villous adenomas. In addition, light microscopy reveals numerous microscopic adenomas, the smallest of which may involve a single colonic crypt (Figure 45.1-10). The dysplasia exhibited by all adenomas is now categorized as low (mild and moderate dysplasia) or high grade (severe dysplasia and carcinoma in situ).

The lifetime risk for colorectal neoplasia is 100%. Although the mean ages for adenoma and colon cancer development in FAP are 16 and 39 years, respectively,[44] reports exist of colon cancer in children as young as 5 years

TABLE 45.1-5 POLYPOSIS SYNDROMES AFFECTING CHILDREN

SYNDROME TYPE	GENE	CLINICAL FEATURE	CANCER RISK

of age,[45] with an estimated incidence of 1 case younger than 20 years per 157 families.[46] Colorectal cancers in FAP have the same localization as sporadic cancer, but in 26 to 50% they are multiple and synchronous.[2,42]

Recently, attention has been paid to adenoma variants such as serrated adenomas, flat adenomas, and foci of aberrant crypts. Endoscopic/histopathologic correlations focusing on the differentiation of neoplastic from non-neoplastic lesions and identification of early malignant transformation have been supported in adult FAP by using new high-resolution videoendoscopes combined with optical zoom and dye spraying to define the mucosal pit pattern.[47]

Genetics: APC Gene and FAP-Associated Germline Mutations. ***Germline Mutations in the* APC *Gene.*** Germline mutations in the *APC* gene on chromosome 5q21[34,35] are responsible for FAP, an autosomal dominant disease that affects approximately 1 in 13,500 individuals.[48] Somatic *APC* mutations are found in the vast majority of sporadic colorectal cancers regardless of the histologic stage, which places *APC* at the very start of the adenoma-carcinoma sequence in humans.

APC *Gene.* The *APC* gene includes 21 exons contained within a 98 kb locus. The largest, exon 15, comprises more than 75% of the 8,535 basepairs of the coding sequence (Figure 45.1-11) and is the target of most germline mutations in FAP patients. The *APC* gene on chromosome 5q21 encodes a large protein consisting of 2,843 amino acids with a predicted molecular weight of greater than 309,000 kD. Studies indicate that *APC* partic-

ipates in a variety of cellular functions, including proliferation, differentiation, apoptosis, adhesion, migration, and chromosomal segregation.[49]

Mutation Penetrance. More than 300 different disease-causing mutations of the *APC* gene have been identified. Most FAP patients carry germline mutations scattered in the 5′ half of the *APC* gene. Two codons, 1061 and 1309, are mutational hot spots and account for approximately 11 and 17% of all germline mutations. About 95% of *APC* germline mutations are either nonsense (28%) or truncating frameshift (67%) mutations, which result in truncated gene products without the C-terminus.[50]

The heterogeneity of the spectrum of *APC* germline mutations and the phenotypic variability observed among FAP families have allowed the establishment of genotype-phenotype correlations at this locus. Germline mutations between codons 168 and 1680 are associated with classic FAP,[51] whereas germline mutations between codons 1250 and 1464, especially around codon 1300, are associated with the highest number of polyps, thousands rather than hundreds of colorectal adenomas with an earlier onset of the disease.[52] The expression of some extracolonic features correlates with specific *APC* germline mutations. CHRPE is associated with germline mutations between codons 457 to 1444[53–55] but is also occasionally described in patients with germline mutations in exon 9.[56] Mutations downstream of codon 1444 correlate with the highest frequency of mandibular osteomas and desmoid tumors (DTs).[57,58]

Attenuated adenomatous polyposis coli (AAPC) is characterized by multiple adenomas, late onset of carcinoma, and, frequently, the absence of extracolonic features.[58,59] This phenotype is associated with germline mutations occurring in the 5′ (codons 78–167) and 3′ (approximately codons 1581–2843) regions of the *APC* gene and in exon 9.[58] The penetrance of AAPC, although lower than that of FAP, might still be high. An attenuated phenotype has also been reported in some families with a complete deletion of one copy of the *APC* gene.[60,61] Some mutations associated with AAPC lead to an unstable messenger ribonucleic acid (mRNA) or protein. Other mutations in alternatively spliced exons, such as those in exon 9, are spliced out of at least some mRNA species, resulting in a nearly full-length protein lacking the exon carrying the mutation.[62]

The established genotype-phenotype correlations might have implications for clinical practice. For example, the

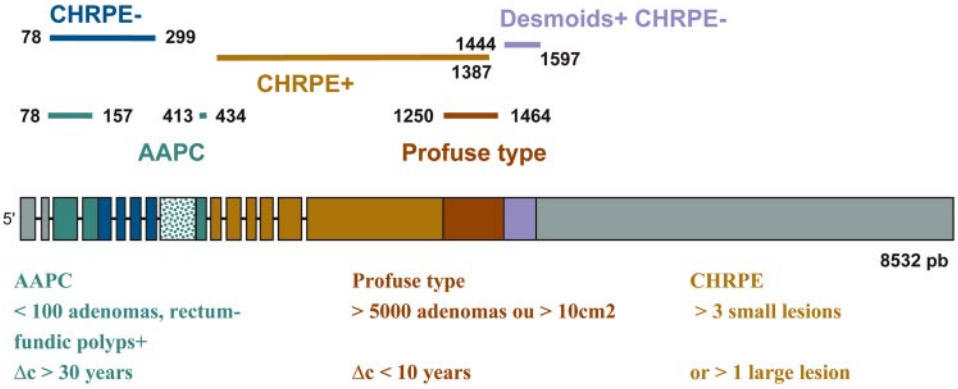

FIGURE 45.1-11 APC protein domains and familial adenomatous polyposis phenotype association with germline mutation position. AAPC = attenuated adenomatous polyposis coli; CHRPE = congenital hypertrophy of the retinal pigmented epithelium.

finding of CHPRE in a family can direct mutation analysis to the exons associated with these lesions. Moreover, the genotype-phenotype correlation regarding DTs has implications for prophylactic surgery because DTs often arise as a consequence of tissue trauma.[63–65]

Nevertheless, considerable phenotypic variability may occur even among individuals and families with identical genotypic mutations.[59,63] In genetic terms, this variability can be explained by the effects of several, as yet undetermined, genetic and environmental modifying factors.

APC *Functional* Domains. The large APC protein comprises several functional domains. Heptad repeats at the amino-terminal end mediate APC homodimer formation.[35,64] Amino acids 453 to 767 show some homology to the central repeat region of the *Drosophila* segment polarity protein armadillo, which controls cell adhesion and motility via modulation of the actin cytoskeleton.[65] A summary of key interactions of APC and β-catenin in the cell, including the Wnt-1 signaling pathway, where binding of Wnt-1 to the frizzled receptor activates disheveled, which inhibits glycogen synthase kinase (GSK) 3β phosphorylation of β-catenin, preventing its proteosomal degradation, is shown in Figure 45.1-12. This leads to the dissociation of the complex formed by axin/conductin, APC, and GSK, resulting in the accumulation of free cytoplasmic β-catenin. β-Catenin is then translocated to the nucleus, where it forms a complex with T-cell factors (Tcfs),[66] resulting in the activation of gene transcription, including the proto-oncogenes cyclin D_1 and c-*myc* and subsequent cell proliferation. Mutations in *APC* have the same effect as Wnt signaling in destabilizing the axin-APC-GSK complex. Also shown in Figure 45.1-12 are the interactions of APC with the microtubule and actin cytoskeleton and the interaction of β-catenin with the E-cadherin cell adhesion system and Tcf transcription factor. Interspersed between these motifs are three SAMP (serine-alanine-methionine-proline) repeats that mediate axin binding.[67,68] APC mediates microtubule binding when transiently overexpressed in epithelial cells and triggers tubulin polymerization in vitro. Further signals are present in the β-catenin and microtubule binding domains, which are thought to mediate nuclear localization and export of APC.[69–72] The C-terminus of APC (residues 2560–2843) interacts with the microtubule-associated protein EB1 and also binds hDLG (human homolog of the *Drosophila* disks large tumor suppressor protein) and the protein tyrosine phosphatase PTP-BL.[73,74]

Recent studies have shown that the C-terminus of APC is involved in chromosomal stability at mitosis.[67,75] APC localizes at the kinetochore of metaphase chromosomes, and this location is likely to be dependent on the interaction between APC and EB1. On the one hand, loss of the former function will lead to nondysjunction and tetraploidy; on the other hand, defects of the latter result in mitotic cells with multipolar spindles that exert multidirectional forces on the kinetochore, resulting in chromosomal breakage and fragmentation.

APC protein shows a diffuse cytoplasmic distribution, accumulating along lateral margins or subapical regions of certain cells, in particular surface cells. However, epithelial cells of the same lineage may show striking differences in the subcellular localization of the APC protein. For example, enterocytes at the base of intestinal crypts are almost always APC negative, whereas expression increases toward the upper third of the crypt and the luminal surface, where all cells are positive. In addition, enterocytes on the luminal surface show accumulation of the APC protein along their apical surfaces. The expression of APC thus seems to increase with enterocyte maturation during the migration of cells from the crypt base to the luminal surface.[76,77]

Model of Carcinogenesis. A general picture is emerging from the analysis of the essential roles of the Wnt signal transduction pathway in providing selective advantage to the nascent tumor cell and in exerting genetic instability to ensure both tumor progression and malignant transformation: the *APC* gene, because it encompasses both functions, plays a central initiating and promoting role in colorectal cancer. Its inactivation and the resulting constitutive activation of the Wnt pathway provide a strong selective advantage by affecting cell proliferation, migration, apoptosis, and, possibly, differentiation of the intestinal stem cell. Subsequently, other synergistic mutational events may allow the mutant *APC* to induce chromosomal insta-

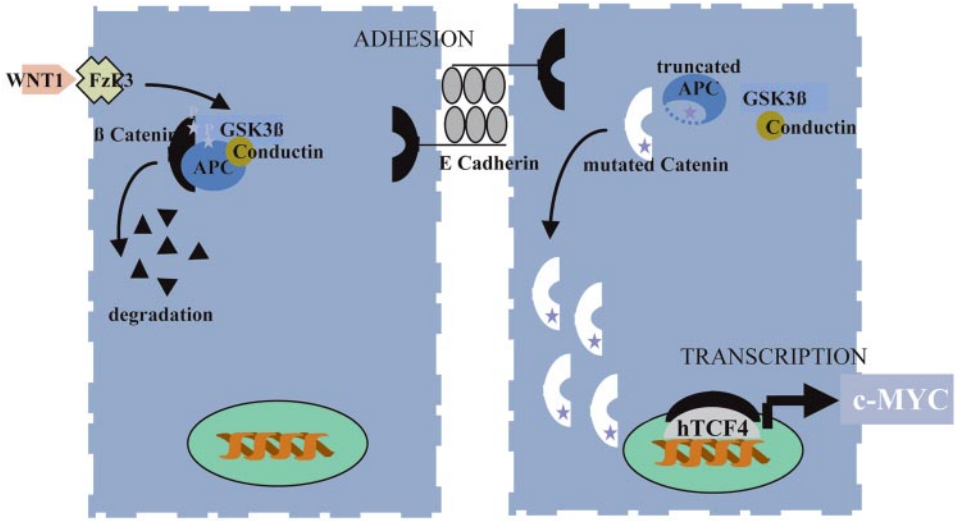

FIGURE 45.1-12 A summary of key interactions of *APC* and β-catenin in the cell, including the Wnt-1 signaling pathway to the frizzled receptor activates disheveled, which inhibits glycogen synthase kinase 3β phosphorylation of β-catenin, preventing its proteosomal degradation. Also shown is the interaction of β-catenin with the E-cadherin cell adhesion system and T-cell factor transcription factor.

bility and accelerate tumor progression along the adenoma-carcinoma sequence.

Based on the above considerations, *APC* has been proposed to have a rate-limiting role in tumor initiation and progression.[78] Loss of β-catenin regulation by *APC* provides the intestinal cell with a selective advantage and allows the initial clonal expansion. At this stage, chromosomal instability caused by loss of the C-terminus functional motifs of APC is latent owing to surveillance by the cell cycle and mitotic checkpoint machinery. The early activation of the oncogenes K-*ras* (by point mutation) and c-*myc* (as a downstream target of the Wnt pathway) will synergize with *APC* in triggering chromosomal instability and the subsequent allelic imbalances at chromosomes 17p and 18q. Additional synergisms between *APC* and other tumor suppressor genes in eliciting aneuploidy and chromosomal instability will progressively lead to malignant transformation and metastasis.

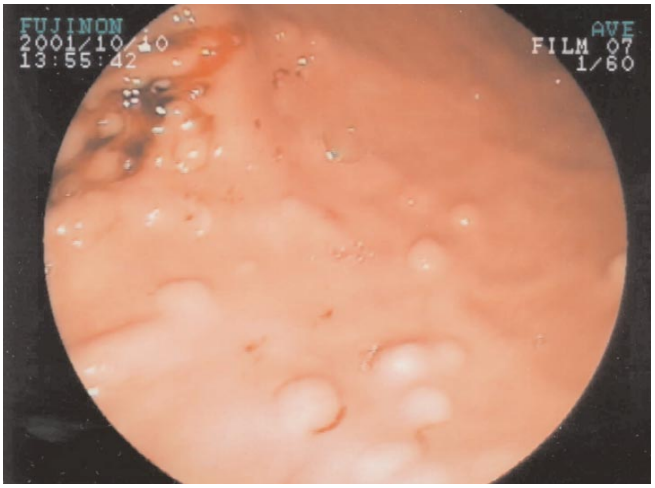

FIGURE 45.1-13 Fundic gland polyps in a child with familial adenomatous polyposis.

Clinical Features. ***Colorectal Adenomatous Polyps.*** FAP is clinically characterized by the occurrence of hundreds to thousands of colorectal adenomatous polyps at an early age and the inevitable development of colon cancer unless colectomy is performed.[79] Accounting for 1% of all colorectal cancer patients, FAP affects both genders equally and has a worldwide distribution.[48] The average age at diagnosis ranges from 34 to 43 years; the average age at colorectal cancer diagnosis is 39 years.[55,80] In pediatric practice, FAP is recognized through family screening. Rarely, rectal bleeding can reveal a sporadic or a familial case.[42]

***Extracolonic* Manifestations.** In addition to polyposis coli, patients with FAP can develop a variety of benign extracolonic manifestations and, infrequently, other cancers, as shown in Table 45.1-6.[81–91]

Extracolonic Adenomas. Fundic gland polyps are occasionally observed at pediatric age, in contrast to antral adenomas (Figure 45.1-13). They do not have a great potential for malignancy change. Subtle flat adenomas can be detected in the duodenum of children with FAP at the same time as colonic adenomas. In adults with FAP, duodenal adenomatous polyps have an average incidence of 61% (Figures 45.1-14 and 45.1-15).[92–94] The relative risk of duodenal cancer and periampullary malignancy is enhanced. At least 1% will develop duodenal cancer, diagnosed at an average age of 47 years.[95] Spigelman and colleagues have elaborated a staging of duodenal polyposis that may help to assess the risk of malignant transformation (Table 45.1-7).[96] Gastric adenomas, usually located in the antrum, infrequently occur in adult patients, but they may be a precursor for malignancy.

Other Manifestations. The extraintestinal manifestations of FAP, first attributed to Gardner syndrome, are listed in Table 45.1-6. Some of these manifestations may contribute to identify at-risk individuals.

Mandibular osteomas are sought by simple and noninvasive screening as orthopantomography.[97]

CHRPE, defined as multiple and bilateral pigmented ocular fundus lesions, is found with increased frequency in some FAP kindreds (Figure 45.1-16).[98,99] It has been identified in infants as young as 3 months old. This abnormality, which generally does not affect vision, is a reliable early marker for gene carriage in FAP, and its absence indicated lack of carriage in families affected with CHRPE.[100]

DTs may dramatically complicate the course of FAP and represent, since the widespread acceptance of prophylactic colectomy, a major cause of death.[101] The lifetime cumulative risk of developing DT is approximately 21%, with a female preponderance (female-to-male ratio 1.5), mainly during the third decade of life. The risk is 2.5-fold

TABLE 45.1-6 EXTRACOLONIC FEATURES IN FAP

CANCERS (LIFETIME RISK)	OTHER LESIONS
Duodenal (1–5%)	CHRPE
Pancreatic (2%)	Nasopharyngeal angiofibromas
Thyroid (2%)	Osteomas
Brain (medulloblastoma) (< 1%)	Radiopaque jaw lesions
Hepatoblastoma (0.7% of children < 5 yr old)	Dental abnormalities
	Lipomas, fibromas, epidermoid cysts
	Desmoid tumors
	Gastric adenomas/fundic gland polyps
	Duodenal, jejunal, ileal adenomas

CHRPE = congenital hypertrophy of the retinal pigment epithelium; FAP = familial adenomatous polyposis.

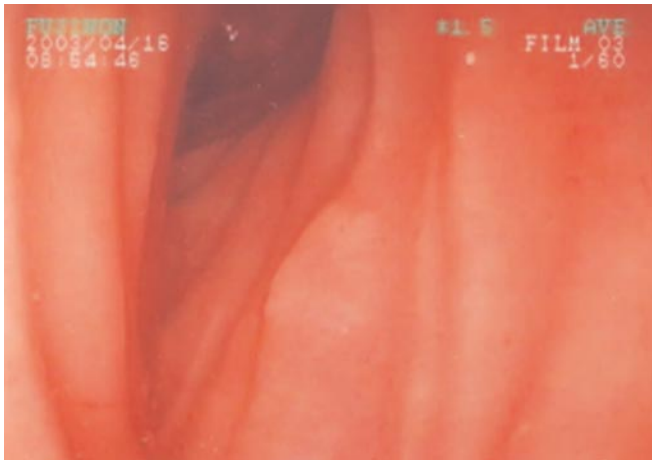

FIGURE 45.1-14 Familial adenomatous polyposis. Tiny, flat, superficially spreading duodenal adenomas.

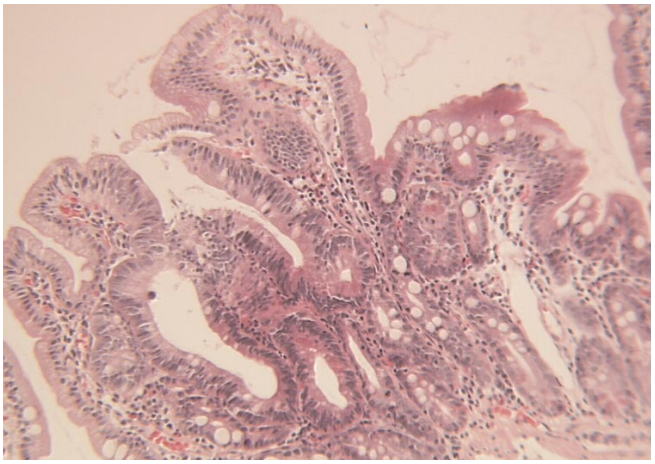

FIGURE 45.1-15 Familial adenomatous polyposis. Light microscopic aspect of duodenal adenomas. (Hematoxylin and eosin; ×250 original magnifications.)

greater in first-degree relatives of FAP patients with DT than FAP patients in general. Eighty percent of DTs occur after prophylactic colectomy within 5 years on average. They consist in desmoplastic mesenteric infiltration or progressively growing masses within the mesentery, retroperitoneum, and abdominal wall. They do not metastasize but are prone to local invasion, causing small bowel obstruction, hydronephrosis, vascular obstruction, and bowel perforation. Their usual development after surgical trauma and their high potentiality of recurrence must be taken into account in therapeutic indications.

Hepatoblastomas occur in 1.6% of children born to a parent with FAP, a relative risk approximately 850-fold greater than the general population, leading some experts to recommend annual serum α-fetoprotein determination and hepatic ultrasonography in at-risk children between 0 and 6 years of age.[102,103] All six children with the FAP mutation who recovered from the hepatoblastoma have developed colorectal adenomatous polyposis.

Diagnosis. The diagnosis of FAP among individuals with a family history is confirmed by the presence of 100 or more adenomatous polyps on colonoscopic examination.[47] However, in children, the finding of even one adenomatous polyp should alert the pediatrician to the possibility of a FAP (Figure 45.1-17). Adults with attenuated FAP exhibit fewer than 100 colorectal adenomas, whereas those with hereditary nonpolyposis colorectal cancer usually exhibit only a few colorectal adenomas, generally localized in the right colon. The simultaneous inheritance of both a germline frame shift mutation in the *APC* gene and a germline splice-site mutation in the *MLH1* gene was recently described in a 10-year-old boy with rapidly progressive FAP.[104]

To differentiate FAP from the other polyposis syndromes and from nodular lymphoid hyperplasia or hyperplastic polyps, which may mimic FAP endoscopically, histology is the key. The diagnosis can be confirmed by mutation analysis. Additionally, in at-risk individuals, the presence of more than three pigmented ocular fundic lesions on ophthalmologic examination confirms the diagnosis of FAP.[100]

Screening. An *APC* gene mutation can be identified in 80 to 90% of FAP families. The integration of genetic testing (Table 45.1-8) into clinical practice provides multiple benefits with earlier detection of lesions and prevention of cancer, removal of patient uncertainty, and the elimination of unnecessary screening. In the setting of a known mutation in a family, genetic testing of relatives can discriminate

between affected and unaffected individuals with a high degree of certainty. Nevertheless, inappropriate use of genetic testing has the potential to misinform affected patients with false-negative results.[41] Written informed consent for genetic testing must be obtained from the patient and/or parents.[105,106] Taking into account that 1% of the FAP patients will develop colorectal cancer between ages 15 and 20 years, genetic testing can be proposed at 10 to 12 years of age.[107] Genetic diagnosis can be achieved by detection of *APC* mutations in DNA from peripheral blood lymphocytes using a commercially available protein truncation assay or by direct DNA sequencing.[108] A child found to be mutation negative in a family with an identified mutant *APC* allele has the same colorectal cancer risk as the general population.

If the pedigree mutation is not found or if informative genetic testing cannot be done, all first-degree family members should undergo endoscopic screening.[28,63,109] Formal recommendations exist for surveillance (Table 45.1-9) of at-risk individuals.[107] In addition, upper endoscopy, surveillance of the stomach, duodenum, and periampullary region is recommended with front-viewing and side-viewing endoscopes.[96] Owing to the increased risk of hepatoblastoma in patients with FAP, screening with α-fetoprotein levels and ultrasound imaging of the liver may be prudent in the children of affected parents from infancy to 7 years of age.[110]

Treatment. ***Colonic Polyposis.*** Colectomy is the recommended treatment for FAP patients to eliminate the risk of colorectal cancer. Timing and extent of surgery, that is, subtotal colectomy with ileorectal anastomosis (IRA) versus proctocolectomy and ileal-pouch-anal anastomosis (IPAA), have been widely debated.[63] IPAA has various disadvantages: (1) a risk of severe postoperative complications necessitating removal of the pouch and construction of an ileostomy (< 5%) and (2) a worse functional outcome compared with that of IRA, although the quality of life after IRA and IPAA seemed to be the same.[111] If FAP has a clinical expression during childhood and adolescence, the decision of an IPAA seems to be the best surgical option because the remaining risk of developing rectal cancer increases over time,[42,112,113] and a secondary proctectomy is needed in approximately half of the cases because of uncontrollable polyposis.[42] Management of young patients is summarized in Figure 45.1-18. After IPAA, the risk of developing one or more adenomas in the ileal pouch at 5, 10, and 15 years is 7%, 35%, and 75%, respectively.[114] There is also a substantial risk for the development of polyps at the anastomotic site; the cumulative risk of developing a polyp at the anastomotic site is 8% at 3.5 years and 18% at 7 years, which can be partially, but not totally, reduced by handsewn anastomosis with mucosectomy.[115] All FAP patients who undergo an IPAA procedure, irrespective of the applied surgical technique, should undergo endoscopic IPAA surveillance at regular intervals of at least once a year.[114,115]

Only patients with a few rectal polyps from families with a similar mild phenotype might be selected for IRA. The results of molecular genetic testing might be used to identify such patients.

Several studies have shown that treatment of FAP patients with a nonselective or selective cyclooxygenase-2 inhibitor (eg, sulindac or celecoxib, respectively) leads to reduction in the number and size of the colonic and rectal adenomas in both short- and long-term studies.[116–118] However, administration of sulindac for primary chemoprevention of FAP failed to prevent the development of adenomatous polyposis in gene mutation carriers,[119] and rectal cancer has been reported after prolonged sulindac chemoprevention.

TABLE 45.1-8 INDICATIONS FOR *APC* GENE SCREENING

TABLE 45.1-9 SCREENING/SURVEILLANCE GUIDELINES IN FAP PATIENTS

At-risk individuals	
Genotyping	*APC* gene mutation (+): flexible colonoscopy annually starting at age 10–12 yr
	APC gene mutation (–): flexible sigmoidoscopy at age 25 yr
If genotype not available	Flexible sigmoidoscopy or colonoscopy annually starting at age 10–12 yr, then 2 yr starting at age 35, then as per the guidelines for average-risk individuals starting at age 50
Affected individuals	Upper gastrointestinal surveillance every 3–4 yr and annually if upper tract polyps
	If retained rectum or J pouch, flexible sigmoidoscopy every 6 months or 1 to 2 yr, respectively
	Annual physical examination and routine blood tests

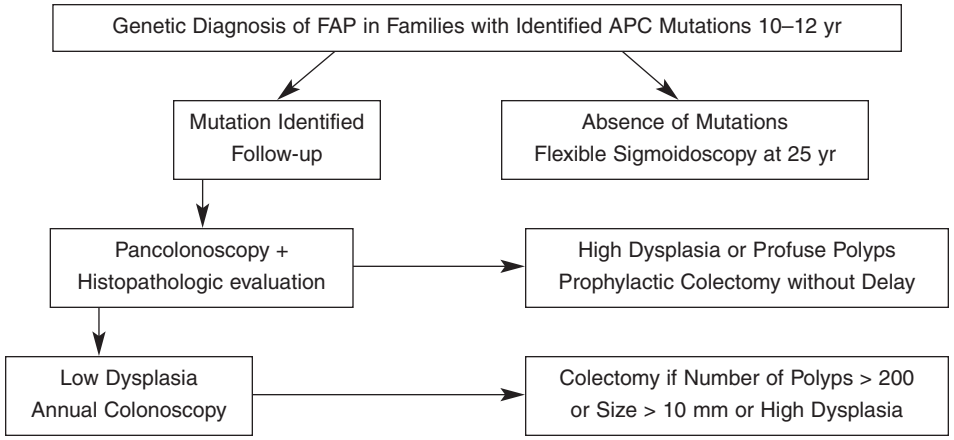

FIGURE 45.1-18 Management of at-risk familial adenomatous polyposis (FAP) patients in childhood and adolescence. Adapted from Hyer W et al.[214]

***Duodenal* Polyposis.** The therapeutic challenge of duodenal polyposis arises in adulthood.[120] Chemoprevention by nonsteroidal anti-inflammmatory drugs is not effective.[121] Endoscopic procedures have limitations, and the only treatment is prophylactic duodenal resection.[122] However, this operation has considerable potential morbidity and mortality.

***Abdominal* DTs.** In FAP families with associated DTs, this additional risk has to be taken into account in surgical management. Timing for surgery as late as possible, at least in patients with a smaller number of polyps and an expected later onset of disease, and performing the colectomy procedure in one stage must be considered. In such families, we prefer to perform an IPAA procedure as the initial prophylactic colorectal procedure because conversion of an IRA to an IPAA may be precluded by mesenteric DTs. Before surgery, abdominal computed tomography is performed in clinically indicated cases and in cases with a family history of desmoid disease.

Other Variants of FAP. Other variants of FAP include attenuated familial adenomatous polyposis (AFAP)[123] and Turcot syndrome, defined as typical FAP together with central nervous system malignancies, in particular medulloblastoma.

***Attenuated* FAP.** The clinical characteristics of AFAP include oligopolyposis, usually less than 100 colorectal adenomas at presentation, which are mostly right-sided, and a delayed onset of colorectal cancer occurring on average more than 12 years later than in classic FAP.[58] Total colonoscopy should be considered in families with an atypical form of polyposis because adenomas may be located in the proximal part of the colon. In such families, the endoscopic examinations may be started at a later age (18–20 years).[63] The adenomas have a flat rather than a polypoid aspect, leading to the initial description as "hereditary flat adenoma syndrome."[123] This condition should not be confused with hereditary nonpolyposis colorectal cancer. In patients with AFAP, fundic gland polyps and duodenal adenomas are more prominent than colonic polyps. Recently, Attard and colleagues described the first pediatric patient with AFAP diagnosed at age 9 in the setting of a strong family history of gastric carcinoma who had multiple fundic gland polyps with severe dysplastic changes requiring prophylactic gastrectomy at age 11.[124]

Turcot Syndrome. Turcot syndrome, or brain tumor polyposis syndrome, is characterized by multiple colonic adenomas associated with a primary brain tumor of various histopathologic types.[91,125,126]

Molecular genetic studies have established a new classification of Turcot syndrome kindreds into two groups according to the type of brain tumor and the genetic defect.[91] The more common group (Turcot syndrome type II) has germline mutations of the *APC* gene and medulloblastoma, which precedes the diagnosis of polyposis in some cases.[127] The other group with the family originally described by Turcot (Turcot syndrome type I) includes patients with glioblastomas and germline mutations in DNA base mismatch repair genes also implicated in hereditary nonpolyposis colon cancer.[91]

Hamartomatous Polyposis Syndromes

Hamartomatous polyposis syndromes are characterized by an overgrowth of cells or tissues native to the area in which they normally occur.[128] This overgrowth of cells or tissues, at least initially, has no presumed neoplastic potential. However, several of these syndromes are associated with an increased lifetime risk of both intestinal and extraintestinal malignancies.

Hamartomatous polyposis syndromes include JPS, Cowden disease (CD), Bannayan-Riley-Ruvalcaba syndrome (BRRS), or Ruvalcaba-Myrhe-Smith syndrome (RMSS) and PJS. In JPS, polyps involving the gastrointestinal tract are the major manifestation of the disease. In contrast, for the other syndromes, they are a component among a variety of extraintestinal features.[129] The mechanism of inheritance for these syndromes is autosomal dominant with variable penetrance. It must be emphasized that, in children, it may be difficult to distinguish patients with JPS and those with CD because extraintestinal manifestations in the latter condition are an age-related phenomenon. Rigorous long-term follow-up in clinical studies of these syndromes is needed to achieve phenotype-genotype correlations.

Juvenile Polyposis Syndrome. First described by McColl and colleagues in 1964,[130] JPS is the most common of the hamartomatous syndromes characterized by multiple gastrointestinal polyps in the absence of the extraintestinal features that are classic for other hamartomatous polyposis syndromes. Most authors support the diagnosis criteria outlined by Giardiello and colleagues.[23] These criteria include either three or more juvenile polyps of the colon or polyposis involving the entire gastrointestinal tract or any number of polyps in a proband with a known family history of juvenile polyps. JPS is inherited in an autosomal dominant manner with variable penetrance, with approximately 25% of cases having a family history of juvenile polyposis.[131]

Presentation. In children, JPS is always symptomatic (in contrast to FAP).[15] Symptoms include rectal bleeding, rectal prolapse, cramping abdominal pain, and intussusception.[2] Most cases of JPS come to medical attention between 2 and 12 years of age,[15] although rare cases of failure to thrive, anemia, and severe hypoalbuminemia resulting from a protein-losing enteropathy have been described in infants.[132,133] Polyps vary in number from 3 to 200[15] and show great variation in size and configuration. In most cases, juvenile polyps are found only in the colon.[131] In a review of 272 cases of JPS by Höfting and colleagues, the most frequently affected site was the colorectum (98%), followed by the stomach (14%), jejunum and ileum (15%), and duodenum (2.3%).[134] When polyps are numerous, follow-up should include serum albumin and α_1-antitrypsin fecal clearance.[135,136] There is an association with congenital birth defects in 15% of cases, including malrotation of the midgut, genitourinary defect, and cardiac defects.[2] The majority of congenital defects have been reported in individuals with the nonfamilial variant of the disease.

Pathology. The typical gastrointestinal polyp in JPS has the same histopathologic aspects as solitary juvenile polyp. In contrast to the polyps of PJS, muscle fibers are not present in the stroma. As hamartomatous polyps enlarge and the mesenchymal component expands, they take on a more serrated or villous-type configuration associated with a more marked degree of epithelial dysplasia.[9,25]

Molecular Genetics*: JPS *and the* SMAD *Pathway. There is evidence of genetic heterogeneity in JPS. Hereditary juvenile polyposis is not linked to *APC*. Subsets of JPS families have mutations in the tumor suppressor gene phosphatase and tensin homolog (*PTEN* 601728) located at chromosome 10q23.3.[137] *PTEN* is a ubiquitously expressed dual-specificity phosphatase that acts as a tumor suppressor and is mutated in several sporadic tumor types.[37] Mutations in this gene are also important in a subset of familial thyroid carcinoma, CD, and BRRS.[37,138] The shared clinical features of CD/BRRS and JPS, coupled with coincident somatic mutation data in juvenile polyps, raise the possibility that *PTEN* defects could cause all of these syndromes.[139,140] However, if about 60% of BRRS and more than 80% of CD demonstrate germline mutations in *PTEN*, germline mutation of *PTEN* as a cause of JPS in a child is controversial because extraintestinal manifestations that would exclude JPS could appear after adolescence, CD having a penetrance well below 10% under 15 years of age, altering an early clinical diagnosis.[141] Moreover, a proportion of JPS patients do not have germline mutations in *PTEN*. Three groups have found no evidence of germline *PTEN* mutations in 21 JPS families and 16 sporadic cases.[142,143] In a recent review of *PTEN*, JPS is not considered a so-called *PTEN* hamartoma-tumor syndrome (PHTS).[141] In summary, the association of germline *PTEN* mutations as a cause for JPS is not yet clearly substantiated. Nevertheless, Huang and colleagues identified a germline mutation of PTEN in a family in which identical twin 6-year-old girls were diagnosed with JPS.[144] Their 55-year-old father lacked manifestations of CD or BRRS and had the same mutation in *PTEN*.

Recently, constitutional mutations in small mothers against decapentaplegic 4 (*SMAD4*), located at chromosome 18q21,[38,145,146] and bone morphogenetic receptor 1A (*BMPR1A*) were shown to cause JPS.[38,145–148] *SMAD4* mutations seem to be the most relevant mutations in JPS patients without stigmata of other polyposis syndromes and account for approximately 50% of the reported familial cases of the syndrome.[38] These genes, which code for proteins involved in transforming growth factor-β (TGF-β) signal transduction, are mutated in a number of gastrointestinal cancers. Other members of the SMAD family (*SMAD1*, *-2*, *-3*, or *-5*) are not involved in the pathogenesis of JPS. No consistent mutations of the deleted in colon cancer gene (*DCC*), which is located at the same locus as *SMAD4*, have been found.[149] *BMPR1A* and its receptors belong to the TGF-β and TGF-βR superfamily, and the recent finding of four JPS kindreds with *BMPR1A* mutations further supports the importance of TGF-β superfamily mutations in JPS.[147]

SMAD proteins transduce signals from TGF-β ligands that regulate cell proliferation, differentiation, and death through activation of receptor serine/threonine kinases. Thus, TGF-β is a potent immunosuppressor, and perturbation of TGF-β signaling is linked to autoimmunity, inflammation, and cancer. Activated SMADs regulate transcription of target genes, including cell-cycle inhibitors such as *p21*, which mediate the antiproliferative response and partially explain the tumor suppressive action of the TGF-β pathway. At late stages of tumor progression, TGF-β promotes tumorigenesis via suppression of the immune system and changes in cell differentiation of epithelial tumor cells. Phosphorylation of receptor-activated SMADs (R-SMADs) leads to formation of complexes with the common mediator SMAD (Co-SMAD), which are imported to the nucleus. Nuclear SMAD oligomers bind to DNA and associate with transcription factors to regulate the expression of target genes. Alternatively, nuclear R-SMADs associate with ubiquitin ligases and promote degradation of transcriptional repressors, thus facilitating target gene regulation by TGF-β. SMADs themselves can also become ubiquitinated and are degraded by proteasomes. Finally, the inhibitory SMADs (I-SMADs) block phosphorylation of R-SMADs by the receptors and promote ubiquitination and degradation of receptor complexes, thus inhibiting signaling.[150]

Multiple somatic genetic alterations, including *APC*, *MMR*, and K-*ras* mutations, seem to play a role in the neoplastic transformation of juvenile polyps coli.[8]

Neoplastic Risk. In a large retrospective review from St Mark's Polyposis Registry published in 1988, 1,032 juvenile polyps from 87 patients were examined.[25] Pathologic specimens were available for re-evaluation from 80 patients. Twenty-two percent of the patients subsequently developed colorectal cancer. The mean age at the time of diagnosis was 34 years. Some patients also developed upper gastrointestinal malignancies.[151] In 1993, Höfting and colleagues found 48 cases of gastrointestinal cancer (18%) among 272 patients with JPS.[134] In 1995, Desai and colleagues re-evaluated the data from the St Mark's Polyposis Registry and estimated that the projected incidence of colorectal cancer alone by the age of 60 was approximately 68%.[131]

Management and Surveillance. Recommendations for endoscopic screening and treatment in patients with JPS are summarized in Figure 45.1-19.[108,129] The proband also should undergo upper gastrointestinal endoscopic screening. It is not clear whether upper and lower endoscopic surveillance is adequate to prevent malignancy. If surgery becomes mandatory, the extent of rectal polyposis is a major consideration in determining the modality of colectomy.[15] There are insufficient data to justify coloproctectomy or prophylactic colectomy solely for the risk of colorectal carcinoma.[23] The therapeutic role of cyclooxygenase inhibitors in pediatric JPS is also unclear.

In three of eight JPS families, polyps were identified in asymptomatic first-degree relatives.[23] Accordingly, first-degree relatives of patients with JPS should be screened by upper and lower endoscopy starting at 12 years of age, even when the subject is asymptomatic. Howe and colleagues recommend incorporating genetic testing into the screening algorithm.[38] However, given the presumed genetic heterogeneity of this syndrome, failure to show a mutation in *SMAD4* does not support lengthening the surveillance interval in asymptomatic first-degree relatives.[38]

Juvenile Polyposis of the Stomach. Juvenile polyposis involving the stomach without intestinal polyps at initial presentation (10–63 years with 4 of the 12 patients younger than 20 years of age), first described by Watanabe and colleagues, may be regarded as a clinical entity separate from generalized gastrointestinal polyposis.[152,153] Anemia (89%) and hypoproteinemia with most patients requiring gastrectomy (67%) are the most striking clinical features. Three subjects developed gastric cancer from 32 to 65 years.

Phosphatase and Tensin Homolog Hamartoma-Tumor Syndromes. PHTS, that is, CD[154] and BRRS,[155] is a rare autosomal disorder characterized by multiple phenotypic abnormalities and hamartomas in the intestine and other tissues. Recent nomenclature favors the term "PHTS" because germline mutations in the *PTEN* gene account for up to 80% of cases of CD and 60% of BRRS patients. Clinical differences are likely caused by allelic variations.[140,141] PTEN is a major dual lipid and protein phosphatase that signals apoptosis and mediates cellular growth arrest by inhibition of phosphoinositol 3-kinase.[156,157] Furthermore, the protein phosphatase, with the ability to dephosphorylate both serine and threonine residues, regulates cell survival pathways, such as the mitogen-activated kinase (MAPK) pathway.

Cowden Disease. CD (MIM 1583350) is an autosomal dominant condition characterized by multiple hamartomas that affect derivates of all three germ layers with an increased risk of breast, thyroid, and endometrial neoplasias.[141,158] The diagnostic criteria for CD have been revised recently (Table 45.1-10).[159] Eighty percent of patients present with dermatologic manifestations among which tricholemmomas are very suggestive of CD. Approximately 40% of affected individuals develop disease of the central nervous system. Macrocephaly is frequently observed.[160] CD in concert with cerebellar gangliocytomatosis is referred to as the Lhermitte-Duclos syndrome.[161] Only 35 to 40% of patients who meet the diagnosis criteria for CD have gastrointestinal polyposis.[130] Polyps can be typical juvenile polyps, ganglioneuromas, or adenomas. It is noteworthy that CD has a

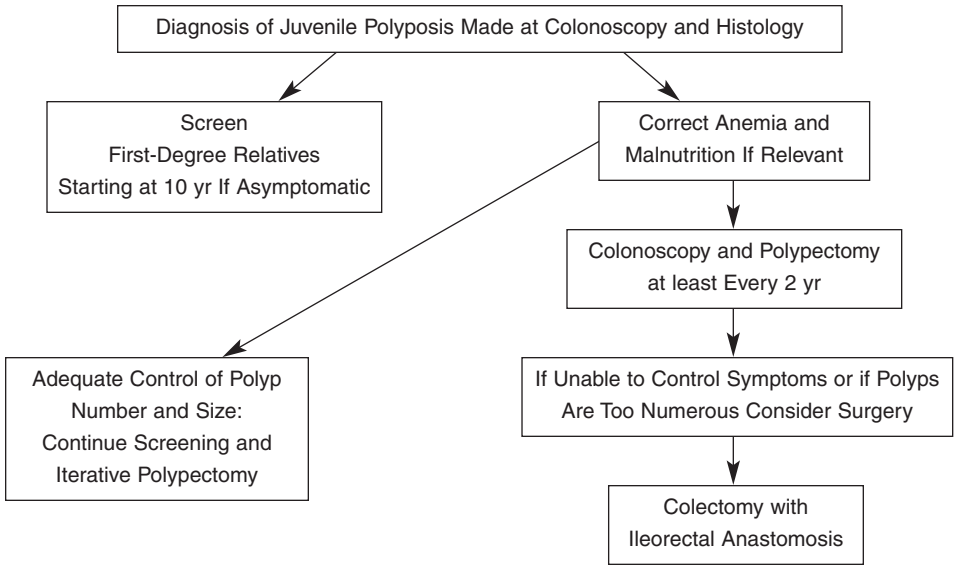

FIGURE 45.1-19 Management and surveillance in young patients with juvenile polyposis syndrome.

TABLE 45.1-10 INTERNATIONAL COWDEN CONSORTIUM OPERATIONAL DIAGNOSTIC CRITERIA

Pathognomonic criteria (mucocutaneous lesions)
Facial trichilemmomas
Acral keratoses
Papillomatous papules
Mucosal lesions
Major criteria
Breast carcinoma
Thyroid carcinoma (nonmedullary), especially follicular thyroid carcinoma
Macrocephaly (megalencephaly)
Lhermitte-Duclos syndrome
Endometrial carcinoma
Minor criteria
Other thyroid lesions (eg, adenoma or multinodular goiter)
Mental retardation
Gastrointestinal hamartomas
Fibrocystic disease of the breast
Lipomas
Fibromas
Genitourinary tumors (eg, renal cell carcinoma or uterine fibroids) or malformation

great variation in expression and carries an age-related penetrance (10% below age 15 years, 90% at age 20 years). There is no reported increase in the risk of invasive gastrointestinal malignancies.

Gastrointestinal polyposis should be addressed by endoscopic surveillance. Although no definite increased risk of colorectal carcinoma has been documented, the true risk may be unrecognized because of the rarity of the syndrome. Screening for breast and thyroid malignancies should begin in the teenage years.

Germline mutations in *PTEN* have been found in 80% of probands with CD, especially in exons 5, 7, and 8, when operational criteria (International Cowden Consortium) are applied to the diagnosis of CD (see Table 45.1-10).[158] The majority of CD cases appear to be isolated; 10 to 50% are familial.

Bannayan-Riley-Ruvalcaba Syndrome. Hamartomatous polyposis is also seen as a component of BRRS associated with macrocephaly, a speckled penis, delayed development in childhood, lipomatosis, and hemangiomatosis. Sixty percent of patients with BRRS have germline *PTEN* mutations.[162] The mutational spectra of BRRS and CD seem to overlap. For some authors, there is a higher frequency of breast tumors, fibroadenomas, and lipomas among the mutation-positive group of patients with BRRS who meet published diagnosis criteria than among the 40% of mutation-negative patients.[163] It is not known if genes other than *PTEN* may also be responsible for BRRS.[164]

Peutz-Jeghers Syndrome. PJS (MIM 1752001) is another hamartomatous gastrointestinal polyposis syndrome associated with a risk of gastrointestinal and extraintestinal cancers. The incidence of PJS is estimated as 1 in 120,000 births.[165] Mucocutaneous melanin deposition, recognized by early investigators,[166,167] is a hallmark for this syndrome resulting from mutations of the *LKB1/STK11* gene, located on chromosome 19p 13.3.[39,168–170]

Clinical Manifestations. Skin pigmentation (Figure 45.1-20) consists of small (1–5 mm) pigmented macules, primarily clustered around the mouth, eyes, and nostrils and sometimes also the perianal area. The buccal mucosa is also affected. These pigmented lesions occur before gastrointestinal polyps but are rarely observed during early infancy. The cutaneous pigment pattern often fades with age, but buccal mucosa lesions tend to persist.[166,167,171,172] PJS is a clinically heterogeneous disorder, and cases of individuals from Peutz-Jeghers kindreds having pigmentation without polyposis, and the converse, have been reported.[167,171,173]

One-third of PJS patients will experience symptoms during the first decade of life,[167] and 50 to 60% of patients will experience them before age 20.[174] Patients present most commonly with abdominal pain secondary to obstruction or impending obstruction with polyp intussusception or gastrointestinal bleeding leading to anemia.[175] According to series, Peutz-Jeghers polyps are preferentially located in the small intestine (more frequently in the jejunum than in the ileum and than in the duodenum)[172–174] or equally distributed in the stomach, colorectum, and small bowel.[176] The small and large bowel polyps tend to be pedunculated (Figures 45.1-21 and 45.1-22), whereas stomach polyps are sessile (Figure 45.1-23). The polyps grow to a very large size and, combined with their pedunculated aspect, can result in recurrent intussusception.

Pathology. In contrast to the inflammatory appearance of juvenile polyps, hyperplasia of the smooth muscle layer occurs in Peutz-Jeghers polyps. Hyperplastic smooth muscle extends in a tree-like manner toward the epithelial layer (Figure 45.1-24). The extensive dilation of cystic-filled spaces, pathognomonic for the juvenile polyp, is not seen in PJS. Invagination of the epithelium will result in islands of epithelial cells trapped within the underlying smooth muscle, resulting in "epithelial cell misplacement" in the absence of cellular atypia and an increased mitotic rate.[175,177] Histologic evidence of hamartomatous-adenomatous-carcinomatous evolution has been demonstrated for stomach, small bowel, and colorectal polyps in PJS.[178,179] In addition, there is evidence that PJS patients are prone to develop adenomatous as well as hamartomatous polyps, particularly in the large intestine.[172,178]

Genetics. Germline mutations in the *STK11/LKB1* gene are reported as the molecular cause in 70% of PJS

FIGURE 45.1-20 Mucocutaneous buccal melanin pigmentation in a patient with Peutz-Jeghers syndrome.

FIGURE 45.1-21 Peutz-Jeghers syndrome: abdominal pelvic computed tomographic scan showing jejunal polyps.

FIGURE 45.1-22 Peutz-Jeghers syndrome: abdominal pelvic computed tomographic scan showing a very large colonic polyp at the splenic flexure.

families and 50% of sporadic PJS patients.[169,180–184] The gene is divided into nine exons that encode a 433–amino acid protein containing a serine/threonine kinase domain, a nuclear localization signal in its N-terminus domain, and a prenylation consensus sequence in its C-terminus. The protein is located in the nucleus of cells but is also detected in the cytoplasm and at cell membranes.[185,186] *LKB1* is widely expressed during embryonic development. Immunostaining of the small intestine reveals that *LKB1* is expressed in two distinct topographic regions: the crypts that contain rapidly dividing stem cells and the top of the villi, where cells undergo apoptosis.[187,188] It has been proposed to act as a tumor suppressor. *LKB1* is also involved in *tp53*-mediated apoptosis.[187] *LKB1* phosphorylates *tp53* at low levels, which might be required for *tp53* activation. *LKB1* also controls cell proliferation. It interacts with the chromatin remodeling protein brahma-related gene-1 (*BRG1*)[189] and with the cell-cycle regulatory proteins LKB1-interacting protein 1 (LIP1) and WAF1.[190–192]

The *LKB1* mutations (truncated protein with incomplete catalytic domains) lead to loss in kinase activity,[180] whereas other cancer susceptibility syndromes are associ-

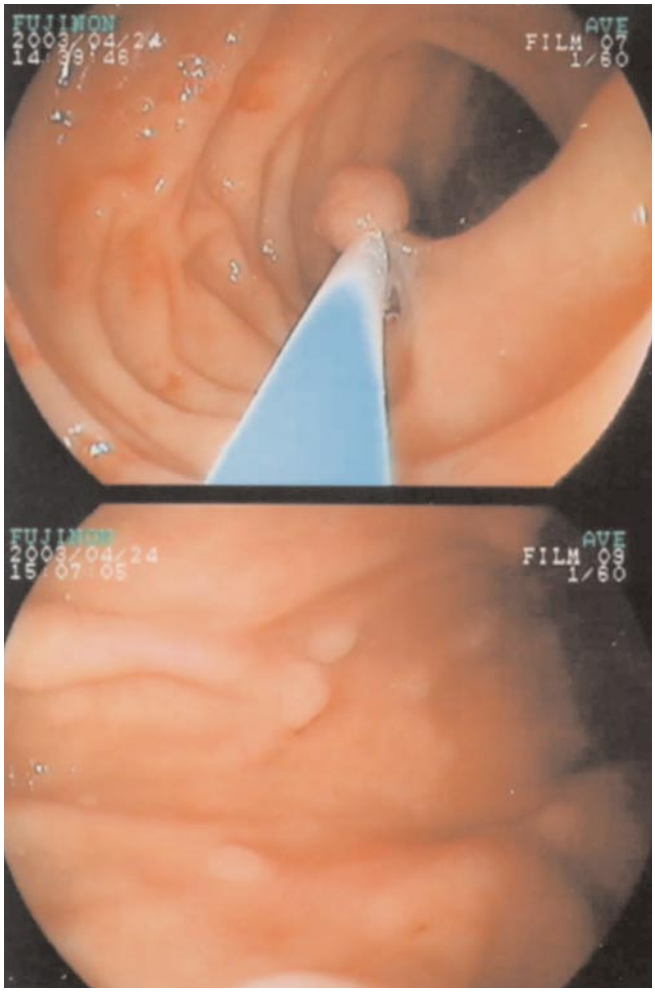

FIGURE 45.1-23. Peutz-Jeghers syndrome: endoscopic view of sessile and pedunculated stomach polyps from the same patient as in Figures 45.1-20 and 45.1-21.

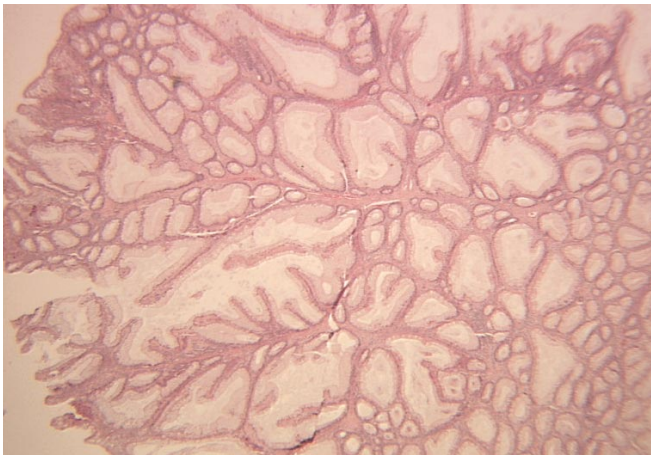

FIGURE 45.1-24 Low-power photomicrograph of Peutz-Jeghers rectal polyp showing bands of smooth muscle extending in a tree-like manner toward the epithelial layer. (Hematoxylin and eosin; ×75 original magnifications.)

ated with activation of kinase activity.[39,193] Allelic imbalance has previously been reported in a number of PJS polyps and found in a colonic adenoma from a PJS patient, strongly suggesting the existence of a hamartoma-carcinoma sequence in tumorigenesis.[194]

There is marked inter- and intrafamily phenotypic variability of expression in Peutz-Jeghers kindreds. The availability of predictive genetic testing may have some value but cannot determine the likely severity of the phenotype.[181] Moreover, not all PJS patients have demonstrable mutations in the *LBK1/STK11* gene.[39,195] However, if the gene mutation is known for previous affected cases in the family, it might have a role in presymptomatic testing for family members without pigmentation.

Cancer Risk. The risk of developing malignancy, both in the gastrointestinal tract and at extraintestinal sites, is increased in adults with PJS.[181] Moreover, malignancy can evolve as early as childhood and adolescence. In a recent meta-analysis of 210 PJS patients, the relative risk of stomach, small bowel, and large bowel cancer developing in PJS male patients was estimated at 235, 279, and 98, respectively, compared with that in the general population.[105] In a series of 222 Japanese patients, with 28 cases of intestinal malignancy, 3 teenagers with advanced gastric cancer were included. Of 70 patients under 16 years identified by a literature search, 5 had tumors, 2 of which were adenocarcinomas (1 gastric, 1 jejunal).[117] The risk of developing pancreatic cancer in PJS is estimated to be increased 100-fold.[196] Metastatic pancreatic cancer was reported in a 14-year-old boy with PJS.[197]

Gonadal tumors have been reported at an increased frequency in females and occasionally in male patients with PJS.[198] Ovarian sex cord tumors with annular tubules (SCTAT), usually found in young adult women,[199] may cause sexual precocity in young girls.[200] Analogous tumors have been identified in male patients, referred to as either large cells calcifying Sertoli cell tumors or as testicular tumors resembling SCTAT.[198,201–203] The clinical presentation is gynecomastia and rapid growth with advanced bone age in prepubescent boys.[199,203] Although often bilateral and multifocal, SCTATs usually have a benign course in the setting of PJS. Other neoplasms of the genital tract have been described in PJS females, but the major risk is breast cancer.[105]

Clinical Management. The gastrointestinal polyposis of PJS carries the dual risk of repeated resections for infarction secondary to intussusception and malignancy. More than three-quarters with PJS had one or more laparotomies owing to the recurrence or progression of polyps.[204] This high reoperation rate might be reduced in skilled hands by removal of other polyps through upper and lower endoscopy and intraoperative enteroscopy. Intraoperative small bowel endoscopy identifies 38% more polyps at laparotomy compared with external palpation and small bowel transillumination.

Children with well-defined mucocutaneous pigmentation should be enrolled into a screening program, as outlined in Table 45.1-11, and an aggressive therapeutic approach taken if symptomatic.[204–210] Every 2 years, the symptomatic PJS patient should have upper and lower endoscopies with polypectomy[206] and some form of examination of the small bowel, such as barium study by enteroclysis or wireless capsule enteroscopy in children over 10 years old. The size of the polyps and their location influence the clinical management (Figure 45.1-25). Patients with symptomatic midgut polyps greater than 1.5 cm in the jejunoileum should be referred for laparotomy with intraoperative endoscopy. During laparotomy, the surgeon can assist in telescoping the endoscope over the entire small intestine. A noncrushing clamp can be placed over the cecum to prevent large bowel distention.[205] Smaller polyps can be removed by an electrocautery snare. Larger, broad-based polyps will require an enterotomy. If needed, a sterile endoscope can also be advanced through the enterotomy site to aid endoscopic examination of the entire small bowel followed by snare resection of polyps. For children who are asymptomatic with small polyps (ie, < 1 cm in size), parents should be counseled about the risk of intussusception. If the child later develops relevant symptoms, he or she should also be referred for consideration for enteroscopy. Extensive small bowel surgical resection should not be undertaken in order to preserve gut function and limit the risk of short-bowel syndrome.[129]

Bourneville Tuberous Sclerosis. Tuberous sclerosis is a dominantly inherited disease with a variable penetrance characterized by the classic triad of mental retardation,

TABLE 45.1-11 SURVEILLANCE GUIDELINES FOR PEUTZ-JEGHERS SYNDROME

SITE	PROCEDURE	ONSET (YR)	INTERVAL (YR)
Stomach	Upper endoscopy	10	2
Small bowel	Small bowel follow-through	10	2*
Colon	Pancolonoscopy	10	2*
Breast	Breast examination	25	1

Pancreas	Endoscopic ultrasonography (if available) or abdominal ultrasonography	30	1–2

*May consider lengthening interval based on clinical history.

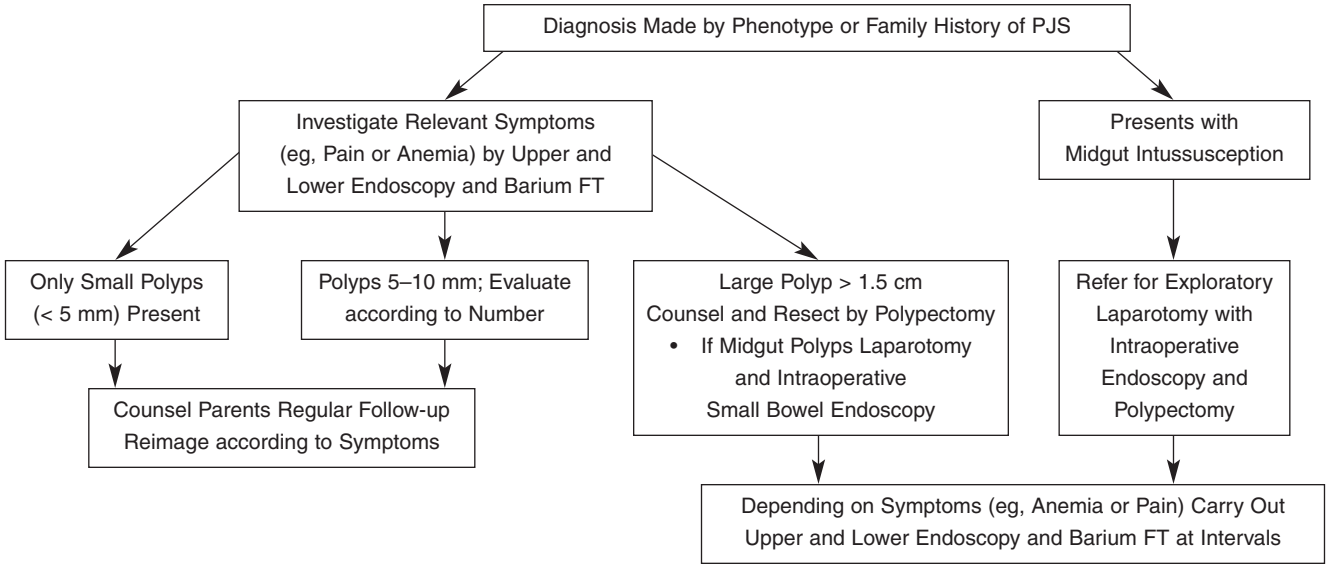

FIGURE 45.1-25 Management and surveillance in patients with Peutz-Jeghers syndrome (PJS). Adapted from Hyer W et al.[214] FT = follow-through.

epilepsy, and adenoma sebaceum in the presence of hamartomatous lesions. Mutations have been identified in two genes: tuberous sclerosis locus 1 (*TSC1*) and tuberous sclerosis locus 2 (*TSC2*). Hamartomatous polyps resembling Peutz-Jeghers polyps diagnosed at a mean age of 12 years, as well as adenomatous polyps diagnosed at a mean age of 45 years, may occur and are often located within the distal 25 cm of the colon.[210] An invasive adenocarcinoma was reported in a 17-year-old girl in association with adenomatous polyps throughout the proximal and distal colon without a family history of colorectal neoplasia.[211]

Hereditary Mixed Polyposis Syndrome

Hereditary mixed polyposis syndrome (MIM 601228) is characterized by atypical juvenile polyps, with mixed features of hamartomas and adenomas located in the colon with the risk of subsequent colorectal cancer. The locus maps to chromosome 6q16.[212]

Hyperplastic Polyposis

Hyperplastic polyposis is an uncommon condition in which large numbers of hyperplastic polyps are present throughout the colon. Keljo and colleagues described a rectal cancer developing in an 11-year-old girl with hyperplastic polyposis.[213]

2. Other Neoplasms

Alison G. Hoppin, MD
Carla L. Nash, MD, FRCPC

Neoplasia represents a major proportion of gastrointestinal disease in adults, but the finding of intestinal tumors in the pediatric age group is usually unexpected. Some familiarity with these rare tumors is advisable, however, because a delay in diagnosis can adversely affect patient outcome.

Rather than provide an encyclopedic list of all forms of intestinal neoplasia, this discussion focuses on three forms: carcinoma, lymphoma, and leiomyosarcoma. These tumors constitute the bulk of intestinal neoplasia in the pediatric age group, and the clinical material presented provides an approach that can be used in diagnosing rarer tumors as well. Where appropriate, a comparison with the corresponding tumors occurring in adults is made. Leiomyomas of the gastrointestinal tract are considered here and in Chapter 28, "Congenital Anomalies of the Stomach and Duodenum," and polypoid benign tumors, including adenomas and hamartomas, are discussed in Chapter 45.1, "Intestinal Polyps and Polyposis." Secretory tumors affecting the gut, including carcinoid tumors, are discussed in Chapter 47, "Secretory Tumors."

BENIGN INTESTINAL TUMORS

Adenomas are by far the most common benign intestinal tumors, followed by leiomyomas and lipomas. Adenomas and lipomas are found primarily in the colon but also can appear in the small intestine, where they present with lower tract bleeding, with abdominal pain, or as the lead point for an intussusception. Lipomas typically present in older adults but also can occur in children.[1] About 70% of intestinal lipomas arise in the colon and roughly 25% occur in the small intestine. Only rarely do lipomas develop in the stomach or esophagus.[2] In contrast, smooth muscle tumors are far more common in the proximal gut, where benign leiomyomas are prominent at all ages; only isolated cases of colonic leiomyomas are reported in children.[3,4] Distinguishing benign from malignant smooth muscle tumors of the intestine can prove difficult. Accordingly, a wide surgical resection is recommended.

ADENOCARCINOMA OF THE INTESTINE

Carcinoma of the Colon

Epidemiology. The overall incidence of carcinoma of the colon and rectum continues to increase, and, in 1999, approximately 129,000 new cases were diagnosed in the United States, where the cumulative lifetime risk is about 6%.[5] Estimates suggest that nearly 147,000 people will be diagnosed in 2003.[6] The incidence of colorectal carcinoma is highest in developed countries in northwest Europe, the United Kingdom, Canada, and the United States and lowest in Africa and Asia.[7] In the United States, the disease is more common in blacks than in whites, until 60 years of age.[6] Individuals from low-risk areas who migrate to high-risk areas develop an incidence of colon carcinoma similar to that of people residing in the high-risk area.

Although there are fewer than 200 cases reported in the pediatric literature, carcinoma of the colon is the most common primary malignant solid tumor of the intestinal tract in childhood. In several large series, approximately 1% of malignant tumors in children are colonic. The frequency of colon cancer increases with age: about 1% of cases of carcinoma of the colon occur in individuals less than 30 years of age.[8] The incidence of colorectal carcinoma in individuals younger than 20 years of age is less than 0.1 cases per million and rises to about 1 case per million in individuals between 10 and 19 years of age.[6,9] Even an infant, however, can develop colon carcinoma; the youngest reported patient was only 9 months old at the time of diagnosis.[10] A slight male predominance of carcinoma of the colon in children has been reported in some series, with a male-to-female ratio of approximately 1.5:1.[11–13] In adults, the incidence of carcinomas of the colon and rectum is also slightly higher in men.[6] Although rare, colon cancer in children demonstrates some unique features, which are discussed below in detail.

Etiology. Much research focuses on identifying the environmental agents associated with the development of colon and rectal cancer. The most convincing evidence comes from large population-based studies that have shown that diets high in fiber reduce the risk of colorectal cancer.[14,15] Fiber is hypothesized to dilute and bind potential carcinogens, reduce the carcinogen exposure time by increasing transit, and decrease the formation of secondary bile acids, among other mechanisms.[16] Small uncontrolled reports also suggest that the risk of colorectal carcinoma is associated with a diet high in calories, fat, and cholesterol, but this has not been confirmed in large well-controlled studies. Prospective studies have shown, at best, a moderate reduction in risk of colorectal adenoma formation with calcium supplementation.[17,18] Even less evidence is available to support anecdotal reports of protection from cancer with several micronutrients, including selenium and folic acid.[19] Exposure to radiation and chemicals, such as

organic solvents, also may play an etiologic role. In one series, 10 of 13 adolescent patients presenting with colon carcinoma had exposure to agricultural chemicals.[20]

As shown in Table 45.2-1, a number of predisposing conditions, including inflammatory bowel disease and the hereditary polyposis syndromes, confer a high risk for colon carcinoma. Lynch classified the development of colon cancer into four types: (1) sporadic, accounting for 70 to 80% (if familial predisposition to the presumed precursor adenomas are considered, heredity may play a role in a high percentage of cases of colon cancer currently categorized as "sporadic"); (2) familial, representing patients with at least two first-degree relatives with a history of colon cancer but no definable genetic inheritance pattern, making up 10 to 20%; (3) hereditary polyposis syndromes with cancer, less than 1%; and (4) hereditary cancer without polyposis syndrome, 5 to 6%.[21] Colon cancer in patients with inflammatory bowel disease constitutes less than 1% of the total.[22] Owing to the relatively small number of cases reported in children, the contribution of predisposing conditions is not well defined, but the incidence of preexisting polyposis or colitis in children with colon cancer is approximately 10%, a frequency that is higher compared with that in adults.[23]

Cancer is a complication of inflammatory bowel disease. In ulcerative colitis, the total duration of the colitis rather than an early age at onset is an important determinant of risk.[24] After the first 8 to 10 years of disease, the cumulative risk of colorectal cancer increases by about 0.5 to 1% per year, reaching a cumulative risk of 16 to 27% by 28 years of age. The anatomic extent of the colitis is another determinant. Patients with ulcerative pancolitis have a 15- to 19-fold risk of colorectal cancer when compared as a standardized incidence ratio with the rate in the general population. Those with left-sided disease have a 2- to 4-fold risk.[25] Colorectal cancer associated with ulcerative colitis has several unique features, including an increased likelihood of multiple lesions, the tendency for a malignancy to arise from flat mucosa rather than an adenoma, and the occurrence in a relatively younger population (mean age in the thirties).[26]

The risk of colorectal cancer in patients with Crohn disease also is increased and is related to the duration and extent of colonic disease.[27] The relative risk of developing small bowel cancer in Crohn disease patients is greatly increased over that of the normal population; however, given the small incidence of small intestinal adenocarcinoma, the absolute risk remains very low.[28] In ulcerative colitis, virtually all intestinal cancers occur at sites of active or past colonic inflammation, whereas in Crohn disease, one-third of digestive tract cancers occur in grossly normal segments of intestine. Additionally, strictures in ulcerative colitis have a high likelihood of being malignant, whereas they are largely due to fibrostenosis in Crohn disease. Many cancers in Crohn disease arise in bypassed segments of bowel. Therefore, in the setting of Crohn disease, the ability to predict the site of cancer may be diminished.

TABLE 45.2-1 CONDITIONS ASSOCIATED WITH COLON CARCINOMA

ENVIRONMENTAL FACTORS
Diet high in calories, fat, and cholesterol and low in fiber
Exposure to radiation or chemicals
DISEASES WITH HERITABLE COMPONENTS
Inflammatory bowel disease (ulcerative colitis, Crohn disease)
Polyposis syndromes: (familial polyposis coli, Gardner syndrome, juvenile polyposis, Peutz-Jeghers syndrome)
Hereditary syndromes without polyposis (Lynch I, Lynch II, familial predisposition to adenoma formation)
ACQUIRED DISEASES
Association with previous ureterosigmoidostomy
Bacteremia or endocarditis secondary to *Streptococcus bovis* infection

Some of the hereditary polyposis syndromes carry a high risk for the development of colon carcinoma. The most notable among these are familial adenomatous polyposis (FAP) and Gardner syndrome. Both of these autosomal dominant disorders are characterized by the presence of adenomas in the colon and, to a lesser extent, the small intestine and stomach. The lifetime risk of colon cancer approaches 100%.[29]

The latency period between the appearance of the adenomas and the development of colon cancer averages 10 years,[30] although carcinoma of the colon in association with this syndrome has occurred as early as in the first decade of life.[31] As might be expected, the frequency of multiple lesions is greater in those with FAP than in the general population with colon cancer.[32]

Hamartomatous polyp syndromes also are associated with an increased risk for the development of colon cancer.[33] Peutz-Jeghers syndrome is associated with both an increased risk of gut luminal cancers (small and large intestine) and extraintestinal cancers (ovarian sex cord tumors, Sertoli testicular cancer, breast cancer); the relative risks of dying from these cancers are about 13 and 9 times that of the normal population, respectively. Peutz-Jeghers syndrome arises owing to mutations in the serine/threonine kinase (*STK11*) gene, also known as *LKB1*, and diagnostic and genetic testing is now possible.[34]

The risk of colon cancer is increased in juvenile polyposis coli, with the carcinoma arising in coexisting adenomas or mixed juvenile adenomatous polyps.[35,36] In one series, 18 of 80 patients with juvenile polyposis developed colorectal carcinoma at a mean age of 34 years. However, insufficient information exists to clearly define the magnitude of the risk.[37] Close endoscopic surveillance is advised, and if numerous polyps exist, subtotal colectomy could be considered. These polyposis syndromes are discussed in more detail in Chapter 45.1.

Autosomal dominant inheritance of the tendency to develop colon cancer can also occur in the absence of hereditary polyposis syndromes. Indeed, hereditary nonpolyposis colorectal cancer (HNPCC; Lynch syndrome) is approximately five times more common than FAP-associated colon cancer.[38] Kindreds with HNPCC can be divided into two syndromes: (1) Lynch syndrome I, or hereditary site-specific colon cancer, which is characterized by an increased incidence of cancer in the colon only, and (2) Lynch syndrome II, or the cancer family syndrome,

which is associated with an increased risk of extracolonic and colonic adenocarcinomas, including endometrial, ovarian, gastric, small bowel, pancreatic, bile duct, and urinary tract cancers. The unique features of HNPCC include a propensity for proximal lesions, an increased incidence of simultaneous and subsequent colon cancers, and a relatively early age at onset (mean age of 45 years). The lifetime colorectal cancer risk approaches 85%; thus, many carriers of the disease opt for prophylactic colectomy in lieu of intensive endoscopic surveillance regimens.[39] Colon cancer may develop even in childhood; one member of a family with HNPCC was diagnosed with adenocarcinoma of the colon at 14 years of age.[40]

An unusual, intriguing predisposing condition for the development of adenocarcinoma of the colon is antecedent ureterosigmoidostomy performed for exstrophy of the bladder (Figure 45.2-1). In a series of 93 patients with ureterosigmoidostomies, 5% developed carcinoma of the colon at the level of the ureteral implants after a mean follow-up period of 18 years. The neoplastic pathogenesis is thought to be due to nitrosamine production from the interaction of colonic bacteria on urine, as well as the production of reactive oxygen radicals by neutrophils at the healing anastomotic site, with subsequent deoxyribonucleic acid (DNA) damage. Careful surveillance of these patients with annual colonoscopy beginning 5 to 6 years after surgery and consideration of colon resection have been suggested.[41]

Although not yet reported in the pediatric age group, an association of *Streptococcus bovis* bacteremia or bacterial endocarditis and carcinoma of the colon has been observed in adults.[42] Subsequent reports have confirmed the need to consider the possibility of a coexisting malignancy in individuals with these infections. A study investigating the fecal carrier rate of *S. bovis* found a similar rate in patients with benign polyps (n = 63) and controls (n = 62) but a higher carrier rate in patients with tubulovillous and villous adenomas (n = 18).[43] However, a smaller prospective study of 19 patients with colorectal cancer compared with 23 age- and sex-matched control patients did not find any difference in fecal carrier rates.[44] More research is required, therefore, before the reasons for the association between *S. bovis* and colon carcinoma are understood.

FIGURE 45.2-1 View of the rectosigmoid colon during a barium enema in a 33-year-old patient who had undergone ureterosigmoidostomy in infancy for repair of bladder exstrophy. A polypoid tumor is seen in the sigmoid colon. Reproduced with permission from the Teaching Collection, Department of Radiology, The Children's Hospital, Boston.

Molecular Biology. Recognition of the genetic component of colorectal cancer is growing rapidly.[45] Colorectal carcinoma is thought to be the consequence of several sequential genetic alterations, known as the adenoma to carcinoma sequence. These may be congenital germline mutations, as in adenomatous polyposis coli, or they may be acquired from the mutating actions of carcinogens. The effects of such genetic mutations can be categorized as activation of proto-oncogenes (as is the case for the *Ras* point mutation found in about half of larger adenomas), inactivation of tumor suppressor genes (adenomatous polyposis coli [*APC*] gene, or deleted in colon cancer [*DCC*] gene), or abnormalities in DNA mismatch repair.

Whereas no specific pattern of mutation explains all colorectal tumors, three chromosomal regions are important in colorectal carcinogenesis. First, the mutated in colorectal cancer (*MCC*) and *APC* genes are located on chromosome 5q. The *MCC* gene is mutated or deleted in some sporadic colorectal cancers but not in hereditary cases, whereas the *APC* gene has undergone point mutations in FAP and Gardner syndrome patients and may be somatically altered in tumors from sporadic colorectal cancer patients. These mutations seem to occur early in the adenoma to carcinoma sequence. Second, the *DCC* gene on chromosome 18q is involved in intermediate stages of carcinogenesis, such as the progression from dysplasia to adenomas.[46] K-*ras* inactivation is also thought to play a role in the intermediate stages of carcinogenesis. Third, the *P53* tumor suppressor gene on chromosome 17p tends to be mutated late in colorectal carcinogenesis. The current hypothesis suggests that these genetic alterations accumulate to transform normal epithelium to adenoma and then to carcinoma.

Another molecular pathway involved in colorectal cancer development involves genes that control the repair of mismatched DNA. Mutations in these genes lead to a phenotypic condition called microsatellite instability. This pathway is found in approximately 15% of sporadic cancers and 85% of HNPCC patients, suggesting that defects in mismatch repair may be one of the most common causes of inherited disease.[47] Six genes involved in the repair of mismatched DNA have been identified to date: *hMLH1*, *hMSH2*, *hPMS1*, *hPMS2*, *hMSH6*, and *hMLH3*. The mutated genes cause cancer by allowing other mutations to occur thousands of times more frequently than those in normal cells. In the great majority of tumors with microsatellite instability, a secondary mutation results in the inactivation of the transforming growth factor-β receptor II, a tumor suppressor gene in colonic epithelium.[29]

Several studies indicate that germline defects in mismatch repair genes occur in up to 60% of young patients with

sporadic colorectal cancer. Almost half of young patients with microsatellite instability have detectable germline mutations in a mismatch repair gene.[48,49] Such heritable defects provide a likely explanation for the varying clinical patterns of disease among younger patients with colorectal cancer.[50]

Pathology. Unlike carcinomas in adults, in whom lesions are more commonly in the left colon and rectum, cancers in children and adolescents tend to be more evenly distributed throughout the large intestine. Up to half of young patients have a primary lesion in the ascending or transverse colon compared with a 40% rate of right-sided lesions in older subjects.[12,51]

Carcinomas of the large bowel in adults are usually moderately to well-differentiated adenocarcinomas. Several subtypes of adenocarcinoma are recognized, however, and include a mucinous or colloid variety characterized by large collections of extracellular mucin (Figure 45.2-2). In adults, this tumor represents up to 15% of colorectal carcinomas.[52] Mucinous and signet ring histology are found in a higher proportion of pediatric cases, representing up to 50% and 10%, respectively, of childhood colorectal carcinoma.[53]

Cancers of the colon and rectum grow locally by transmural invasion, eventually penetrating through the bowel wall. Regional lymphatics and, subsequently, distant lymph nodes then become seeded by tumor. The most common sites of hematogenous spread are to the liver, lungs, and bone. The most commonly employed scheme for classifying the progression of local and regional invasion of colonic cancers is a modification of the Dukes' system by Astler and Coller.[54] Tumors in class A are limited to the mucosa; class B1 tumors have extended into, but not through, the muscularis propria; B2 tumors have penetrated the bowel wall through serosa but do not involve lymph nodes; C1 tumors are limited to the bowel wall and involve lymph nodes; C2 tumors have penetrated the bowel wall through serosa and involve lymph nodes; and D tumors have distant metastases.

Younger patients tend to have more advanced carcinomas at initial diagnosis. Enker and colleagues compiled data from a number of reports of colon cancer in younger patients (Table 45.2-2): in this scheme, 2% of patients had tumors classified as Dukes' class A, 16% as class B, 47% as class C, and 34% as class D.[55] This may be due to vague symptoms at presentation, a delay in diagnosis, and a higher incidence of aggressive tumor pathology.

Clinical Features. The most common presenting symptom in children with carcinoma of the colon is abdominal pain, reported by approximately 95% of patients. Vomiting, weight loss, rectal bleeding, and changes in bowel habits also are frequent symptoms.[12,13] Lesions of the right colon typically become large before causing symptoms of obstruction or bleeding. In contrast, more distal tumors frequently produce concentric narrowing of the lumen, with resultant constipation and blood loss. As noted in Table 45.2-3, lesions of the left colon in childhood result in presenting symptoms of constipation and rectal bleeding more frequently than do right-sided lesions.[13] Overall, the presenting symptoms are somewhat different from those of adults, in whom abdominal pain is less common and in whom rectal bleeding, weight loss, and changes in bowel habits are more frequent.[13] This may relate to the predominance of left-sided lesions in adults compared with the more uniform location of cancers in children. The most common physical findings in children with colon cancer are abdominal masses and distention, which are apparent at presentation in over 50% of patients.[13] Other physical findings are summarized in Table 45.2-4.

Diagnosis. Because carcinomas are distributed throughout the colon in children, many lesions are too proximal to

be seen during flexible sigmoidoscopy. Colonoscopy is more sensitive than barium contrast studies and provides the advantage of allowing biopsy specimens to be obtained.[56] Ultrasonography, nuclear medicine, computed tomography, magnetic resonance imaging, and positron emission tomography studies each may be used in demonstrating metastatic disease.[57]

The use of carcinoembryonic antigen (CEA) levels for the management of adult patients with colon cancer is well established.[58] However, little information is available about the merits of using this serologic marker in children. One study noted that 4 of 20 children with advanced colon cancer had normal CEA levels.[12] Another study calculated that CEA testing (using adult normal ranges) has a specificity of 77% and a sensitivity of 64% for recurrent colorectal cancer in patients under 18 years of age. Carbohydrate 19-9 antigen is not sufficiently accurate to prove clinically useful.[59] The use of molecular markers in fecal DNA for the detection of colon cancer in children and in adults warrants further study.[60]

Differential Diagnosis. The differential diagnosis of childhood carcinoma in the colon includes intestinal carcinoids, tuberculosis of the bowel, inflammatory bowel disease, appendicitis, and enteric duplication cysts or other benign causes of intestinal obstruction. Other malignant tumors can be considered, but they are extremely rare.

Treatment. The primary treatment for children with carcinoma of the colon is surgery. A wide resection of the involved segment of bowel with removal of the lymphatic drainage should be performed. In one series, however, complete resection was possible in only 40% of children because of the advanced tumor stage.[12] Resection of the omentum and ovaries should be considered owing to the high rate of recurrence from lymphatic spread.[12,61]

Adjuvant chemotherapy or primary chemotherapy for patients with metastatic disease has provided little benefit in young patients with colon carcinoma. Most often, 5-fluorouracil, either alone or in combination with agents such as nitrosurea, levamisole, and interferon-α, is employed.[62] Most responses to chemotherapy are modest (ie, less than 50% reduction in tumor size) and transient.[12] Early studies of camptothecan derivatives (topotecan and irinotecan) have shown activity in pediatric xenographs, including colon cancer,[63] and clinical pediatric trials are ongoing.[64] Other chemotherapeutic agents, such as oxaliplatin and capecitabine, have not been examined in children. In the near future, molecular markers may well provide predictors of response to therapies[65,66] and thereby provide the opportunity for more individualized treatment regimens.

Radiation therapy improves symptoms, resectability, and survival in adult patients with advanced rectal cancer.[67] Few studies are available in children, but in one series, two patients were treated preoperatively with success in conversion to a resectable cancer.[12] The precise roles of chemotherapy, radiation therapy, combination therapy, and newer therapeutic modalities in the treatment of colon cancer in the pediatric age group await further study.

Unfortunately, the prognosis for children with colonic carcinoma remains dismal. Five-year overall survival rates of less than 3% are reported.[12] Long-term survivors are those patients presenting with less advanced disease. Contributing to the poor prognosis is the pattern of delayed recognition of colon cancer in children and young adults and the predominance of aggressive pathologic types.[51]

Conclusions. Although colonic adenocarcinoma is the most frequent primary intestinal malignant tumor in childhood, it is still uncommon. As a result, diagnosis is often delayed. Future efforts should focus on developing prevention strategies[68] and enhancing early detection. A search for an underlying hereditable risk factor also should be undertaken.[69] Evaluation of the role of nonsurgical therapies in the management of children with established colon cancer must be considered in the context of clinical research trials.

Adenocarcinoma of the Small Intestine

Even in adults, adenocarcinoma of the small intestine is rare, although it does account for approximately half of malignant neoplasms in the small intestine.[70] Such tumors are most commonly found in the duodenum. Adenocarcinomas of the small intestine in childhood should prompt a search for an underlying predisposition, including, for example, Peutz-Jeghers syndrome, Gardner syndrome, and small bowel Crohn disease. Adenocarcinoma of the small intestine complicating Crohn disease was reported in a 21 year old whose inflammatory bowel disease–related symptoms began at 10 years of age.[71] Of 36 cases of adenocarcinoma of the small bowel arising in patients with regional enteritis described by Nesbit and colleagues, 28 occurred in the ileum and 11 developed in previously bypassed bowel.[72] The location of small intestinal adenocarcinomas makes the surveillance of subjects at high risk particularly

difficult. Unexplained bleeding or symptoms of obstruction call for consideration of this diagnosis. Contrast studies remain the primary investigative tool.

INTESTINAL LYMPHOMA

Primary small intestinal lymphomas account for up to 20% of all small bowel malignancies in Western Europe and North America.[73] The incidence of non-Hodgkin lymphoma (NHL) increases with chronologic age. Striking differences exist between these tumors in adults and children with regard to histology, site of occurrence, clinical behavior, and recommendations for treatment. Important differences also are noted between intestinal lymphomas reported in Western populations and those in other populations.[74]

Epidemiology. Lymphoma is the third most common malignant neoplasm of children in the United States, accounting for 10% of all cancers diagnosed in children under 19 years of age.[6] In the developed world, 40% of children with NHL present with abdominal tumors.[75] Primary involvement of the gastrointestinal tract probably occurs in less than half of all patients with NHL. Unlike adults, in whom the stomach is most often involved,[76] the most common sites in affected children are the distal ileum, cecum, and appendix. The ratio of affected males to females in children is approximately 2:1. This gender difference diminishes with increasing age,[77] although male predominance for primary gastrointestinal lymphoma persists through all age cohorts.[78]

The spectrum of gastrointestinal lymphoma varies geographically, likely owing to altered frequency of risks factors. An extraordinarily high rate of Burkitt lymphoma exists in equatorial Africa. Immunoproliferative small intestinal disease (IPSID), also known as Mediterranean lymphoma, is clustered in the Middle East and North Africa.[79] A case series of 37 Iraqi children with primary intestinal lymphoma included 11 children with Mediterranean lymphoma. The remaining 26 had lymphomas localized to the ileum or ileocecal region; half of these tumors were characterized as Burkitt lymphoma.[80]

Pathology. Multiple typing systems currently are employed for the classification of lymphomas. The need for international standards has driven the development of a consensus classification scheme by the International Lymphoma Study Group. This scheme is reproducible and clinically relevant.[81] Nevertheless, most childhood lymphomas still are classified by more traditional histologic typing methods, such as the Luke-Collins or Rappaport systems. About 60% of childhood lymphomas are of the non-Hodgkin type,[82] which comprise the bulk of lymphomas affecting the intestine. The childhood lymphomas are subclassified into three main categories: small noncleaved cell, large cell, and lymphoblastic (Table 45.2-5). In the Rappaport classification, the small noncleaved cell category is known as "undifferentiated." Abdominal lymphomas in children are usually of the small noncleaved cell or undifferentiated histologic type, whereas a smaller proportion are of the large cell type. Small noncleaved cell lymphomas can be subdivided into Burkitt and non-Burkitt types.[83] Burkitt lymphoma may be the endemic form seen in equatorial Africa, which accounts for 50% of all childhood cancers in the region,[84] or the sporadic form seen in Europe and the United States. These histologic types of gastrointestinal NHL have similar staging and treatment approaches. IPSID is an exception and is discussed separately.

Risk Factors. Predisposing conditions include both inherited and acquired immunodeficiency states. The former include ataxia-telangiectasia, Wiscott-Aldrich syndrome, common variable immunodeficiency, X-linked lymphoproliferative syndrome (Duncan syndrome), and severe combined immunodeficiency syndrome. Post-transplant lymphoproliferative disease also results in intestinal lymphoma. Currently, these predisposing conditions are recognized only in a minority of children with NHL. Nevertheless, the presence of an intestinal lymphoma should prompt the careful assessment of immune function in all affected children.

The association between immunodeficiency and intestinal lymphomas likely relates to specific infectious triggers. Indeed, in the X-linked lymphoproliferative syndrome, Epstein-Barr virus infection triggers the development of B-cell lymphoma.[85] Epstein-Barr virus infection also is closely associated with the development of lymphomas in immunosuppressed transplant patients.[86] Epstein-Barr viral DNA is present in 95% of endemic Burkitt lymphomas compared with 15% of sporadic Burkitt lymphomas.[82] Recent evidence indicates that Epstein-Barr virus infection is also related to Hodgkin lymphoma in young persons.[87]

Intestinal lymphomas occur with increased frequency in adults with unrecognized and untreated celiac disease.[88] Most of these tumors are aggressive T cell–derived

TABLE 45.2-5 CLASSIFICATION OF CHILDHOOD NON-HODGKIN LYMPHOMAS

LUKES-COLLINS CLASSIFICATION	RAPPAPORT CLASSIFICATION	IMMUNOPHENOTYPE
DIFFUSE		
Small noncleaved cell	Undifferentiated	Mostly B cell
Burkitt		
Non-Burkitt		
Lymphoblastic	Lymphoblastic	Almost all T cell
Large cell	Histiocytic	B, T, or null cell
NODULAR (HODGKIN DISEASE)	—	Reed-Sternberg cell (B-cell origin)

NHLs. They usually involve the small intestine but may occur in other extranodal tissues. One study suggested that a strict gluten-free diet can protect against the development of lymphoma in patients with celiac disease.[89] Such an association also has been reported in children with celiac disease,[90] but these findings require confirmation from other centers.

Crohn disease in adults also is complicated by an increased incidence of small bowel lymphoma.[91] Although lymphoma of the colon is uncommon, 24 cases of primary colonic lymphoma associated with ulcerative colitis have been reported, suggesting an association between the two disorders.[92]

Molecular Biology. Karyotype translocations are frequently observed in NHLs. For instance, there is a consistent alteration in the transcription of the c-*myc* oncogene in Burkitt lymphomas. In these lymphomas, genetic material on chromosome 8, including c-*myc*, is translocated in proximity with the genes encoding immunoglobulins (Igs) on chromosomes 14, 2, or 22.[82] The c-*myc* gene is thereby deregulated, probably by virtue of its proximity to elements that normally regulate Ig transcription. Overexpression of c-myc, in turn, represses the transcription of tumor suppressor genes. In sporadic Burkitt lymphoma, the translocation itself results in the deregulation of c-*myc*, whereas in endemic Burkitt lymphoma, c-*myc* is deregulated only by the combination of Epstein-Barr virus DNA and an otherwise silent translocation.[84]

Clinical Features. Children with abdominal lymphoma frequently have presenting symptoms of abdominal pain, distention, a change of bowel habits, and nausea or vomiting. A right lower-quadrant mass occasionally may be palpable. Because primary intestinal lymphomas often involve the terminal ileum, cecum, and appendix, they occasionally result in ileocecal intussusception (Figure 45.2-3). With extensive involvement, ascites may be present. Bone marrow involvement occurs in roughly one-third of patients with undifferentiated lymphomas but is rare in endemic Burkitt lymphoma. The endemic form is also characterized by a high frequency of involvement of the mandible (70% in children younger than 5 years), as well as spinal or central nervous system involvement (30%, respectively).[93] In contrast, involvement of the bone marrow is less common than in the sporadic form of Burkitt lymphoma. In both populations, relapse in the meninges remains a serious problem for children with advanced-stage abdominal undifferentiated lymphomas.[77]

Diagnosis. Diagnosis of NHL requires biopsy for histopathologic examination, immunophenotyping, and cytogenetics. With extensive disease, a bone marrow aspirate and biopsy or cytocentrifugation and examination of ascitic fluid may prevent the need for laparotomy. Findings on barium follow-through may be confused with Crohn disease, certain cases of appendicitis, and various benign lesions, including leiomyomas and enteric duplications (Figure 45.2-4).

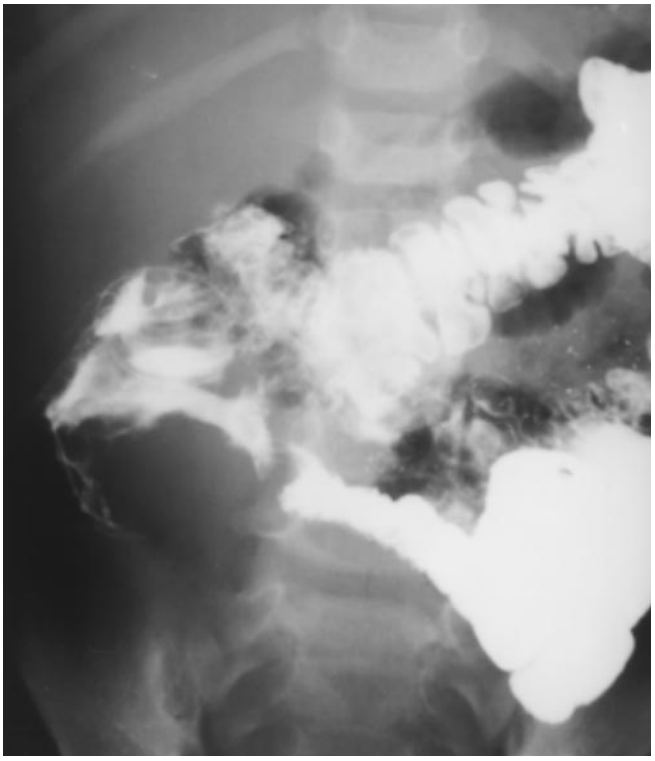

FIGURE 45.2-3 A barium enema study in a 4-year-old boy with a 2-month history of abdominal pain. The barium column stops abruptly in the ascending colon at the site of an ileocecal intussusception. Laparotomy revealed a Burkitt lymphoma of the ileocecal valve. Reproduced with permission from the Teaching Collection, Department of Radiology, The Children's Hospital, Boston.

Formal staging studies should be performed expeditiously because the progression of disease can be rapid, and therapy should be initiated without undue delay. Investigations should include chest radiography, a nuclear medicine gallium scan, computed tomography or magnetic resonance imaging of the abdomen, a spinal tap, and a bone marrow aspirate and biopsy. Leukoerythroblastosis on peripheral blood smear suggests bone marrow involvement. Serum lactate dehydrogenase levels are nonspecific but may correlate with tumor burden. Lymphocyte-derived factors are under investigation as possible prognostic markers.[93]

Treatment. If an evaluation does not reveal extensive abdominal involvement or ascites and if the bone marrow studies yield normal results, the primary bowel lesion and associated mesentery should be resected and a primary anastomosis performed. Mesenteric lymph nodes should be removed for histopathology. Surgical resection likely is of benefit only if most of the tumor burden can be removed and if it does not delay initiation of chemotherapy.[94]

Most chemotherapy protocols include cyclophosphamide, methotrexate, vincristine, prednisone, and an anthracycline. Patients with lymphoblastic lymphomas do better with the inclusion of a consolidation phase of cytarabine, L-asparaginase, 6-thioguanine, and carmustine. Induction therapy is followed by maintenance treatment in all affected children; although those with localized or completely resected intra-abdominal tumor require less intensive

FIGURE 45.2-4 Contrast study of the small bowel in a 3-year-old boy with a 6-week history of abdominal discomfort and malaise. His mother had noticed an abdominal mass when bathing him. The ileum is noted to be nodular and narrowed. At surgery, an ileal Burkitt lymphoma was seen. Reproduced from the Teaching Collection, Department of Radiology, The Children's Hospital, Boston.

treatment. Central nervous system prophylaxis is indicated in all patients with advanced disease but can be omitted in those with completely resected ileocecal primary tumors.[94] All patients with a large tumor burden are at risk for rapid tumor lysis during initial chemotherapy, with resulting metabolic derangements. Therefore, these children should receive allopurinol, vigorous hydration, and urinary alkalinization. Although there is no role for radiation therapy, even in localized intestinal disease, most patients with involvement of the central nervous sytem are given cranial irradiation.

Prognosis. In patients with abdominal disease without bone marrow or central nervous system involvement, the expectancy of cure with combined surgical resection and combination chemotherapy is up to 95%.[95] Chronologic age and gender do not have prognostic significance, except in Burkitt lymphoma, for which younger children tend to have a more favorable prognosis. The presence of bone marrow involvement or cranial disease at the time of initial diagnosis confers a poorer prognosis. Intestinal perforation complicating surgical exploration or chemotherapy with tumor necrosis also seems to be associated with a higher mortality.[88]

Immunoproliferative Small Intestinal Disease

Also known as Mediterranean lymphoma and α-chain disease, IPSID occurs in the Mediterranean basin, Iran, Pakistan, Taiwan, and South Africa and is reported only very rarely outside these areas. It is characterized by the proliferation of IgA-secreting B lymphocytes throughout the small intestine. High levels of IgA heavy chains can be detected in serum.[80,81] The pathogenesis of IPSID has not been entirely delineated, but one current hypothesis suggests that repeated enteric infections result in antigenic stimulation and immune cell proliferation. A recent study indicates that *Campylobacter jejuni* infection could well be involved in the etiology of α-chain disease.[96] Most cases of IPSID occur in patients between 10 and 40 years of age who live in conditions of poor sanitation; younger children occasionally are affected.[80] Patients with IPSID present with symptoms of malabsorption and a protein-losing enteropathy. Most have chronic diarrhea, abdominal pain, and weight loss.

A diffuse infiltrate of plasma cells is present throughout the lamina propria of the small intestine. The villus-crypt structure can be distorted to such a degree as to mimic gluten-sensitive enteropathy. In advanced IPSID, a large cell immunoblastic lymphoma develops that is frequently multifocal.

Early in the course of this disease, antibiotics may induce remission,[97] but molecular analyses suggest that even benign-appearing plasma cells represent a neoplastic process.[79] The combination of surgery, radiation therapy, and chemotherapy is used to treat advanced stages. No large clinical trials have been conducted owing to the rarity of the condition. Although long-term remissions have been recorded, long-term survival rates generally vary between 23 and 67%.[79]

LEIOMYOSARCOMA

Intestinal leiomyosarcoma is extremely rare in childhood, accounting for 0.3% of all neoplasms in children less than 15 years of age.[98] About half of childhood cases occur during infancy.[99] Less than half of reported childhood leiomyosarcomas occur in the digestive tract. A review of 47 cases in the literature suggested a slight female predominance.[100] Leiomyosarcomas present with intestinal bleeding, bowel obstruction, or intussusception. Only 4 of 47 cases of pediatric gastrointestinal leiomyosarcoma presented with an intussusception, whereas almost 30% of adults with an intussusception have a leiomyosarcoma as the lead point.[100]

Pathologic features and the treatment of leiomyosarcomas are discussed in more detail in Chapter 28 with tumors of the stomach (where they arise most commonly).

SUMMARY

Knowledge of those disorders predisposing the patient to the development of intestinal malignancies, such as inflammatory bowel disease, hereditary polyposis syndromes, and immune deficiencies, is essential for the timely diagnosis of intestinal tumors in children. In addition, it provides for the institution of a surveillance program for high-risk family members entering adulthood.[101,102] For both diagnosis and

management strategies, a multidisciplinary approach involving experts from radiology, pathology, surgery, and oncology is critical. Major advances in the care of these patients await further progress in the basic science laboratory and the translation of such findings to the bedside.

CHAPTER 46

HYPOMOTILITY DISORDERS

1. *Idiopathic Constipation*

Joseph M. Croffie, MD, MPH
Joseph F. Fitzgerald, MD, MACG

A regular pattern of defecation is considered by many to be a sign of good health. In fact, many parents of children with constipation believe that a backup of stools can lead to accumulation of toxins in the blood. It is not surprising, therefore, that constipation has been found to be the most common digestive complaint in the United States. Surveys reveal that cathartics and laxatives are prescribed to about 3 million Americans yearly by family physicians and internists.[1] The exact prevalence of constipation in children is not known, but the problem leads to approximately 3% of visits to the general pediatric outpatient clinic[2] and 10 to 25% of visits to the pediatric gastroenterologist.[3,4]

DEFINITION

The definition of constipation varies among individuals. To some, it is hard stools; to others, it is large stools; and to many more, it is infrequent stools. Of 100 mothers in a rural Michigan maternity ward surveyed by Potts and Sesney, 45% defined constipation as "not being able to have a bowel movement," 23% defined it as "hard stools," 10% defined it as "no stool in several days," and 6% defined it as "pain or pressure while stooling."[5] These mothers erroneously estimated the frequency of stools in the first week through 1 month of age, when their expectations were compared with published data. Because the word "constipation" has different meanings for different people, it has been difficult to compile data on normal and abnormal patterns in children.[6] A good working definition includes all of the definitions given by the mothers in the above survey: it would slightly modify the definition in Webster's English dictionary to read "a term used to describe the subjective complaint of passage of abnormally delayed or dry, hardened feces, often accompanied by straining and/or pain."[7] The guidelines of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition similarly define constipation as "a delay or difficulty in defecation, present for two or more weeks and sufficient to cause significant distress to the patient."[8] It is easier to set standards in terms of stool frequency than in terms of size, consistency, degree of straining, or pain. In adults, the normal frequency of defecation ranges from three per day to three per week.[9,10] Lemoh and Brooke studied 55 children, aged 3 days to 2 years, and showed that stool frequency gradually decreases from a mean of four per day during the first week of life to about two per day at 2 years of age.[11] Weaver and Steiner reported that stool frequency in 350 English preschool children aged 1 to 4 years declined from an average of 1.6 per day at 1 year of age to 1.2 per day at 4 years of age.[12] In this latter group, 96% had stool frequencies ranging from three per day to three per week. Weaver's group also studied 240 infants aged 2 weeks to 20 weeks, half of whom were breastfed and the other half formula-fed, and found that 93% of these infants passed one to seven bowel movements per day.[13] Breastfed infants had more frequent stools initially, but by 16 weeks of age, both groups were passing an average of two stools per day.

One can surmise then that normal stool frequency ranges from an average of four per day during the first week of life to two per day at 1 year of age. The normal adult range of three per day to three per week is attained by 4 years of age. These data reflect the average stool frequency in normal infants and children in industrialized countries, not in developing countries, where the normal diet is rich in fiber and normal stool frequency may be different.

NORMAL DEFECATION

Stool is normally propelled down the colon to the anorectum, where it is stored until it can be eliminated in a socially acceptable manner. The anorectum stores and eliminates stool through a complex mechanism involving muscles of the pelvic floor, the autonomic and somatic nervous systems, and the group of muscles controlling the anal sphincters. These interactions have become understood as techniques to study anorectal physiology, such as anorectal manometry, electromyography (EMG), and defecography, have become available. The internal and external anal sphincters surrounding the anal canal form an angle (the anorectal angle) with the puborectalis mus-

cle (Figure 46.1-1). This angle is approximately 85 to 105° at rest.[14] The bolus of stool is propelled into the anorectum during defecation, where distention of the wall results in a temporary reflex relaxation of the internal anal sphincter, allowing stool to come in contact with sensitive receptors in the anal canal. The external sphincter simultaneously contracts, giving the individual time to decide if circumstances are appropriate to allow stool to escape. If the individual decides to allow stool to escape, increased intrarectal pressure from straining moves the fecal material toward the anal canal and the puborectalis muscle relaxes, allowing the pelvic floor to descend. Descent of the pelvic floor straightens the anorectal angle, the external anal sphincter is inhibited, and the fecal material is evacuated. If defecation is to be deferred, voluntary contraction of the puborectalis muscle and the external anal sphincter muscle decreases the anorectal angle to less than the usual 85 to 105°; defecation is prevented, and the rectum accommodates its contents.[15] In newborn babies and very young infants, the role played by the cerebral cortex in these normal events is not yet developed; therefore, defecation occurs when the internal sphincter relaxes.

PATHOGENESIS AND MECHANISMS OF CONSTIPATION

Difficulties with defecation may result from dysfunction in any portion of the normal mechanism of defecation. Such dysfunction may result from aberrations in anatomy or physiology. Constipation is termed idiopathic when it cannot be explained by any anatomic, physiologic, radiologic, or histopathologic abnormalities. Although the exact mechanism of idiopathic constipation is not known, it is generally believed that a multiplicity of factors may be involved. The final common pathway is likely to be a decrease in propulsive forces, impaired rectal sensation, or a functional outlet obstruction. A decrease in propulsive forces may result from a genetic predisposition or a structural abnormality of the colon. Abrahamian and Lloyd-Still obtained a family history of constipation in greater than 40% of 186 constipated children.[16] Concordance for constipation is reported to be six times greater among identical twins than among fraternal twins,[17] and evidence for a congenital syndrome of early-onset constipation has been identified in adults using dermatoglyphics.[18] Recently, Hubner and colleagues described four patients with severe constipation and abnormal gastrointestinal motility who lacked the connective tissue layer between the circular and longitudinal muscles of the bowel on resected specimens in addition to having abnormal submucosal ganglia.[19] They referred to these findings as "desmosis of the colon."[19] Hutson and colleagues found reduced numbers of excitatory substance P–immunoreactive nerve fibers in circular muscles of laparoscopic colon muscle biopsies obtained from a number of children with slow-transit constipation.[20]

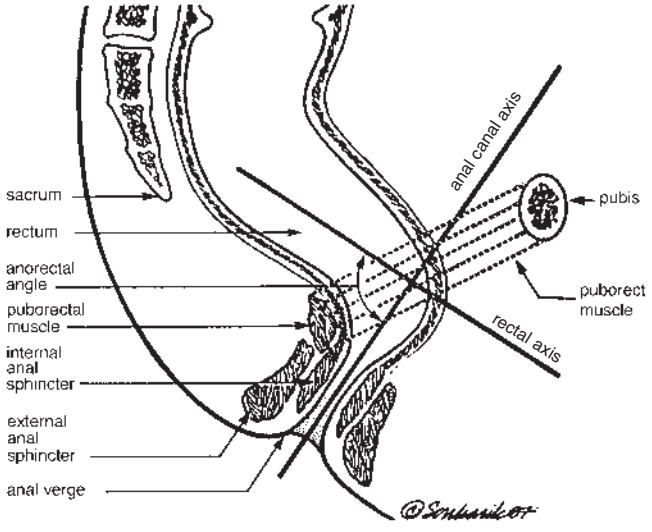

FIGURE 46.1-1 Anatomy of the anorectal region.

Impaired rectal sensation, whether primary or secondary, may lead to chronic constipation. It is known, for example, that children with spinal cord lesions may develop constipation because of impaired rectal sensation. Meunier and colleagues found that 65% of 144 children with severe constipation had significant impairment of rectal sensation, which may have been secondary to the megarectum resulting from chronic fecal retention.[21] It could be argued, however, that impaired rectal sensation itself could be the primary event leading to constipation in some children. Functional outlet obstruction leading to constipation may result from spasticity of the levator ani or impaired relaxation of the puborectalis muscle.[22] It is commonly believed that dietary fiber promotes laxation.[23] Although there are no randomized controlled studies in children to support this belief, some case-control studies have shown an association between decreased fiber intake and constipation in children.[24,25]

Although all of the above mechanisms could lead to chronic constipation, it is believed that most childhood chronic constipation results from intentional or subconscious withholding of stool. Usually, an acute episode precedes the chronic course. The acute episode may occur as the diet is changed from human milk to cow's milk, either because of a higher protein-to-carbohydrate ratio in cow's milk or, possibly, because of allergy to cow's milk protein.[26] The stool, which becomes firm and smaller in quantity, is passed less frequently and with great effort. Anal irritation, and often an anal fissure, develops, and defecation becomes painful. If this acute problem is not treated promptly, a pattern of withholding develops as the passage of stool becomes associated with pain.[27] At the urge to pass stool, the infant typically screams, stiffens the body, and tightens the gluteal muscles, while making a great effort to prevent escape of stool. The face might become flushed during this process, and parents often misinterpret these signs as an extreme effort to pass stool.

In toddlers, conflict arising out of coercive or inappropriately early toilet training is an additional factor that may initiate a pattern of stool retention.[28,29] In older children, a retentive pattern may be initiated by situations that make stooling inconvenient or uncomfortable, such as a school with unpleasant toilet facilities[30] or group A β-streptococcal

anusitis.[31,32] Toddlers and older children tend to cross their legs, stand rigidly upright, squat quietly in corners, walk on tiptoes, or hold onto furniture as they wait for the call to stool to pass.[2,27] The urge to defecate passes as the rectum accommodates to its content. A vicious cycle of retention develops as increasingly larger volumes of stool, desiccated by colonic absorption of the water content, must be expelled, often with increasing difficulty and pain. Prolonged stretching of the rectal walls, associated with chronic fecal retention, leads to an atonic and desensitized rectum, which perpetuates the situation because large volumes of stool must now be present in the rectum to initiate the call to stool. Some of these patients tolerate rectal distention volumes in excess of 500 mL at anorectal manometry.[33,34] This functional megacolon, which can be demonstrated on a barium enema, may be confused with the megacolon associated with Hirschsprung disease by the untrained eye.

When large volumes of stool in the rectal vault stretch the rectum, the internal anal sphincter relaxes while the anal canal is shortened, as demonstrated by Loening-Baucke and Younoszai.[35] Eventually, the external anal sphincter is no longer able to function adequately when the fecal mass pushes against it. Unformed stool, escaping around the impaction, leaks uncontrollably into the undergarment. This condition is referred to as encopresis.[36]

ENCOPRESIS

Encopresis is incontinence of stool not resulting from organic defects or illness.[36] This fecal incontinence characteristically ceases for several days following expulsion of a megastool. The term encopresis was introduced in 1926 by Weissenberg to describe the fecal equivalent of enuresis.[37] Although encopresis is considered by some to be caused by emotional upheavals,[38] rarely is a nonconstipated child with severe psychological disturbances seen who passes stool into clothing.[27] Furthermore, psychotherapy has been unsuccessful as a sole treatment for encopresis.[35] It is now generally accepted that chronic constipation resulting from functional fecal retention, often called psychogenic constipation, is the major cause of encopresis. Fecal incontinence owing to organic disorders, including spinal cord lesions or anatomic lesions of the anorectum, is not encopresis.

Encopresis rarely occurs before 3 years of age. In 102 encopretic patients seen at Boston Children's Hospital Medical Center over an 18-month period in the early 1970s, the mean age was 7 years, 4 months.[39] At the James Whitcomb Riley Hospital for Children/Indiana University Medical Center in Indianapolis, 274 children with constipation were seen in the gastroenterology clinic in l992.[40] Seventy-five of these children had fecal soiling. The median age of these encopretic patients was 9 years (Figure 46.1-2). Boys are more likely to experience encopresis than girls. The male-to-female ratio in the Boston study was 5.8:1[39]; in the Indianapolis study, it was 2:1.[40]

Encopresis is a source of considerable embarrassment for the child, who must deal with taunting by peers. These patients may suffer significant emotional setbacks as a result of this problem,[16,41] with loss of self-esteem and confidence.[32] Encopresis also is the source of a good deal of frustration for the parents who must deal with the smelly, dirty laundry and often angry school officials. These parents are convinced that their child has an anatomic abnormality of the colon by the time they arrive at the office of the pediatric gastroenterologist. Often punishment and psychotherapy have been tried, without beneficial results. Many parents are visibly relieved when the pathophysiology of the condition is explained to them. A few demonstrate initial skepticism, finding it difficult to accept the simple explanation for a problem that they have become convinced has an organic basis.

Encopresis often resolves spontaneously before late adolescence,[42] but Rex and colleagues have reported four patients with encopresis whose ages ranged from 16 years to 20 years, showing that this condition may persist into young adulthood.[34]

CLINICAL SIGNS AND SYMPTOMS OF CHRONIC CONSTIPATION

In many children, longer intervals between bowel movements may be the only complaint. Symptoms and signs associated with chronic constipation include abdominal pain, anorexia, vomiting, abdominal distention, excessive flatulence, and blood-streaked stools. Constipation in infants and toddlers may come to parental attention because of increasing irritability, because of a poor appetite associated with the lack of bowel movements, or when they demonstrate withholding behavior. Constipation in most older children comes to attention because of fecal soiling. Initially, the parents assume that the soiling of underclothes is due to reluctance to use the toilet, and they consult a physician only after negative reinforcement has failed. Occasionally,

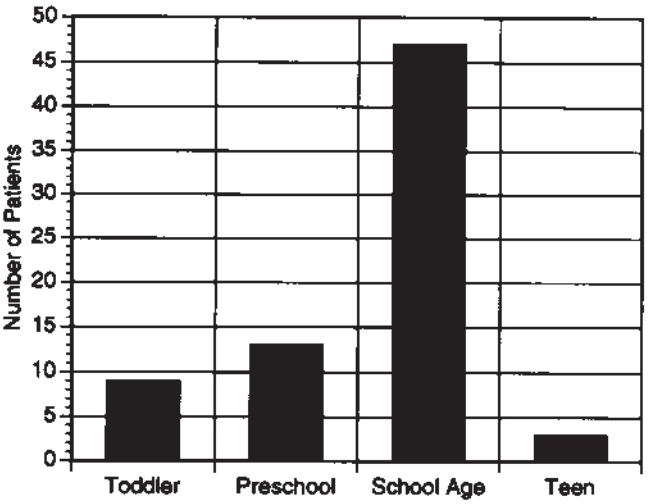

FIGURE 46.1-2 Age distribution of 72 children referred to the James Whitcomb Riley Hospital for Children for management of encopresis in 1992. Encopresis rarely occurs before 3 years of age or after 12 years of age. The median age in this group of encopretics was 9 years.

patients referred for chronic diarrhea are found to have retained stool and incontinence on rectal examination. Enuresis and recurrent urinary tract infections may be associated with encopresis, particularly in girls.[43,44]

DIFFERENTIAL DIAGNOSIS

Constipation is a symptom, not a disease. As such, it may be seen in a heterogeneous group of patients. Although no organic cause is identified in most cases, it is important to be able to identify the many conditions whose symptom complex may include constipation. Table 46.1-1 lists some of these conditions. The most common condition that must be differentiated from idiopathic constipation is Hirschsprung disease, a colonic motility disorder resulting from segmental colonic aganglionosis, with a prevalence of 1 in 5,000 live births and a male-to-female ratio of 4:1.[45] It is believed to account for 20 to 25% of all cases of neonatal intestinal obstruction[27] and 3% of constipated children referred to the gastroenterologist.[32] It can lead to severe enterocolitis with fever, diarrhea, and severe prostration, which may be fatal if the diagnosis is not recognized early.[46] Most affected infants develop difficulties with defecation during the first few weeks of life. Other signs and symptoms associated with the condition include abdominal distention, refusal to feed, and bilious vomiting. In the older infant or child in whom the diagnosis is not made earlier in life, there may be persistent abdominal distention, recurrent fecal impaction, and failure to thrive. Examination of the rectum in patients with Hirschsprung disease usually reveals an empty vault, although stool is palpable in the abdomen. A gush of air and liquid stool may follow withdrawal of the examining finger. In some patients with short-segment or ultrashort-segment Hirschsprung disease, the diagnosis may not be made until later in life.[47,48] These patients have long histories of chronic constipation and may have ganglion cells on rectal biopsy, despite anorectal manometric findings consistent with Hirschsprung disease. They are thought to have impaired innervation of some length of the sphincter mechanism.[47] Contrary to the earlier teaching that fecal soiling is not seen with Hirschsprung disease, these patients may soil, but the soiling is much less severe than one would expect from the degree of rectal impaction.[32]

TABLE 46.1-1 SOME ORGANIC CAUSES OF CONSTIPATION

ABNORMALITIES OF COLON AND RECTUM	
Chronic intestinal pseudo-obstruction	
Anal stenosis	
Anal or colonic stricture—post NEC or IBD	
Postsurgical repair of imperforate anus	
Ectopic anus	
SPINAL CORD LESIONS

Multiple sclerosis	
DRUGS	OTHERS
Analgesics	Celiac disease
Antacids	Cystic fibrosis
Anticholinergics	Lead toxicity
Bismuth	
Iron	
Cholestyramine	
Psychotropics	

IBD = inflammatory bowel disease; NEC = necrotizing enterocolitis.

EVALUATION

Clinical assessment is all that is needed for diagnosis and treatment of most children with chronic constipation. A thorough history and physical examination will identify most patients with an organic cause for constipation, leading to appropriate laboratory and imaging studies to make a diagnosis. Attention should be paid to age at onset of constipation and frequency of bowel movements. A dietary history may identify inadequate fluid intake, undernutrition, or a diet deficient of bulk. Often one elicits a history of constipation beginning when an infant was weaned to a cow's milk–based infant formula or was changed from infant formula to whole cow's milk. In an older child, a change in school or travel away from home may precede the onset of constipation. Inquiry into perinatal history, particularly the age at passage of meconium, and family history may be helpful in excluding Hirschsprung disease. Most patients with Hirschsprung disease fail to pass meconium within the first 48 hours of life,[49] and 20% of children with Hirschsprung disease have a family history of the condition.[45] A history of stool withholding decreases the likelihood of an organic cause for constipation. We have found it helpful to describe to parents the various postures assumed by children who withhold because many parents may not be aware of the significance of these postures and, therefore, may not volunteer this information. Inquiry into the size of bowel movements may also help differentiate between idiopathic constipation and constipation attributable to an organic lesion. The child with anal stenosis or Hirschsprung disease may pass pencil-thin stools, whereas the child with constipation secondary to voluntary withholding usually passes large stools, which may clog the commode. The presence of vomiting, abdominal distention, failure to gain weight, and weight loss suggest an organic cause for constipation and should lead to a thorough investigation.

A thorough physical examination is essential to eliminate a major illness complicated by constipation. The

abdomen is only mildly distended in functional constipation, even when large volumes of stool are retained, because gas is not retained with the stool. A fecal mass is palpable in the suprapubic region and the left lower quadrant in about 40% of patients.[50] Bowel sounds are normal. Examination of the perianal region may reveal evidence of fecal soiling. There may be stool in the underwear. Careful examination of the perianal region may identify ectopic placement of the anus, a correctable problem when recognized and operated early.[51,52] The anogenital index can be calculated when necessary. This is the distance in centimeters from the vagina or scrotum to the anus, divided by the distance from the vagina or scrotum to the coccyx. The normal anogenital index in females is 0.39 ± 0.09, whereas 0.56 ± 0.2 is normal for males.[53] An anal fissure, significant circumferential perianal erythema indicative of streptococcal anusitis, or anal trauma suggestive of sexual abuse may be identified as a reason for withholding. Scybalous stool may be palpated within the rectum or rock-hard stool may be palpated just within the internal anal sphincter. An empty rectum in the presence of a palpable fecal abdominal mass is highly suggestive of Hirschsprung disease. The lumbosacral region of the back should be examined for evidence of myelodysplasia or sacral agenesis, and a neurologic examination of the lower extremities should be performed to exclude an occult spinal cord lesion. A patulous anus, sacral dimple beneath a tuft of hair, flat buttocks, or absent reflexes in the lower extremities suggest an underlying neurologic disorder.[27] Patients with a systemic disorder are identified by the presence of other abnormal physical findings.

FIGURE 46.1-3 A plain radiograph of the abdomen showing a dilated rectum impacted with stool in a child with constipation.

INVESTIGATIONS

Most infants and children with chronic constipation require no laboratory investigation. In a small proportion of these children, clinical evaluation alone is insufficient and/or simple treatment measures are ineffective. In this small group of patients, diagnostic tests such as plain radiographs of the abdomen, barium enema, anorectal manometry, and rectal biopsy may be useful. A urinalysis and urine culture may be indicated in the patient presenting with accompanying complaints such as abdominal pain, enuresis, dysuria, urgency, or increased urinary frequency.

Plain radiographs of the abdomen may be necessary to establish a fecal impaction in the child who resists rectal examination and in the obese child when abdominal and rectal examinations are suboptimal. The rectum of the impacted fecal-retentive child is dilated and filled with stool to the anal verge (Figure 46.1-3).

The barium enema should be performed on an unprepared colon if the intent is to detect the transition from aganglionic to ganglionic bowel, which is typical of Hirschsprung disease (Figure 46.1-4). Usually, the ganglionic segment is dilated with stool, creating a rectosigmoid index (obtained by measuring the maximal diameter of the rectum and comparing it with a similar measurement of the sigmoid colon) of less than 1, with normal being greater than 1. If stool is removed before the barium enema, this transition zone may be difficult to identify, and the rectosigmoid index may be deceptively normal. A transition zone may not be seen in infants simply because there has not been enough time to distend the ganglionic portion of the colon with stool.[49] Loening-Baucke and colleagues calculated the sensitivity and specificity of barium enema in the diagnosis of Hirschsprung disease in the neonate to be 75% and 67%, respectively.[54] If the initial barium enema is not diagnostic, 24- and/or 48-hour follow-up plain radiographs of the abdomen, which should include a direct lateral radiograph of the rectum and sigmoid, may demonstrate delayed excretion of the barium and suggest the diagnosis.

Anorectal manometry may reveal abnormalities of defecatory function not detectable by physical examination.[55] To perform these studies, most use a manometric balloon or balloons attached to a catheter and connected to a physiograph or computer via a transducer.[14] The two most common manometers are the open-tipped perfusion manometer and the closed triple-balloon manometer (Schuster-type balloon manometer) (Figure 46.1-5). The perfusion manometer is probably the most accurate for recording resting and squeeze pressures of the anal canal. Pressures are measured using a 1 cm station pullout or a continuous pullout technique. Distention of a balloon at

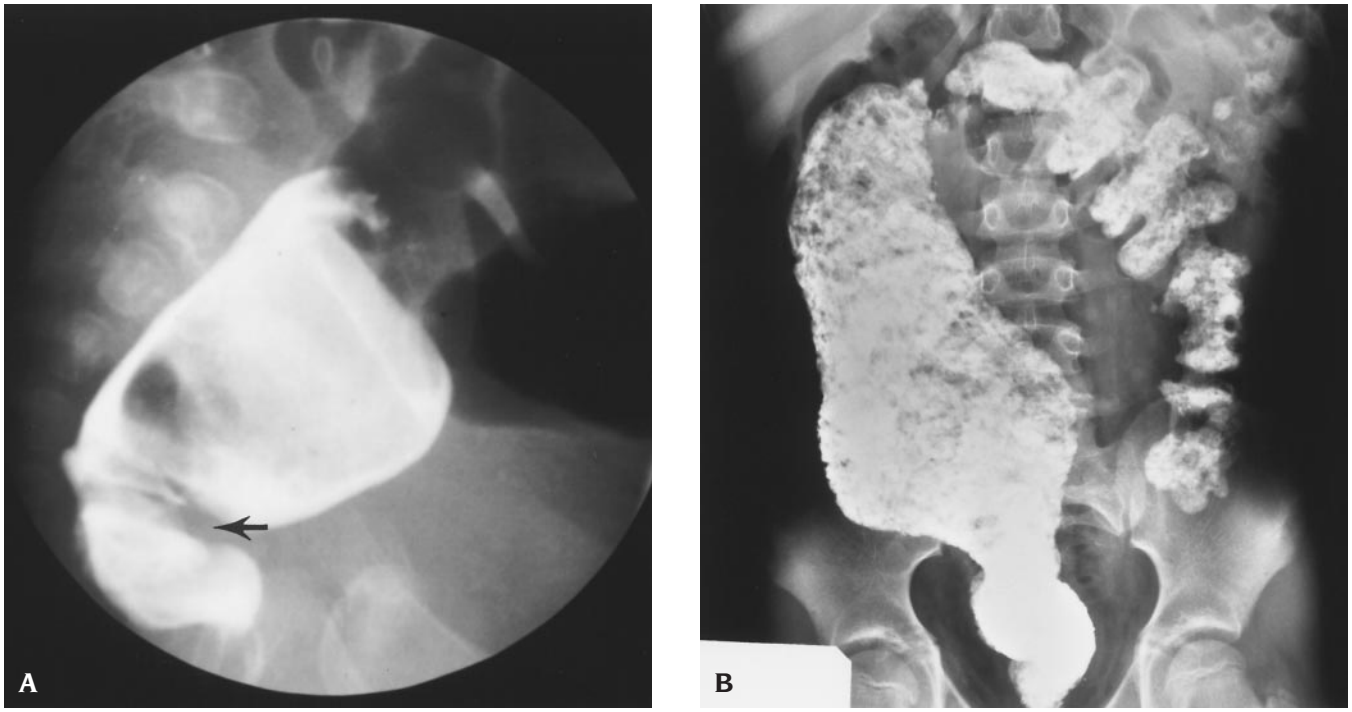

FIGURE 46.1-4 *A,* Barium enema demonstrating the transition from aganglionic to ganglionic bowel in a patient with Hirschsprung disease. Arrow points to transition zone. The ganglionic proximal segment is dilated with stool and barium, creating a rectosigmoid index of < 1.

the tip of the catheter with different volumes of air allows one to determine rectal sensory thresholds and elicit reflex relaxation of the internal anal sphincter. The triple-balloon system consists of a hollow cylinder surrounded by two balloons designed to sit in the internal and external anal sphincters. A rectal distention balloon passes through the hollow cylinder. This apparatus allows for simultaneous pressure recordings from the proximal rectum, internal anal sphincter, and external anal sphincter. It is most efficient for evaluating internal anal sphincter and external anal sphincter responses to rectal distention and for evaluating a subject during simulation of defecation.[14]

Anorectal manometry allows one to determine the threshold for rectal sensation, that is, the smallest volume of distention that is sensed by the subject; the threshold for internal sphincter relaxation, which is the smallest volume of rectal distention required to produce relaxation of the internal anal sphincter; the threshold for constant sensation of urgency (critical volume), which is the volume of rectal distention required to produce a persistent urge to defecate; the maximum tolerable volume, that is, the volume of rectal distention at which the subject refuses further distention; and maximal squeeze pressures of the external anal sphincter.[56] Many investigators have performed these studies,[21,50,57–59] but a lack of standardization in methods of performing anorectal manometry has resulted in inconsistencies. Efforts are now being made to standardize the performance of this and other motility tests in children.[60] Some normal values established by consensus of an International Working Group[56] are as follows: threshold for rectal sensation: ≤ 10 mL in a laboratory using rapid balloon inflation by handheld syringe, 30 mL if the inflation is gradual, 25 mL or less for children; threshold for internal sphincter relaxation: 10 to 20 mL; threshold for constant urge to defecate: ≤ 220 mL with an average of 115 mL; and maximum tolerable volume: 140 to 440 mL in adults and 110 to 280 mL in children.[33] Benninga and colleagues studied 13 healthy children aged 8 to 16 years using the perfused catheter technique.[59] They reported normal values for maximal anal resting tone of 33

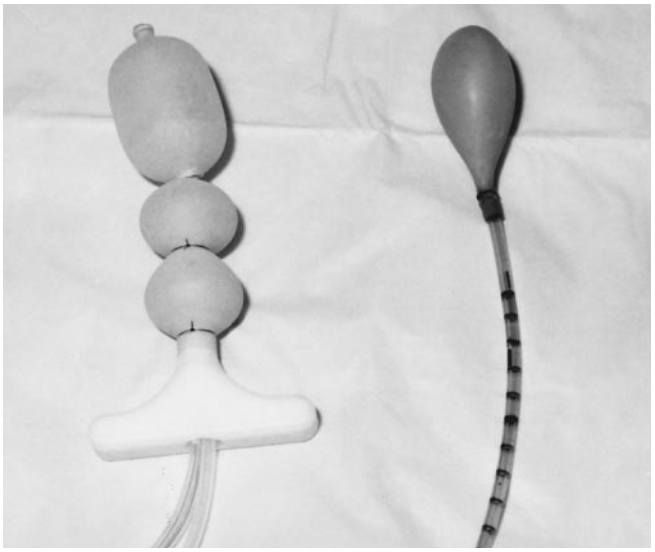

FIGURE 46.1-5 Anorectal manometry catheters. The open-tipped water-perfused catheter is on the right. The Schuster-type triple-balloon catheter is on the left.

to 90 mm Hg and for maximal squeeze pressure of 81 to 276 mm Hg; a threshold for rectal sensation of 5 to 50 mL; a threshold for internal sphincter relaxation of 5 to 40 mL; and critical volume of 90 to 180 mL.

Despite these inconsistences, anorectal manometry is a good screening test for Hirschsprung disease. A fall in internal anal sphincter pressure is seen after distention of the rectum with air, the rectoanal inhibitory reflex. This reflex is present in healthy infants and children, with the probable exception of neonates delivered before 39 weeks of gestation.[61,62] It is absent in Hirschsprung disease (Figure 46.1-6) because the aganglionic segment blocks the normal intramural pathway from rectum to internal sphincter.[63]

In the short- and ultrashort-segment forms of Hirschsprung disease, the rectoanal inhibitory reflex is absent, despite the presence of normal ganglion cells on rectal biopsy. The rectoanal inhibitory reflex may also be absent in patients with hyperganglionosis.[64,65]

Anorectal manometry has identified functional abnormalities in some children with chronic idiopathic constipation, including an increased rectal sensory threshold, decreased rectal contractility on attempted defecation, and paradoxical contraction of the external anal sphincter and puborectalis muscles during attempts at defecation.[21,40,57,66,67] The latter condition is called anismus[68] or pelvic floor dyssynergia.[56] Loening-Baucke and Cruikshank found failure of relaxation of the external anal sphincter in 50% of a group of chronically constipated children with encopresis.[50] Meunier found similar abnormalities in 77% of a group of constipated children.[69] Wald and colleagues found that 36% of children with encopresis exhibited an inappropriate contraction of the external anal sphincter during simulated defecation compared with 10% of control children.[57] Keren and colleagues found similar abnormalities in 78% of 18 constipated and encopretic children.[58] Whereas Meunier and colleagues[21] and Molnar and colleagues[70] found a significantly higher threshold for rectal

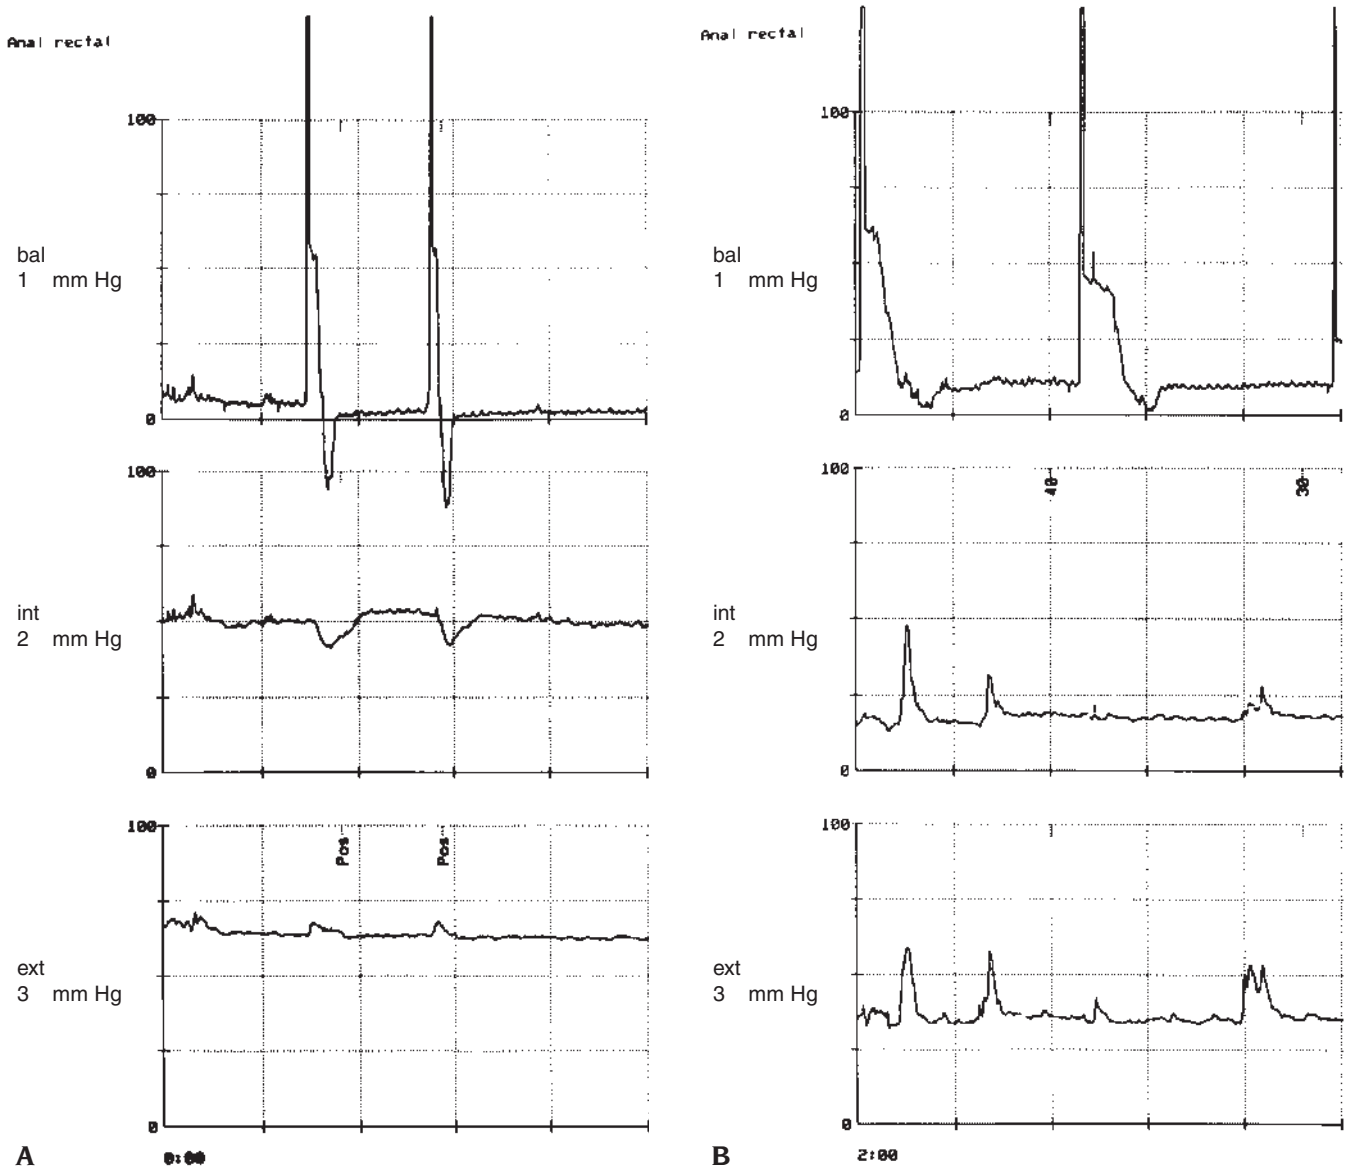

FIGURE 46.1-6 Anorectal manometric tracing demonstrating: *A,* Normal relaxation of internal anal sphincter and contraction of external anal sphincter on rectal distention. *B,* Absence of relaxation of internal anal sphincter in a patient with Hirschsprung disease.

sensitivity in constipated children compared with controls, Wald and colleagues[57] found no significant difference in mean rectal sensory threshold between encopretic children and control children. The difference between the two groups, however, appears to be related to the different methods of bowel preparation employed by the individual investigators prior to manometry.

These manometric abnormalities in children with chronic idiopathic constipation have responded to biofeedback treatment in some cases. It is presumed, for example, that paradoxical contraction of the external anal sphincter during attempts at defecation is the result of self-conditioning brought on by previous painful defecation and that it should respond to a retraining program.[57,58]

Anal sphincter EMG may be performed at the time of manometry to evaluate activity of the external anal sphincter and puborectalis muscles and for biofeedback treatment in children.[40] It involves the use of surface or needle electrodes connected through an EMG analyzer to a monitor or physiograph.

Defecography is a radiographic means of studying defecation dynamics. A barium paste is introduced into the rectum, and the patient is instructed to evacuate the paste while a series of radiographs are obtained. This study allows one to measure the anorectal angle at the time of straining and to assess the activity of the puborectalis sling.[71] Because of the need for exposure to radiation, this test has not been used routinely to evaluate children with constipation.

Colorectal transit studies obtain objective data to support a suspected dysfunction in colonic motility. In the original technique described by Hinton and colleagues, the subject ingests 20 radiopaque markers on a single day.[72] Daily radiographs of the abdomen are obtained to follow the progress of the markers through the colon until all have been expelled, up to a maximum of 7 days. One may radiograph the stool for markers, but this technique fails to identify segmental abnormalities. To minimize exposure to radiation, Metcalf and colleagues introduced a modification of the Hinton technique.[73] The patient ingests 20 markers at the same time each day for a period of 3 days. A single radiograph is obtained on the fourth day. A second radiograph may be obtained on day 7 in borderline cases and to verify apparent segmental delay. By either technique, markers are counted in the right colon, left colon, and rectosigmoid colon, using the spine and pelvis as landmarks.[74] Segmental transit is obtained by multiplying the number of markers in the segment of interest by 1.2 (the number of hours in a day divided by the number of markers ingested). Total colonic transit is obtained by counting markers in the entire colon and multiplying by 1.2. If the Hinton technique is used, the number of markers present in a segment of interest or in the entire colon on each radiograph is counted and the sum total is multiplied by 1.2.[72] With the Hinton technique, many normal adults pass the first marker within 3 days and 80% of the markers within 5 days.[72] The upper limit of normal for total colonic transit time is about 68 hours in adults[73] and between 50 and 62 hours in children, depending on the technique used.[75,76] These studies allow one to identify patients who may have abnormal motility in particular segments of colon and to differentiate between three groups of patients with chronic idiopathic constipation.[74] In one group, markers are retained too long in the entire colon (slow-transit constipation, a subgroup of which has delay in the right colon and is said to have colonic inertia). In a second group, there is a holdup in the left colon and rectosigmoid (distal constipation, a subgroup of which has normal transit through the colon with virtually no transit through the rectum and is said to have outlet obstruction). Such a situation may be seen in children with retentive constipation or paradoxical anal contraction during defecation.[77] The third group has a normal colorectal transit time (normal-transit constipation). Transit studies are performed frequently in adults. They have been found helpful in selecting and monitoring therapy.[78] They may be helpful in providing objective information in children who report or whose parents report constipation but who have no objective findings of constipation on repeated physical examination. They may also be helpful in classifying children with constipation into the subgroups described above.[77]

Colonic motor function can be precisely evaluated by colonic manometry. Manometry helps to identify children in whom a neuropathy or myopathy may be the cause of intractable constipation.[79] In some patients, colonic manometry may identify segmental abnormalities that may be amenable to surgical management.[80]

Because the diagnosis of Hirschsprung disease depends on histologic evidence of aganglionosis, a rectal biopsy is performed in those patients in whom Hirschsprung disease is strongly suspected. These would be patients with intractable constipation who have an abnormal barium enema or absence of the rectoanal inhibitory reflex on anorectal manometry. The mucosal suction biopsy that does not require anesthesia is of little or no risk. In our experience, the depth of these biopsies, except in infants, is often not sufficient to allow adequate study of the submucosa for ganglion cells, often necessitating repeat biopsies. Beyond infancy, we prefer the forceps biopsy technique done under general anesthesia. If properly performed, this technique almost always provides adequate tissue depth. We use propofol for anesthesia, and endotracheal intubation is usually unnecessary. A small risk of bleeding exists when an abnormally dilated internal hemorrhoidal vein is accidentally injured during the procedure. We obtain two biopsy specimens from the lateral walls of the rectum approximately 3 cm from the anal margin.

To the trained eye, a simple hematoxylin-eosin stain allows identification of ganglion cells in the submucosa if they are present. The absence of ganglion cells in the submucosa, often accompanied by the presence of hyperplastic neural elements, is characteristic of Hirschsprung disease, except perhaps in premature newborns. The hyperplastic neural elements associated with Hirschsprung disease may be enhanced by staining with acetylcholinesterase.[81] Other abnormalities of the enteric plexus causing constipation that may be diagnosed from a good biopsy specimen include the hyperganglionosis seen in association with intestinal neuronal dysplasia[64,65] and hypoganglionosis.[82]

TREATMENT AND PREVENTION OF CHRONIC IDIOPATHIC CONSTIPATION AND ENCOPRESIS

For most children with chronic constipation, a well-organized treatment strategy is all that is required once constipation has been confirmed. Such a program should be designed to clear any existing impaction, prevent reimpaction, and establish a regular bowel habit.

We outline the age-related treatment strategy that has been successful at our institution.

Infants on breast milk are less likely to develop constipation than their counterparts on regular cow's milk–based formula, possibly owing to the higher carbohydrate-to-protein ratio of breast milk. Occasionally, a solely breastfed infant is referred for evaluation of infrequent stools; these infants are usually perfectly healthy, with a small amount of salve-like stool in the rectal vault. We reassure the mothers, explaining that the infant's infrequent stools relate to almost complete absorption of their breast milk, leaving very little residue for stool formation.

For most infants with simple, acute constipation, dietary measures, including an increase in fluid and carbohydrate intake, often correct the problem. In infants with persistent hard stools, one to two teaspoons of maltsoup extract (Maltsupex) or dark karo syrup added to a feeding two to three times per day may be helpful. If an anal fissure develops, it should be treated promptly. An ointment such as petroleum jelly should be applied liberally to the fissure to reduce irritation from friction during the passage of stool. For older infants, increasing the intake of fluids containing sorbitol, such as apple, prune, or pear juice, may help soften the stool. A stool softener such as docusate sodium or an osmotic laxative such as lactulose or sorbitol may also be prescribed to soften the stool. Prompt treatment of a fissure is essential to prevent the development of a tendency to withhold stool. We have seen infants as young as 6 weeks of age withhold stool. For such infants, the treatment measures described above may be ineffective. We have safely treated infants over the age of 6 months with a mineral oil–based preparation in a dose of 10 cc twice per day, and there is no risk for pulmonary aspiration. In younger infants or older infants with a vomiting history and, therefore, at risk for pulmonary aspiration, we have tended to use a senna preparation in a dose of one-third to one-half of a teaspoon at bedtime until regular, soft stools are passed. Electrolyte-free polyethylene glycol (PEG) may also be used in this group of patients.

Toddlers and older children with simple acute constipation usually respond to increased fluids, especially sorbitol-containing fruit juices, and increased dietary fiber intake. Most toddlers and older children with chronic constipation referred to the pediatric gastroenterologist are voluntary stool-withholders. In many school-age and teenage children, withholding may have been ignored or not noticed during the preschool years, and encopresis is the reason for concern. Where there is a clear history of withholding, treatment should begin with a careful explanation of the basis of the problem, an intervention termed "demystification" by Levine and Bakow.[83] We describe to the parents and child the circumstances leading to a tendency to withhold stool and how fecal soiling results. This careful explanation is a very important part of a successful management strategy. The older child is intrigued that someone finally understands his or her problem, and the parents are often relieved that the child does not have a serious organic problem. Following the demystification process, we outline our strategy for management to the parents and child. Phase 1 is to clear existing impaction with three hypertonic phosphate enemas, approximately 3 cc/kg (maximum 135 cc) each over a 36-hour period. Excessive administration of phosphate enemas may result in systemic absorption of phosphorus (and sodium), leading to hyperphosphatemia and hypocalcemia, and even death, in very young infants and in patients with Hirschsprung disease.[84,85] Enemas must be used with caution in this group of patients. Occasionally, a patient with an unusually large impaction who has not responded to enemas and/or large-volume intragastric infusion of an isotonic PEG solution is manually disimpacted under anesthesia.

Phase 2 of our treatment strategy is designed to overcome the tendency to withhold stool and prevent reimpaction. Mineral oil has traditionally been prescribed in sufficient doses to overcome withholding. The authors prescribe $\frac{1}{2}$ to $2\frac{1}{2}$ ounces twice daily, depending on the patient's age. The mineral oil is given between meals, preferably in the midafternoon and at bedtime, so as to not interfere with the absorption of fat-soluble vitamins. Evidence indicates that there is no interference with fat-soluble vitamin absorption if the mineral oil is given at these times.[86,87] Electrolyte-free PEG 3350 (MiraLax, Braintree Labs, Braintree, Massachusetts) is quickly becoming first-line therapy for childhood constipation among many physicians. Studies in adults have suggested that a PEG-electrolyte solution administered in low doses is safe and efficacious for the long-term treatment of chronic constipation.[88–91] The limitation of this solution is its salty taste. DiPalma and colleagues were the first to show that an electrolyte-free PEG solution is equally safe and efficacious in adults with chronic constipation.[92] Two recently published studies looked at the safety and efficacy of electrolyte-free PEG 3350 in children with chronic constipation. Loening-Baucke compared 21 children treated with magnesium hydroxide with 28 children treated with electrolyte-free PEG 3350 at doses of 0.6 ± 0.2 g/kg/d.[93] At 12 months, 61% of the group on PEG 3350 and 67% of the group on magnesium hydroxide were doing well. Soiling was more common in the group of children treated with PEG 3350. All of the children on PEG 3350 were compliant with the medication, whereas 33% of the children on magnesium hydroxide refused to take the medication. There were no significant side effects with the PEG. Pashankar and Bishop treated 24 children with PEG 3350 for 8 weeks starting at an initial dose of 1 g/kg/d and having the patients adjust the dose as necessary to obtain two soft stools per day.[94] Twenty children completing the study demonstrated an increase in stool frequency from 2.3 ± 0.4 per week to 16.9 ± 1.6 per week. Four of nine with soiling were

cured, whereas the others improved. The effective dose was 0.8 g/kg/d. The children were very compliant with the medication and preferred it over their previous laxatives. The data on PEG 3350 are quite promising. More studies comparing PEG 3350 with other commonly used laxatives are needed to determine if this new laxative is superior to other currently available, cheaper laxatives. Our division is in the middle of one such study designed to compare PEG 3350 with three other commonly used laxatives in children with retentive constipation.

Phase 3 of our program aims at helping the older, toilet-trained child establish a regular bowel habit. The child should sit on the toilet, with proper foot support to allow for hip flexion and to help leverage, for 5 to 10 minutes after breakfast and after the evening meal to take advantage of the gastrocolic reflex to evacuate the rectum. Rewards such as stickers may be used to provide positive reinforcement.[95] We stress the importance of this aspect of the management because a regular bowel habit should evolve and persist during the period when the medication is being weaned and after it is discontinued. Advice is also given at this time on increasing water and fiber intake. We provide a fiber-content sheet to the family and establish a goal of age plus 5 g/d for the child. Unflavored psyllium may be used to reach the daily fiber goal. Finally, we provide the family with reading material and an outline of the treatment strategy to reinforce our discussion and encourage them to communicate any problems they encounter with our office.

It is important to monitor these patients initially at 1-month intervals. If the patient's interval history is satisfactory and rectal examination reveals loose or no stool in the rectal vault, the mineral oil is reduced or the PEG 3350 solution is continued. A return of soiling indicates recurrence of impaction and necessitates restarting the treatment protocol. We occasionally encounter a patient with megarectum who has a large amount of loose stool in the rectal vault on examination. It is obvious from the loose stool that the patient is compliant and is taking the medication as prescribed. In these patients, the addition of a nighttime dose of a colon stimulant, such as senna, might hasten the return of normal colonic tone. The stimulant laxative is weaned as quickly as possible to prevent dependence. The mineral oil should be slowly tapered over 4 to 6 months. The PEG 3350 solution should be taken for 3 months and then tapered over 1 to 2 months.

A common pitfall is premature discontinuation of medications. We no longer schedule return appointments when the patient is having a soft stool daily, is no longer withholding stool, and is no longer soiling. Parents are advised to treat acute recurrences of constipation promptly to prevent the reappearance of a withholding pattern. Adequate fluid and fiber intake is again encouraged.

Table 46.1-2 summarizes the treatment protocol used in our institution for children with chronic retentive constipation. Other laxatives used by pediatric gastroenterologists include magnesium hydroxide (1–3 cc/kg/d in two divided doses),[2] sorbitol (1–3 cc/kg/d in two divided doses), lactulose (1–3 cc/kg/d in two divided doses), and cisapride (0.2 mg/kg/d), although the data on the efficacy of this medication are conflicting.[96–100] Cisapride is currently no longer available in the United States. We have had little experience with magnesium hydroxide or cisapride and very little success with lactulose, sorbitol, and other stool softeners in children who *clearly* withhold. This, we suspect, is because any water gained during transit through the small bowel and proximal colon with these agents is lost in the distal colon, where it is reabsorbed with ongoing stool avoidance. Continued withholding is impossible with appropriate doses of mineral oil and PEG 3350 solution because of their ability to retard colonic absorption of fecal water.

The child with infrequent bowel movements and no history of withholding who continues to have problems despite compliance with prescribed therapy may need testing to exclude occult organic disease. Serum calcium, thyroxine/thyroid-stimulating hormone, and antiendomysial antibody (or antitissue transglutaminase) titer may be requested to exclude idiopathic hypocalcemia, thyroid disease, and celiac disease.[101–104] Some of these patients may benefit from a short course of a stimulant laxative such as senna or a bulk laxative such as psyllium. Also, some of these patients may benefit from PEG 3350 solution.

Patients with obvious emotional disturbances and those with fecal soiling and no documented impaction on repeated examinations are best treated by a psychiatrist or behavioralist.[36]

For those patients not responding to the treatment program outlined above, anorectal manometry and/or rectal biopsy should be performed to exclude Hirschsprung disease. An unprepared barium enema is a reasonable alternative if facilities for performing a rectal biopsy or manometry are not available. It should be noted that short- or ultrashort-segment Hirschsprung disease may be diagnosed only by anorectal manometry, where failure of relaxation of the internal anal sphincter on rectal distention is documented. In some patients undergoing anorectal manometry, abnormal defecation dynamics, such as a decreased sensory threshold to rectal distention or paradoxical contraction of the external anal sphincter and puborectalis muscle during simulated defecation, may be uncovered.[21,33,58,66,105,106] Such patients may benefit from biofeedback training to help them relax the external anal sphincter muscles when straining to defecate and to decrease the threshold for rectal sensation.

BIOFEEDBACK TREATMENT

Biofeedback therapy has been used in the last two decades to manage various disorders of defecation in both adults

TABLE 46.1-2 TREATMENT STRATEGY FOR CHRONIC RETENTIVE CONSTIPATION

Careful explanation of the mechanism of constipation
Hypertonic phosphate enemas every 12 h × 3 to clear impaction
Mineral oil, 0.5 to 2.5 ounces twice daily (between meals) or electrolyte-free PEG 3350 (MiraLax), 1 g/kg/d in $^1/_2$ ounce water per g qd or divided bid
Encourage patient to sit on toilet for 5 to 10 min after breakfast and the evening meal with proper foot support
Monitor patients at monthly intervals
Continue treatment for 4 to 6 mo

and children. It is based on operant conditioning, the pavlovian principle of learning through reinforcement, and was first used by Kohlenberg to correct fecal incontinence.[107] Patients are shown a tracing of normal defecation dynamics during biofeedback training. They are then allowed to see their own tracing, and the abnormalities are pointed out to them. Using the monitor or the physiograph for feedback, these patients are encouraged to correct the abnormalities on their tracings by trying different maneuvers (Figure 46.1-7). Sensory retraining is achieved by training the patient to sense progressively smaller volumes of rectal distention using the rectal balloon. Several studies now suggest that biofeedback therapy is beneficial in treating some patients with chronic constipation and encopresis. Wald and colleagues reported 67% success in those patients treated with biofeedback compared with 33% in those treated with mineral oil.[108] Keren and colleagues treated 12 patients with chronic constipation who paradoxically contracted their external anal sphincter while straining to defecate.[58] All 12 children successfully learned to relax their anal sphincter during defecation, and their bowel habits improved. Loening-Baucke studied 43 children, 20 of whom were assigned to conventional therapy, including disimpaction, followed by magnesium hydroxide (2 cc/kg/d) and a bowel regulation program.[109] The remaining 23 children received this conventional therapy and biofeedback training. Eighty-six percent of the patients receiving biofeedback treatment learned to relax their external anal sphincter during straining. At follow-up after 7 months, one patient in the conventionally treated group had recovered compared with 12 of the biofeedback-treated group. At 12 months, 16% of the conventional group had recovered compared with 50% of the biofeedback group. Others have reported similar successes in both adults and children.[106,110–113] These studies indicate that biofeedback treatment is effective in a subpopulation of children with chronic idiopathic constipation and encopresis who are found to have abnormal defecation dynamics on anorectal manometry, at least in the short term. Some recent studies have not found it to be significantly different from conventional therapy in the long term.[114,115] Biofeedback should be considered in patients failing conventional therapy because a small group of patients with intractable constipation and/or encopresis may benefit from this therapy.

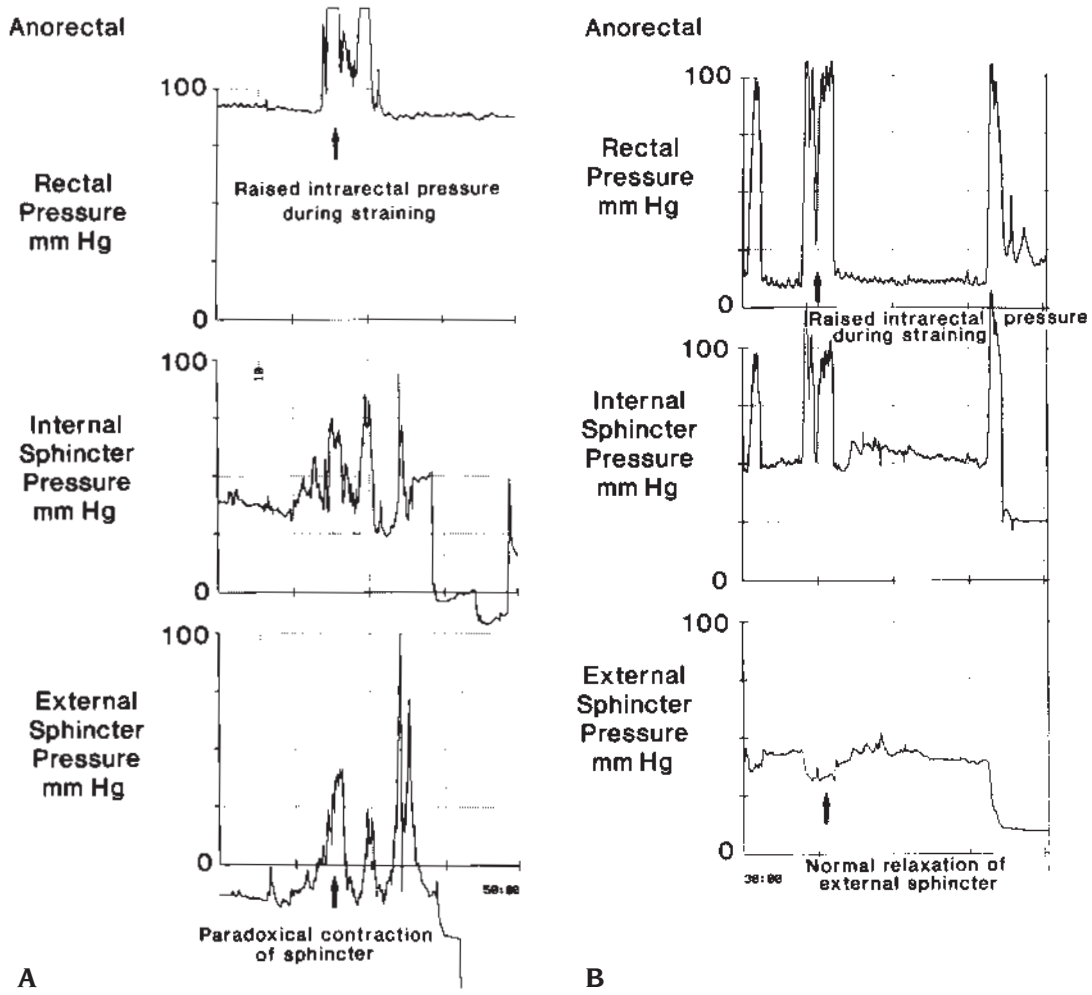

FIGURE 46.1-7 *A,* Manometric tracing of a patient demonstrating paradoxical contraction of the external anal sphincter during simulated defecation. *B,* Same patient after 3 sessions of biofeedback training. Note relaxation of the external anal sphincter during simulated defecation. (The internal sphincter tracing may reflect intrarectal pressure during straining and, therefore, should be ignored during simulated defecation).

In patients with persistent problems despite adequate treatment, it may be necessary to proceed to further studies, including magnetic resonance imaging of the lumbosacral spine to exclude occult spinal cord abnormalities and colonic manometry to exclude occult myopathy or neuropathy.

SURGICAL TREATMENT

Surgical procedures ranging from anorectal myectomy to proctocolectomy have been used to treat some adults with intractable constipation. These procedures have a very high complication rate and often have failed to correct the problem.[116–118] Obviously, there is no place for proctocolectomy in the management of children with chronic idiopathic constipation, except in a very small number of patients with debilitating symptoms and persistently abnormal colonic manometry in a nondilated colon.[80] Myectomy should be reserved for patients with well-documented absence of relaxation of the internal anal sphincter on rectal distention and a normal rectal biopsy indicating short- or ultrashort-segment Hirschsprung disease (recently also referred to as anal achalasia).[119,120]

The Malone appendicocecostomy for antegrade colonic enemas (MACE procedure), initially designed for treatment of patients with intractable fecal incontinence, may be used to manage children with intractable constipation. This procedure uses the appendix as a conduit to the cecum. After wrapping the cecum around the base to prevent reflux, the appendix is brought out to the abdominal wall as a stoma through which the colon can be irrigated with tap water or saline in an antegrade fashion (Figure 46.1-8).[121–126] To avoid complications associated with appendicocecostomies, cecostomy buttons can be placed endoscopically for the delivery of antegrade enemas.[127]

PROGNOSIS

The long-term outcome in children with chronic idiopathic constipation, with or without encopresis, is not well established. Several studies have been reported, and treatment approaches were similar except for the type of laxative used. Davidson and colleagues monitored 99 patients treated with high-dose mineral oil, a bowel training program, and close follow-up over several years and reported a 90% success rate.[86] Levine and Bakow followed 110 encopretic children treated with a similar program over a 1-year period and reported a 78% success rate.[83] In their study in which a group of children with encopresis was randomized to receive biofeedback treatment or mineral oil treatment,

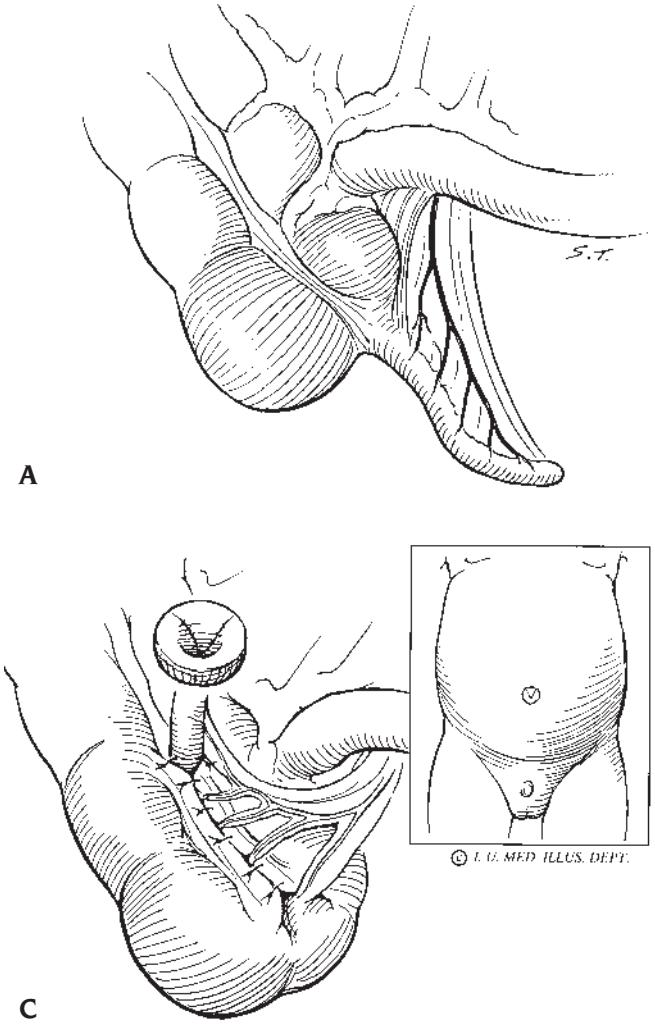

FIGURE 46.1-8 *A,* Anatomy of the cecum and appendix. *B,* The cecum is wrapped around the appendix to create a nonrefluxing appendicocecostomy. *C,* A nonrefluxing appendicocecostomy ready for antegrade enemas. Wald and colleagues reported a 71% success rate at 12 months in patients treated with mineral oil who did not have abnormalities of defecation dynamics on manometry.[108] On the other hand, Abrahamian and Lloyd-Still reported only a 47% success rate based on a 40% response to questionnaires sent to 186 patients seen over a 7-year period.[16] Most of these patients were treated with syrup of senna in combination with dioctyl sodium sulfosuccinate. Their follow-up was left to the referring physicians. In this group, the presence of soiling at the time of initial presentation was the only predictor of poor outcome, whereas the presence of abdominal pain correlated with a positive outcome. Loening-Baucke reported a 43% success rate at 12 months in 97 children with chronic constipation, with and without encopresis, treated with magnesium hydroxide.[128] Factors predictive of a poor outcome in this group were the presence of an abdominal fecal mass or soiling at the time of initial presentation. Notice that the common denominator in all three studies reporting greater than a 70% success rate was the use of mineral oil and close monitoring. This supports our opinion that in retentive constipation (which is the majority of chronic idiopathic constipation in children), mineral oil is quite effective and, with close monitoring, improves constipation in many patients. This view is, in fact, supported by a study in which Sondheimer and Gervaise randomized a group of children with chronic constipation, with and without encopresis, to receive either mineral oil or senna.[129] After 6 months, 89% of the mineral oil group was having daily bowel movements compared with 50% of the senna group. Soiling was reported by 6% of the mineral oil group compared with 44% of the senna group. Fifty-five percent of the mineral oil group had successfully discontinued regular medication compared with 22% of the senna group. Our 1994 survey of 274 patients seen in our clinic in 1992 showed a 75% success rate based on a 73% response rate. More recently, Staiano and colleagues, who treated patients with lactulose after initial disimpaction, reported persistence of constipation in 52% of 62 children after 5 years of follow-up.[130] Early onset of constipation (< 1 year) and a family history of constipation seemed to predict poor outcome. Sutphen and colleagues reported resolution of constipation in 70% of 43 children followed for an average of 6.8 years.[131] The patients were not treated with a single laxative. Some were treated with magnesium salts, some with mineral oil, and others with senna; no mention is made of how the type of laxative used was determined. An enema was given if the child went a day without a bowel movement. The main predictor of outcome was the duration of symptoms prior to referral to a gastroenterologist. The longer the period prior to referral, the poorer was the outcome. We await long-term follow-up studies of patients treated with electrolyte-free PEG 3350 to see how it impacts the overall success rates in the treatment of children with chronic constipation.

CONCLUSIONS

Constipation is a very common problem during childhood. In its acute form, it is easily corrected by increasing fluid and dietary fiber intake. If not properly treated in the acute stage, a cycle begins when painful defecation leads to deliberate withholding of feces, which may result in an acquired megacolon and, often, overflow incontinence. Once a withholding pattern has evolved, many patients will do well on a program that includes careful explanation of the pathophysiology of the disorder to all involved, evacuation of any impaction, the use of a laxative in sufficient doses to overcome withholding, a program to regularize the bowel habit, and, above all, close follow-up. In those not responding to this mode of treatment, an unprepared barium enema and anorectal manometry will identify those needing a rectal biopsy to exclude Hirschsprung disease. Anorectal manometry will also identify a subgroup with abnormal defecatory dynamics who may benefit from biofeedback treatment. Magnetic resonance imaging of the lumbosacral spine and colonic manometry may be necessary to identify occult spine abnormalities and occult myopathy or neuropathy of the gastrointestinal tract. A role for colonic transit studies has not been well defined in pediatric patients with chronic constipation. It is conceivable that in school-age children and teenagers with chronic constipation in whom a history of withholding is denied, this study will be obtained to differentiate those with slow-transit constipation from those with a functional outlet obstruction so that appropriate therapy can be initiated. Studies are needed to determine what percentage of children with chronic idiopathic constipation suffer with constipation as adults.

2. Dysmotilities

Sibylle Koletzko, MD

The motility of the small and large intestine is a function of the intestinal smooth muscle, which is controlled by the enteric nervous system (ENS) and the interstitial cells of Cajal (ICC). The autonomic and central nervous systems, gastrointestinal hormones, and immune system modulate gastrointestinal motility. Any disturbances of one or more of these systems may lead to dysmotility, which may be restricted to a particular bowel segment or may involve the entire gut, with or without the esophagus and stomach. This chapter is a systematic review of intestinal dysmotility disorders. Many of the diseases may finally result in chronic intestinal pseudo-obstruction, which represents the extreme end of the clinical manifestation and is discussed in Chapter 46.4, "Chronic Intestinal Pseudo-obstruction Syndrome."

Usually, dysmotility diseases are classified into primary visceral myopathies, primary visceral neuropathies, and secondary to toxic, metabolic, infectious, or other systemic disorders affecting the smooth muscle or the enteric or extrinsic nervous system (secondary myopathies and neuropathies; see also Chapter 46.4, Table 46.4-1).[1] Some diseases do not fit into this rough classification because both the muscle layer and the enteric nervous plexuses are involved either primarily, as in some of the mitochondrial disorders, or secondarily, as in fibrosis or ischemia. The term "idiopathic" is applied if the disorder does not fulfill the criteria of a recognizable genetic syndrome, if there is no apparent underlying disease, and if affected tissue is unavailable for investigation or appears normal under histologic examination.

Further classification may change, especially within the primary disorders, which are mostly based on histopathologic findings.[2] Many techniques have been applied, including different types of fixation, cutting and staining of the tissue, light and electron microscopy, and several enzyme histochemical and immunohistochemical methods. Interpretation of morphologic features for histologic diagnosis is a subjective integrating process that is influenced by an individual's expertise and subject to marked interobserver variation.[3] Comparisons of morphologic findings between single case reports or series of patients are therefore difficult to interpret. Few data on the normal postnatal maturation and appearance of the ENS are available. Postmortem studies have limitations owing to autolytic processes and prefinal conditions of the child. The available data indicate that not all enteric nerve cells are morphologically mature at birth, and maturation continues for at least the first 2 to 4 years of life.[4,5] For example, the absence of silver-positive enteric nerve cells, which is considered abnormal in adults, is consistently found in preterm infants and is a normal variant in children up to the age of 1 year.[6] Secondary phenomena owing to severe chronic bowel dilatation or therapeutic interventions (ie, drugs or surgery interrupting the flow of the chyme) need to be distinguished from primary pathology. In clinical practice, histologic classification of neuromuscular disorders of the gut is also hampered by the fact that full-thickness biopsies are usually required for the pathomorphologic diagnosis. Exceptions are Hirschsprung disease and a few other neuropathies in which a definite histologic diagnosis can be made from rectal suction or deep forceps biopsies. After exclusion of aganglionosis, the knowledge of the exact neuromuscular classification hardly alters therapeutic management in most affected children with primary dysmotility disorders. Therefore, full-thickness bowel biopsies are usually not justified unless an operation is necessary for other clinical indications (ie, ileostomy, resection).

Classification has also been attempted based on clinical phenotypes such as age at onset, bowel and bladder involvement, or mode of inheritance. This approach can be very misleading, but it is helpful in a few cases with specific (distinguished) concurrent extraintestinal features. For example, the megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS) describes a certain phenotype, but histopathologic investigations reveal myopathic changes in most children, myopathic and neuropathic changes in other children, or both. In some children, no histologic abnormalities are found. Progress in molecular genetics should help to define additional familial forms of gastrointestinal motility disorders.

Clinical Manifestations

Clinical symptoms are variable and often nonspecific. The location of the affected bowel (diffuse or segmental) seems a more important determinant of clinical manifestation than the underlying cause. Within the same family with a defined genetic disorder, a spectrum of symptoms may occur, ranging from none to chronic intestinal pseudo-obstruction.[7] Primary and secondary neuromuscular disorders of the intestine may present at any age, but most children become symptomatic during the neonatal period or early infancy.[8–10] In congenital disorders, antenatal ultrasonography may show dilated bladder and/or bowel loops in a mother with or without polyhydramnios.[8,9,11–13] After birth, the main symptoms are bilious vomiting, failure to pass meconium, severe constipation, and a distended abdomen. Differentiation from mechanical obstruction is often very difficult, and many of

TABLE 46.2-1 NEUROMUSCULAR DISORDERS PRESENTING IN INFANCY, CHILDHOOD, OR ADOLESCENCE THAT MAY CAUSE SYMPTOMS OF INTESTINAL DYSMOTILITY INCLUDING PSEUDO-OBSTRUCTION

DISORDERS OF THE INTESTINAL SMOOTH MUSCLE
Primary visceral myopathies
Familial visceral myopathies
Autosomal dominant with megaduodenum
Autosomal recessive (mitochondrial-gastrointestinal encephalomyopathy)
Autosomal recessive without extraintestinal manifestations
Autosomal recessive with gastroparesis and tubular, narrow small intestine
X-linked with abnormal muscle layering
Nonfamilial or sporadic visceral myopathies
Infantile or childhood visceral myopathy
African degenerative leiomyopathy
Megacystis-microcolon-intestinal hypoperistalsis syndrome
Secondary visceral myopathy
Progressive systemic sclerosis and other connective tissue diseases
Enteric myositis (autoimmune myopathy)
Muscular dystrophy
DISORDERS OF THE ENTERIC NERVOUS SYSTEM (MYENTERIC PLEXUS)
Primary visceral neuropathies
Familial visceral neuropathies
Autosomal dominant without extragastrointestinal manifestations
Autosomal dominant with neuronal intranuclear inclusions
Autosomal recessive, autosomal dominant, or X-linked with short bowel, malrotation, and pyloric hypertrophy
With neurologic involvement
Associated with multiple endocrine neoplasia type IIB
Associated with neurofibromatosis
Nonfamilial or sporadic neuropathies
Hypoganglionosis
Hyperganglionosis
Qualitative abnormalities of ganglion cells
Secondary or acquired visceral neuropathies or intestinal motility disorders
Infections
Toxic agents and drugs
Radiation
Inflammation (post–necrotizing enterocolitis, Crohn disease, autoimmune ganglionitis, celiac disease)
Autonomic neuropathy (familial, secondary, idiopathic)
Endocrine disease
Metabolic disease
Eating disorders (anorexia, bulimia)

Familial or sporadic forms of aganglionosis are excluded; see Chapter 46.3.

these infants undergo exploratory laparotomy. If the bladder is involved, failure to void and urinary infection owing to incomplete emptying may be the initial symptoms. Common symptoms reported in children with an acquired dysmotility disorder include abdominal distention, constipation, vomiting, failure to thrive, dyspepsia, and abdominal pain. Intermittent diarrhea occurs in some children as a result of bacterial overgrowth and malabsorption.

Chronic intestinal pseudo-obstruction is a term that describes the most severe symptoms associated with dysmotility (see Chapter 46.4). Pseudo-obstruction can occur in most intestinal neuromuscular diseases (Table 46.2-1).[14,15] It was defined by pediatric and adult gastroenterologists in a consensus report as "a rare, severe, disabling disorder characterized by repetitive episodes or continuous symptoms and signs of bowel obstruction, including radiographic documentation of dilated bowel with air-fluid levels, in the absence of a fixed, lumen-occluding lesion."[14] The rather strict definition that makes radiologic signs obligatory has been criticized because in some patients with severe disabling symptoms, bowel dilatation and air-fluid levels are found only intermittently. Dilated bowel loops with air-fluid levels can be observed in newborns with severe diarrhea owing to congenital transport defects, that is, chloride diarrhea, imitating a severe gastrointestinal motility disease. Chronic intestinal pseudo-obstruction, which is a phenotype, not a disease entity, is discussed in Chapter 46.4.

DISORDERS OF THE INTESTINAL SMOOTH MUSCLE

Intestinal dysmotilities are less frequently caused by smooth muscle than by neural disorders. In general, symptoms are more severe, and the prognosis is worse in primary myopathies compared with primary neuropathies. Most affected children develop symptoms at birth or shortly thereafter. Definite diagnosis requires careful study of the full thickness of the gastrointestinal wall with sectioning across muscle fibers. A characteristic myopathic pattern on antroduodenal manometry may support the diagnosis in cases in which no tissue is available for investigation. The term "hollow visceral myopathy" is used when smooth muscle of both the gastrointestinal and the urinary tract is affected.

Primary Visceral Myopathies

Primary disorders of the intestinal smooth muscle represent abnormalities in morphogenesis, resulting in alterations in intestinal muscle layering (additional muscle coat or an absence of a muscle layer) or intrinsic myocyte defects comprising varying degrees of fibrosis, myocyte atrophy, vacuolation, or an altered contractile protein. Smith and Milla identified five histologic phenotypes of smooth muscle disease in full-thickness biopsies from children with functional obstruction using routine microscopy, histochemistry, immunohistochemistry with monoclonal antibodies against different neural and smooth muscle markers, and electron microscopy.[9] Routine microscopy on paraffin sections of the smooth muscle was abnormal in only 15 of 27 patients. In the remaining patients, myopathic changes would have been missed without application of other techniques. Twenty-five of the children had a primary myopathy, and two had an acquired enteric myopathic disorder.

Clinically, primary visceral myopathies occur as familial genetic diseases with a defined mode of inheritance or as sporadic cases. Four types of familial visceral myopathies (FVMs) have been described. They may begin at any age, but particularly in the second decade; therefore, they should be considered when symptoms begin in school-age children. A few families with probable hereditary forms of infantile or childhood visceral myopathies have been reported; all affected children presented at birth, during infancy, or during early childhood.[16]

FVM Type 1. Familial occurrence of megaduodenum resembling type 1 FVM was first described in 1938 in a German family.[7] Since then, several families have been reported and confirmed that type 1 FVM is transmitted by an autosomal dominant inheritance, although there is female predominance in frequency and severity.[16,17] The disease is characterized by esophageal dilatation, megaduodenum, and an elongated, redundant, usually dilated colon.[1,18] Barium studies show an aperistaltic esophagus and often normal gastric emptying but a flaccid and dilated duodenum with prolonged retention of barium (up to 19 days in one case).[19] The small intestinal caliber is normal, except the proximal jejunum, which may be dilated. The bladder is affected in about half of the cases, but megacystis is often asymptomatic.

Most patients, especially females, become symptomatic around puberty with recurrent abdominal pain, nausea, vomiting, heartburn, and severe constipation or, occasionally, diarrhea. Some affected family members remain asymptomatic despite abnormal barium studies. About 10% of all patients develop pseudo-obstruction.[1] Mydriasis is common in type 1 FVM.

Schuffler and Pope investigated full-thickness intestinal biopsies of a 15-year-old girl with type 1 FVM by using different staining methods, including Masson trichrome in addition to electron microscopy. They observed marked thinning and degeneration and vacuolation of smooth muscle with replacement by fibrous tissue.[16]

Treatment that depends on the severity of symptoms includes dietary modification with a low-fat, low-fiber, low-lactose diet and intermittent use of antibiotics to treat bacterial overgrowth. Neostigmine was helpful in one patient to improve severe constipation, although systemic side effects limit the use of the drug.[18] Surgical treatment is indicated in patients refractory to dietary and medical management and in cases with pseudo-obstruction. Side-to-side duodenojejunostomy to drain the duodenum or partial duodenal resection below the papilla of Vater and anastomosis with the jejunum have benefited carefully selected patients.[19,20]

FVM Type 2. This disease, first reported as oculogastrointestinal muscular dystrophy, was recently renamed mitochondrial neurogastrointestinal encephalomyopathy.[1,21] The mode of inheritance is autosomal recessive. Phenotypic features include external ophthalmoplegia with ptosis and diplopia, a cardiac conduction defect, mild muscular atrophy, and dilatation of the entire gastrointestinal tract with scattered small bowel diverticula.[22] Gastrointestinal symptoms may develop during teenage years with dyspepsia, heartburn, abdominal pain, and weight loss. Skeletal muscle biopsy specimens show the "ragged" red fibers that are typical of mitochondrial myopathies. A deficiency of cytochrome-*c* oxidase in the muscle fibers was demonstrated,[21] and lactate levels are often elevated. The histologic features of the gastrointestinal smooth muscle are similar to those of type I FVM. The prognosis is poor. Most patients require total parenteral nutrition because neither medical nor surgical treatment is effective.

FVM Type 3. Anuras and colleagues reported four siblings with dilatation of the entire gastrointestinal tract but no extraintestinal manifestations.[23] One of the siblings died at age 7 years with intestinal obstruction; the others became symptomatic during adulthood. The prognosis of this autosomal recessive disorder is poor.[1]

FVM Type 4. Two families have been described with this type 4 FVM, which is characterized by gastroparesis, a tubular narrow small intestine, and a normal esophagus and colon.[24,25] Symptoms, including vomiting, abdominal pain and distention, and diarrhea, occurred as early as 2 years of age. The hypertrophy of circular muscle layer produces the tubular narrowing of the small intestine. An autosomal recessive trait is assumed because in one family two siblings and in the other family three siblings were affected.

Familial Childhood Visceral Myopathy with Diffuse Abnormal Muscle Layering. Three related males have been described with this disorder: the index case, his half-brother from the same mother, and his maternal uncle, suggesting an X-linked inheritance.[9] All presented during the neonatal period with vomiting and abdominal distention. All had short gut and malrotation. The most striking histologic finding was an extracircular muscle coat between the outer and inner layer of the muscularis propria; the myenteric plexus appeared to be embedded within them.

Sporadic Infantile or Childhood Visceral Myopathy. Most cases occur sporadically, but new dominant mutations may be responsible for some.[26] In families with several members affected, a dominant gene with variable expressivity and incomplete penetrance, or an autosomal recessive inheritance, is possible.[26,27] Most affected children develop symptoms at birth or within the first year, including severe constipation, bowel dilatation, and abdominal distention. Failure to thrive and malnutrition are common. When the disease progresses to chronic intestinal pseudo-obstruction, most patients depend on long-term parenteral nutrition or require bowel transplant. Distal to the esophagus, the entire gastrointestinal tract is affected and markedly dilated. Almost all patients have involvement of the urinary tract system with megaureters and megacystis (hollow visceral myopathy).[26,28] Microscopic findings from the small and large bowel reveal gross fibrosis of the muscularis propria identified with the Masson trichrome staining and profound atrophy of the smooth muscle cells,[29] similar to those from adults with familial and sporadic forms of visceral myopathy.[30] α_2-Actin deficiency could be shown in some sporadic cases.[29] Smith and Milla related these changes to an intrinsic myocyte defect and/or changes in the extracellular matrix. Using different staining techniques, they distinguished two subtypes: a myopathy with autophagic activity and a pink blush myopathy with nuclear crowding.[9] The prognosis is poor in patients with diffuse disease; many die during childhood owing to complications of mal-

nutrition or long-term total parenteral nutrition.[12,31] Some patients tolerate oral feeding and survive into adulthood.

African Degenerative Leiomyopathy. This disease is now recognized as a distinctive, nonfamilial form of degenerative visceral myopathy of uncertain etiology that occurs largely in Africa (particularly southern, eastern, and central Africa). Histologic features include atrophy of myocytes with vacuolated cytoplasm, extracellular edema, and gross fibrous replacement in the circular muscle layer.[29,32] Neuronal loss was absent, but hyperplasia of the myenteric plexus was observed in some cases.[30] Bowel dilatation with severe constipation and pseudo-obstruction developed after the age of 6 months, with a mean age of presentation of 9.5 years.[29] The bladder was affected in about 10% of the patients. Therapy included neostigmine, a low-residue diet, laxatives, enemas, and surgical intervention. Steroids or another immunosuppressive treatment has not been tried.

Megacystis-Microcolon-Intestinal Hypoperistalsis Syndrome. This most severe form of pseudo-obstruction was first described in 1976 by Berdon and colleagues,[33] and more than 90 cases have been reported to date. MMIHS affects female infants four times more often than males.[34] In some cases, the syndrome can be detected by prenatal ultrasound scans showing megacystis, hydronephrosis with hydroureter, and/or bowel abnormalities or gastric distention.[34] The syndrome is identified by a marked, nonobstructive bladder enlargement, a dilated aperistaltic proximal small bowel, a narrowed distal small bowel, and a malrotated microcolon located entirely on the left side of the abdomen.[33] Occasionally, a megaesophagus is associated.[35] The intestinal length is shortened to up to one-third of normal. MMIHS is usually caused by a myopathy with vacuolar degenerative changes of the smooth muscle cells.[36] However, the phenotype can also be a manifestation of a neuropathy with hypo- or hyperganglionosis and giant ganglia, indicating genetic heterogeneity. Based on findings from affected siblings, an autosomal recessive pattern of inheritance has been suggested in some families.[37,38] However, most cases are sporadic.

There is now some indication that the absence of the α3 subunit containing nicotinic acetylcholine receptor plays a role in this congenital disorder. The neuronal nicotinic acetylcholine receptor subunits are widely expressed throughout the central, peripheral, and autonomous nervous systems. They are pentamers made up by at least eight α subunits (α2–α9) and three β subunits (β2–β4) encoded by 11 distinct genes. Transgenic mice lacking the α3 or both β2 and β4 subunits show some of the phenotypic features of MMIHS. Richardson and colleagues used in situ hybridization and immunocytochemistry to study the expression of this subunit in tissue from 10 patients with MMIHS and 12 control children. They found a wide distribution of α3 messenger ribonucleic acid in the enteric ganglion cells, smooth muscle, and epithelium of normal small bowel but not in MMIHS patients.[39] However, in affected individuals with MMIHS and/or their parents, no loss of function mutations have been identified to date within the genes encoding for α3 or β3 subunit.[40]

After birth, the children develop massive abdominal distention, which is often relieved when a huge bladder, which may contain several hundred milliliters of urine, is catheterized. Most patients require several operations on the gastrointestinal and urinary tract and continue to remain dependent on parenteral nutrition. The prognosis is poor because there is no effective medical treatment. Most children die within the first year of life owing to renal insufficiency, postoperative complications, or sepsis.[37] No patient has reached adulthood. Bowel transplant may be an option for some children.

The MMIHS must be differentiated from the prune-belly sequence owing to early intrauterine urethral obstruction. This disorder affects predominantly male infants, who present with a dilated abdomen, constipation, hydronephrosis, megacystis, and often intestinal malrotation but no intestinal hypoperistalsis or microcolon.

Systemic Disorders Involving the Intestinal Smooth Muscle (Secondary Myopathies)

Most secondary myopathies have been described in adults because it may take several years of a disease process such as a connective tissue disorder until the intestinal smooth muscle layer is damaged. With modern histologic techniques and the availability of intestinal manometry, secondary myopathies are recognized even in young children. It is important to identify these entities because sometimes medical treatment can achieve symptomatic improvement and prevent secondary complications or progression of the disease process.

Connective Tissue Disorders. Scleroderma or progressive systemic sclerosis is a systemic disease characterized by excessive deposition of collagen and other matrix elements by fibroblasts in the skin and, in the systemic form, in multiple internal organs. It is associated with prominent and often severe alterations of the microvasculature, the autonomic nervous system, and the immune system. Gastrointestinal involvement with symptoms of clinical relevance occurs in approximately 50% of patients with progressive systemic sclerosis.[41] It affects most patients with the diffuse cutaneous systemic sclerosis, but less often and later, it affects patients with the limited cutaneous systemic sclerosis, the CREST variant (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, telangiectasias). The esophagus is the most commonly affected organ, with 75 to 90% of all patients showing abnormalities on esophageal motility testing. Involvement of the anorectum is the next most frequent manifestation (50–70%), followed by small bowel hypomotility in 40%. In spite of severe dysmotilities, clinical symptoms may be mild or absent owing to a concurrent visceral sensory neuropathy.

The lesions of scleroderma are similar throughout the gastrointestinal tract, with atrophy and fragmentation of the muscularis propria, collagen infiltration, and fibrosis in the late stage of the disease. The findings are more marked

in the circular than in the longitudinal layer. The same histologic findings have been reported in adults and even in a child with intestinal myopathy, who did not have any cutaneous manifestations of scleroderma.[42]

Symptoms of small bowel involvement of scleroderma include nausea, vomiting, distention, abdominal cramps, diarrhea with malabsorption, or severe slow-transit constipation if the colon is markedly affected. Fecal incontinence is the most common colonic presentation of systemic sclerosis. Episodes of pseudo-obstruction occur only in patients with advanced systemic sclerosis. Manometric studies in patients with gastric and intestinal involvement of scleroderma may show a complete absence of the migrating motor complex (MMC), which predisposes the patient to bacterial overgrowth and bezoar formation. In the early stage of the disease with predominant neuropathic impairment, MMCs can be generated by the long-acting somatostatin analog octreotide, the cholinergic agonist cisapride, or the motilin agonist erythromycin.[43] Treatment of intestinal dysmotilities in scleroderma is symptomatic and supportive, with dietary modifications, prokinetic drugs (cisapride, octreotide, and erythromycin), antibiotics against bacterial overgrowth, and loperamide in cases of diarrhea.[41]

Gastrointestinal dysmotilities, including chronic intestinal pseudo-obstruction owing to progressive atrophy and fibrosis of the intestinal smooth muscle, have occasionally been reported in patients with Ehlers-Danlos syndrome, dermatomyositis, polymyositis, or mixed connective tissue disease.[44] Smooth muscle dysfunction with bowel dilatation can also result from systemic lupus erythematosus–induced vasculitis.[45]

Chronic Enteric Myositis and Autoimmune Myopathy. Infiltration of intestinal smooth muscle layer by lymphocytes is found in Crohn disease and other forms of chronic intestinal inflammation associated with altered motility. Four young women have been reported with diffuse polyclonal lymphoid infiltration of the intestinal muscularis propria by McDonald and others.[46] These patients became symptomatic between 18 and 35 years of age with diarrhea, vomiting, and abdominal distention and later developed episodes of intestinal pseudo-obstruction. Only one of the four patients was treated with immunosuppressive drugs (cyclophosphamide and prednisone) and responded with some improvement of her symptoms.

Acquired myositis of the muscularis propria was reported in two children who presented with functional intestinal obstruction at 1 and 2.5 years of age.[9] Dense lymphocytic infiltrates, mainly of T cells, were found along the large and small intestine. Antibodies against smooth muscle were detected in one of the patients, indicating an autoimmune process.

Muscular Dystrophy. Myotonic muscular dystrophy is a progressive systemic disease characterized by myotonia and wasting of skeletal muscle. The major features of the congenital form of the disease are reduced fetal movements and polyhydramnios, severe muscular hypotonia, facial diplegia, respiratory insufficiency, difficulties in sucking and swallowing, and skeletal anomalies such as talipes equinovarus. Cataracts and endocrine disturbances, which are typical for the adult form of the disease, are not found in infants and young children. Involvement of the smooth muscle of various organs, including the gastrointestinal tract and the bladder, is well documented. Histologic studies of small intestinal and colonic smooth muscle have shown similar changes to those described in dystrophic skeletal muscle, with swollen, partially destroyed smooth muscle cells that are progressively replaced by fat. Motor abnormalities are found in the entire gastrointestinal tract, from the esophagus to the anal sphincter. Gastrointestinal symptoms with dysphagia, abdominal cramping, diarrhea, malabsorption, or severe constipation are frequent and may precede other clinical manifestations of the disease for years. Lenard and colleagues reported on two brothers whose mother and maternal grandmother were affected by the adult form of the disease.[47] The younger brother, who presented with typical features of congenital myotonic dystrophy at birth, developed severe constipation and megacolon during the second year of life. The presenting symptoms of the older brother were repeated episodes of pseudo-obstruction in the neonatal period and diarrhea, vomiting, and abdominal distention during the first 2 years of life. Thereafter, he suffered from severe constipation with encopresis owing to megacolon. Repeated electromyographic examinations between 2 and 6 years of age were normal, and the first myotonic tracing was obtained when he was 8 years of age.

Duchenne muscular dystrophy is an X-linked disorder that causes skeletal and cardiac muscle degeneration leading to progressive weakness and death, usually from respiratory failure. Histologic studies of skeletal muscle show myofiber degeneration accompanied by necrosis and accumulation of fat and connective tissue and hypertrophy of the remaining muscle fibers. The cause of the disease is a deficiency of dystrophin, which has also been identified in the heart and in smooth muscle. Visceral smooth muscle involvement of the gastrointestinal tract can be detected by manometry with a typical myopathic pattern in many children, even in those who have only minimal skeletal muscle symptoms and an absence of gastrointestinal dysfunction. Symptoms such as diarrhea, constipation, and abdominal cramping may be related to dysmotility of the small and large intestine. Chronic intestinal pseudo-obstruction as a complication of Duchenne muscular dystrophy is rare.[48]

DISORDERS OF THE ENTERIC AND AUTONOMOUS NERVOUS SYSTEM

The ENS is a collection of neurons in the gastrointestinal tract, which has been referred to as the "brain of the gut." It can function independently of the central nervous system (CNS). The cell bodies of the ENS are grouped into small ganglia that are connected by bundles of nerve processes forming two major plexuses. The myenteric (or Auerbach) plexus is located between the longitudinal and circular muscle layers and primarily provides them with

motor innervation. The submucous (or Meissner) plexus, which lies in the submucosa between the circular muscle layer and the muscularis mucosae, is important in regulating secretory control. The ganglia of the plexus consist of tightly packed nerve cell bodies, terminal bundles of nerve fibers, and glial cells, which even outnumber enteric neurons. There are numerous projections between the two plexuses, and both are connected to the central autonomic neural network in the CNS by parasympathetic and sympathetic nerves.[49]

The ENS controls the segmental and forward propagating contractions, the exocrine and endocrine secretions, the microcirculation, and the immune and inflammatory processes in the gastrointestinal tract. Both quantitative (eg, hypo- or hyperganglionosis or aganglionosis) and qualitative abnormalities (ie, degeneration, immaturity) of the ENS have been identified using different staining methods, including silver stains and immunohistochemistry.[11,50] However, the results should be interpreted with respect to age because there are notable postnatal alterations in the myenteric plexus with a steep decline of nerve cell density.[5] To date, these specific abnormalities have not been linked to specific symptoms; most patients have disturbances in gastrointestinal transit and functional obstruction from infancy. Excessive intestinal secretion or other features of ENS dysfunction often remain clinically unrecognized. Visceral neuropathies are called diffuse if the entire small and large intestine is affected or segmental with only certain parts of the bowel being involved. Apart from aganglionosis (see Chapter 46. 3, "Hirschsprung Disease"), only a few visceral neuropathies (ie, ganglioneuromatosis[51] or neuronal intranuclear inclusion neuropathy[52] can be classified by investigating only the submucous plexus in specimens obtained from rectal suction or deep forceps biopsies.[11]

Intestinal Neuronal Dysplasia

Intestinal neuronal dysplasia (IND or IND type B) is a term that has been used over the last three decades to describe different quantitative (ie, hypo- and hyperganglionosis) and qualitative (ie, immature or heterotopic ganglion cells) abnormalities of the myenteric or submucous plexus or both. The term has raised confusion and controversy among clinicians and pathologists. IND has been observed in an isolated form and proximal to an aganglionic segment. It has been reported in all age groups, mostly infants, but also in adults with chronic constipation not dating back into childhood.[53] It was first considered to be a developmental defect of the submucous plexus,[54] but others suggested that some of the histologic features may be secondary to functional or mechanical obstruction.[55] Other intra- and extraintestinal anomalies are found in a high percentage of children diagnosed to have IND.[56] Diagnosed often in Switzerland and Germany,[3,57] IND was rarely reported in British or North American series.[58–60] One of the main criteria of IND, the presence of giant ganglia in the submucous plexus defined as more than seven ganglion cells per ganglion,[61] has been considered a normal finding of the enteric plexuses in patients without any gut dysmotility.[62,63] The confusion was complete when IND was used not only as a histologic description but also as a clinical diagnosis. Although neither retrospective nor prospective studies showed a correlation between the morphologic features of IND and symptoms or long-term outcome, surgical procedures were recommended. Sphinctermyetomies and bowel resections have been performed in both children and adults with uncomplicated constipation who were found to have IND on intestinal biopsies. The histologic definitions of IND have changed considerably over time, and this may be responsible for some of the discrepancies.[60,64] However, even when the same criteria for the diagnosis of IND were applied to a prospective study of rectal biopsies, the interobserver variation was enormous and close to chance agreement.[3] In this study, 377 coded specimens from 108 children, aged 4 days to 15 years with intestinal dysmotilities, were judged for 20 histologic features and a final diagnosis by three pathologists, who had previously participated in a consensus meeting on diagnostic guidelines. There was complete agreement for the diagnosis of Hirschsprung disease, but in only 14% of the remaining children was there a concordant diagnosis by the pathologists. The criteria were significantly more often fulfilled in infants compared with older children. Furthermore, the diagnosis of IND had no prognostic value for the outcome in constipated children, as assessed by clinical symptoms 1 year after the biopsies.[3]

Genetic studies in children with histologic features of IND could not identify any mutations in the coding regions of the *RET*, *GDNF*, *EDNRB*, and *EDN3* genes.[65,66] Mice with mutations of *Hox11L1*, a homeobox gene involved in nervous system development, show a megacolon with an ENS pathology with increased neuron numbers in the colon.[66] The human homolog of this gene has been found on chromosome 2p13.1,[67] but, to date, no patients with gastrointestinal motility disorder and proposed histologic features of IND have been found to have a mutation of this possible candidate gene.

Because the term IND describes neither a specific histologic nor a clinical entity, it should be used with caution or not at all until better defined. Therefore, IND has not been included in Table 46.2-1 and is not further discussed in this chapter.

Primary Visceral Neuropathies

Primary visceral neuropathies can be subdivided into familial visceral neuropathies, which follow a certain trait of inheritance, and sporadic cases characterized by distinct morphologic and clinical findings. In clinical practice, many neuropathic motility disorders remain unclassified (idiopathic).

Familial Visceral Neuropathy. *Familial Visceral Neuropathy without Extraintestinal Manifestations.* This is an autosomal dominant disorder that affects mainly the large and distal part of the small bowel.[68] Age at onset differs within the same family, but symptoms develop after infancy. Severe slow-transit constipation, with or without intermittent diarrhea, nausea, abdominal distention, and cramping, is the main complaint. Pseudo-obstructive

episodes with severe intestinal dilatation occur in approximately half of the patients and may require colonoscopic decompression. There is no evidence of extrinsic autonomic dysfunction. Histologic findings include a markedly reduced number and degeneration of argyrophilic neurons and nerve fibers of the myenteric plexus, with hypertrophy of the smooth muscle. No Schwann cell proliferation, intranuclear inclusions, or inflammatory cells are observed. Subtotal colectomy may give transient relief but may accelerate small bowel disease; therefore, it is contraindicated.

Familial Visceral Neuropathy with Neuronal Intranuclear Inclusions. This neuropathy is probably an autosomal dominant disorder because it was described in three siblings (two female, one male) and their father.[52] Most patients develop symptoms during childhood. Gastrointestinal symptoms included dysphagia, diarrhea, constipation, and intestinal pseudo-obstruction. Autonomic dysfunction, ataxia, dysarthria, mental retardation, and dementia are part of this neuropathic disease. Characteristic eosinophilic intranuclear inclusions have been identified in the neurons of the degenerated myenteric plexus all along the gastrointestinal tract.[11] The same inclusions are found postmortem in nerve cells of the central and peripheral nervous systems.[69] In some patients, the intranuclear inclusions could be detected within the ganglion cells of the plexus mucosus on rectal biopsies.[52,70] Electron microscopy and histochemistry identified the inclusions as nonviral proteins. Manometric studies showed a typical neuropathic pattern with lack of phase III of the MMC and irregular, nonpropagated contractions in the small intestine. There is no treatment; some patients survive into mid- or late adulthood.

Familial Visceral Neuropathy with Short Bowel, Malrotation, and Pyloric Hypertrophy. This sequence has been described in several families.[71] Symptoms of functional obstruction occur in the neonatal period, and most patients die during the first year of life. Morphologic studies of the bowel showed abnormalities of the myenteric plexus, with shrunken, degenerated neurons, clumped chromatin within the nuclei, and lack of argyrophilic neurons. This syndrome may be inherited in an autosomal recessive pattern because it occurred in siblings of both genders and in families with consanguineous marriages.[71,72] An autosomal dominant pattern was likely in one family with an infected 2-year-old girl, her mother, and her maternal grandfather (personal observation, 2003). In addition to malrotation, short bowel, and pyloric hypertrophy, an abnormal ileocecal connection with an absent appendix was noted during laparoscopy in all three. Recently, Auricchio and colleagues performed linkage analysis in a family in which, over four generations, only the male members related through female members were affected. The authors assigned the defect to a gene locus on the chromosome Xq28 region but suggested that the same clinical entity may be associated with different loci.[73]

Familial Visceral Neuropathy with Neurologic Involvement. Several families with at least two affected siblings have been reported. Symptoms occurred during early childhood with neuropathic gastrointestinal dysmotilities and involvement of the peripheral or central nervous system. The trait of inheritance remains unclear. Faber and colleagues reported two Jewish families of Iranian origin with a progressive sensory and motor peripheral neuropathy, ophthalmoplegia, and hearing loss but no evidence of CNS involvement.[74] The description and combination of the pathologic findings make a mitochondrial disorder likely. Cockel and colleagues described a familial disorder defined by megaduodenum, dilatation of the small bowel, steatorrhea, mental retardation, and calcification in the subcortical white matter of the brain and basal ganglia.[75] The age at onset was during childhood. The myenteric plexus appeared normal on conventional light microscopy, but silver staining revealed a degeneration of argyrophobic cells. A similar case was reported by Navarro and colleagues.[11]

A de novo mutation of the *SOX10* gene with a heterozygous deletion of 1 bp (795delG) in the last coding exon with chronic intestinal pseudo-obstruction, peripheral neuropathy with unusual multiplication of nerve fascicles, and deafness since early infancy has been described in an 8-year-old girl.[76]

Familial Visceral Neuropathy (Ganglioneuromatosis) Associated with Multiple Endocrine Neoplasia Type IIB. Of the three different multiple endocrine neoplasia (MEN) type II syndromes (MEN IIA, MEN IIB, and isolated medullary thyroid carcinoma), MEN IIB is the only form that involves the gastrointestinal tract. The susceptibility gene for these autosomal dominant inherited disorders is the *RET* proto-oncogene located on chromosome 10, which encodes a receptor tyrosine kinase. The *RET* plays an important role in the development, function, and migration of cells of neural crest origin. In MEN IIB, 94% of cases are due to a single identical germline point mutation at codon 918 in exon 16. In the remaining patients, a mutation at codon 883 in exon 15 or no *RET* mutation was found. Approximately 50% of diagnosed cases seem to be due to de novo mutations. In most affected patients, gastrointestinal dysmotility is the first manifestation of the disease. It is important to be aware of possible other symptoms in combination with the typical features of MEN IIB (Table 46.2-2).

The characteristic pathologic finding of intestinal ganglioneuromatosis is an increased density of ganglion cells in the submucous and myenteric plexus, with penetration of hyperplastic nerves into the mucosal zone. Hyperplasia of the nervous tissue is characterized by large ganglionic nodes with numerous glial cells. Acetylcholinesterase staining reveals increased activity along the hypertrophic myenteric plexus and within the lamina propria, but less than that observed in Hirschsprung disease. These abnormalities are present along the entire gastrointestinal tract, from the mouth to the anus, including the appendix. Ganglioneuromatosis may be confused with isolated, diffuse, or segmental hyperganglionosis, characterized by an excess of intestinal neurons only or, preferentially, in the myenteric plexus (see below).

Colonic dysfunction with chronic constipation and bowel dilation are the prominent clinical features. If it presents at birth, this disorder may be confused with Hirschsprung disease. Serious complications of ganglioneu-

TABLE 46.2-2 FEATURES OF MULTIPLE ENDOCRINE NEOPLASIA TYPE IIB

GASTROINTESTINAL MANIFESTATIONS
Abdominal distention
Feeding problems
Dysphagia
Vomiting
Chronic constipation
Paradoxal diarrhea
Megacolon
Intestinal pseudo-obstruction
Ganglioneuromatosis
FACIAL ABNORMALITIES
Thickened and everted upper eyelids
Prominent eyebrows
Neuromas on eyelids and conjunctiva
Thickened corneal nerves
Elongated face
Thickened lips
Neuromas of buccal mucosa, tongue, and palate
MARFANOID HABITUS/MUSCULOSKELETAL MANIFESTATIONS
Tall stature
High-arched palate
Long extremities
Kyphoscoliosis or lordosis
Joint laxity
Pes cavus
Pectus excavatum
Slipped capital femoral epiphysis
DENTAL ABNORMALITIES
TUMORS
C-cell hyperplasia/medullary thyroid carcinoma
Pheochromocytoma
Parathyroid hyperplasia

Adapted from de Krijger RR et al.[76]

romatosis are failure to thrive, chronic intestinal pseudo-obstruction, severe colonic diverticulosis, and bowel perforation. Defunctioning ileostomy or elective subtotal colectomy for chronic constipation may be required. Gastrointestinal symptoms often develop years before other features of the syndrome are recognized and MEN IIB is diagnosed.[77] Searching for a *RET* mutation is recommended in patients with apparently isolated intestinal ganglioneuromatosis or hyperganglionosis proven by rectal suction biopsy or a resected bowel segment.[51] Early diagnosis of MEN IIB is essential to perform prophylactic thyroidectomy before medullary thyroid carcinoma develops and to screen for development of pheochromocytoma.[78]

Visceral Neuropathy Associated with Neurofibromatosis (von Recklinghausen Disease). Single or multiple neurofibromas in the small intestine occur in about 10% of patients with this autosomal dominant disorder. Intestinal neuromas may cause both functional and mechanical obstruction.

Nonfamilial or Sporadic Visceral Neuropathies. *Hypoganglionosis.* Hypoganglionosis is defined by a reduced number of ganglion cells in the myenteric plexus and in the submucous plexus in some cases. The location of the sample within the bowel is important for comparison with age-matched controls, and the same methods of tissue preparation (cutting, staining, counting) need to be applied to both. Whereas aganglionosis is easily recognized on rectal suction biopsies, hypoganglionosis of the myenteric plexus requires a full-thickness sample of adequate size (> 1 cm length). Because the subjective impression of hypoganglionosis can be very misleading, morphometric measurements are required using standardized neuron counts in a sufficient number of sections. The few published studies on neuronal density in control subjects gave very conflicting results, perhaps because of the different methods applied or the different selection criteria used for controls. Neuronal density is affected by the age of the patient, tissue freshness, different diseases, and intestinal dilatation, especially when the specimen is cut transversely to the long axis of the bowel. Sections should be at least 30 µm apart to avoid counting each neuron more than once. In postmortem specimens from non–gut-diseased children of different ages, Smith reported a mean neuronal density of 3.6 per mm for the jejunum, 4.3 per mm for the ileum, and 7.7 per mm for the colon, with no major differences between transversal and longitudinal sections.[79] Depending on the section thickness and various techniques used, neuronal density may differ by a factor up to 200.[5]

Hypoganglionosis can always be detected in a short segment, called the transitional zone, proximal to the aganglionic bowel in Hirschsprung disease. An extensively long hypoganglionic segment may cause symptoms of dysmotility after the pull-through operation. Non–Hirschsprung disease–related hypoganglionosis, with a clinical picture similar to the histology of the transition zone, has been reported in many children with severe chronic constipation. It was the most frequent diagnosis in two large series reported on children with chronic intestinal pseudo-obstruction owing to visceral neuropathy.[11,50] Navarro and colleagues reported hypoganglionosis of the myenteric plexus in 13 of their 26 patients.[11] Ganglions were smaller than normal and often infiltrated with collagen fibers. Ganglion cells were sparse and sometimes difficult to identify with conventional staining techniques. Immunostaining with different neuronal markers confirmed the paucity of the nervous tissue. Between the ganglion nodes, there were numerous and thickened Schwann nerve fibers that stained strongly with acetylcholinesterase. In the majority of their patients, hypoganglionosis was confined to the distal segment of the colon. Diffuse disease was reported in only two patients, one of whom presented with intestinal obstruction on the second day of life, had a severe course of the disease, and died of sepsis 1 year later. The second patient with diffuse hypoganglionosis presented at the age of 1 month with pseudo-obstructive episodes. She was the only patient in this series who developed extraintestinal symptoms with severe progressive peripheral neuropathy, absent deep tendon reflexes, ataxia, and tetraplegia. In addition to hypoganglionosis and Schwann cell hypertrophy, she had intranuclear inclusions within the enteric neurons and in peripheral nerve cells. Her disease fit the pattern of familial visceral neuropathy with intranuclear inclusions described above. This case illustrated that visceral hypoganglionosis (like hyperganglionosis; see below) is not confined to a certain disease entity. The second series

of children with intestinal pseudo-obstruction owing to visceral neuropathies was reported by Krishnamurthy and colleagues.[50] They performed hematoxylin and eosin and silver staining on biopsies from 26 children aged 2 months to 10 years and 14 control infants who died of several non–gut-related causes. They distinguished three groups of patients by different morphologic criteria. Group 1 consisted of three children with absence of the myenteric plexus by hematoxylin and eosin and silver staining but the presence of submucosal neurons. Group 2 included four patients with hypoganglionosis of the myenteric plexus by hematoxylin and eosin staining but no nerve tracts and meshlike structures of the myenteric plexus by silver staining. Group 3 consisted of 19 patients with normal or slightly abnormal neuron density but deficiency of argyrophilic neurons by silver staining. The latter finding has to be interpreted with caution in infants because argyrophilic neurons were found to be absent in preterm babies and could be detected in only some non–gut-diseased infants until the age of 1 year.[6] Many neurons in these patients were abnormal, with scant cytoplasm, enlarged nuclei, and prominent chromatin. Argyrophilic neurons, when present, were small and had few processes. The authors speculated that a maturational arrest at different stages of development could be responsible for the findings. In the first two groups, migration of the neurons may have been arrested or hampered, whereas in the third group, the maturation process of normally migrated neurons was disturbed. Maturation of enteric neuronal structures continues after birth. This postnatal maturation process may explain why some of the patients with pseudo-obstructive symptoms at birth show improvement or complete resolution of their gastrointestinal dysmotility during the first years of life.

The clinical course of patients with hypoganglionosis varies markedly. Most cases present in the newborn period with symptoms of Hirschsprung disease, but some become symptomatic as late as 4 years of age. Most undergo operation (ileostomy, colonic resection, and pull-through procedure), which relieves symptoms in only a few; many children remain dependent on parenteral nutrition or die. This diverse outcome emphasizes that clinical decisions should not be based on the morphologic finding of enteric hypoganglionosis.

Hyperganglionosis. Hyperganglionosis is characterized by an excess of intestinal neurons in the myenteric plexus with or without involvement of the submucous plexus. Knowledge of normal neuronal density is a conditio sine qua non for this diagnosis. Because hyperplasia of the submucosal plexus with large ganglia containing more than seven ganglion cells (giant ganglia) was one of the main criteria of IND, the age dependency of neuronal density is relevant to the accuracy of diagnosis. Several authors reported a significantly higher proportion of infants, especially newborn babies, fulfilling these criteria compared with older children.[3,58,80] In non–gut-diseased children, a higher neuronal density in the submucosal plexus is found in infants than in older children.[81] Using whole-mount preparations stained with reduced nicotinamide adenine dinucleotide phosphate diaphorase histochemistry (identical to nitric oxide synthetase) and cuprolinic blue (a general neuronal marker), Wester and colleagues described an exponential decrease of ganglion cells within the myenteric plexus meshwork during the first 4 years of life.[5] Therefore, the finding of hyperganglionosis in a young infant with dysmotility needs to be interpreted with caution.

Severe hyperganglionosis is the hallmark of the visceral neuropathy (ganglioneuromatosis) occurring in patients with MEN IIB. In fact, many of the young children reported to have severe hyperganglionosis later developed medullary thyroid carcinoma; some of them were initially labeled as having intestinal neuronal dysplasia.[51,82] Severe myenteric and submucous plexus hyperplasia with signs of penetration of hyperplastic nerves into the mucosal were typical findings in children with MEN IIB, reported by Navarro and others.[11] In contrast, four patients with no signs of MEN IIB on follow-up showed only mild to moderate hyperganglionosis. Their findings were much more pronounced in the myenteric than in the submucosal plexus. Three patients presented with obstructive symptoms and one with enterocolitis during the neonatal period. Two of these children became asymptomatic after ileostomy, and the other two recovered without surgical treatment.

These observations underline the quantitative and qualitative differences between isolated hyperganglionosis and ganglioneuromatosis associated with MEN IIB. Infants and children with severe hyperganglionosis, especially when the submucous plexus is involved, should be investigated for a mutation within the *RET* gene, regardless of a negative family history for MEN IIB. In contrast, mild hyperganglionosis in a young infant seems to be have a much better prognosis and may be an age-related variation of the normal enteric maturation process.[5] Further work is needed, using more sophisticated techniques, to clarify whether isolated mild or moderate segmental hyperganglionosis is a distinct entity that causes long-term motility problems.

Hyperplasia of the myenteric and submucous plexus proximal to the transition zone has been reported in patients with Hirschsprung disease.[3] Most of them had increased acetylcholinesterase activity in the lamina propria of the affected bowel segment. The significance of these findings for motility problems after the pull-through procedure remains controversial. Nevertheless, patients with disabling motility disturbances after a pull-through procedure or after colostomy, who have proven hyperganglionosis in both plexuses, may benefit from resection of the affected part of the colon. Interestingly, mucosal neuromas or extraintestinal features of MEN IIB have not been reported in patients with Hirschsprung disease–associated hyperganglionosis. The *RET* mutation found in aganglionosis results in a loss of function effect, whereas in MEN IIB mutations, a common gain of function effect has been shown. It is unknown whether patients with Hirschsprung disease–associated hyperganglionosis have more mutations in the *RET* gene than patients without these morphologic findings in the bowel proximal to the aganglionic segment.

Qualitative Abnormalities of Ganglion Cells. These have been reported in children of all ages presenting with primary intestinal motility disorders. These morphologic

findings may be an expression of immaturity or degeneration and are almost always seen in hypo- or hyperganglionosis. However, qualitative abnormalities may be detected in patients with no changes of neuronal density and normal-looking enteric nerve plexuses on conventional light microscopy,[11,50] even when more sophisticated techniques, including Smith silver stain and immunohistochemistry for different neural markers and excitatory and inhibitory neurotransmitters, are applied.[80,83] The qualitative pathologic changes may occur as an isolated visceral neuropathy but also in association with malrotation of the bowel, gastroschisis, omphalocele, or other gut malformations or in combination with extraintestinal abnormalities.[84] Clinical symptoms are nonspecific and indistinguishable from other enteric neuropathies.

Secondary or Acquired Visceral Neuropathies

In secondary or acquired neuropathies, the damage of the ENS is due to a known agent (ie, toxic, infectious) or secondary to a systemic disease (ie, endocrine or metabolic disorder, chronic inflammation). Secondary visceral neuropathies may manifest at any age, even after birth if the damaging agent was present in utero. They occur less often in children compared with adults because it may take many years to cause neuronal damage severe enough to cause dysmotility.

Infectious Agents. Infectious etiologies are proposed for several functional bowel disorders. Most symptoms, such as abdominal pain, fullness, or nausea after enteritis, are transient and resolve over weeks or months. Chagas disease caused by infection with *Trypanosoma cruzi* is a well-known example of ENS destruction; neuronal degeneration is not caused by the parasite itself but is due to an autoimmune response elicited by the infection. The most common clinical presentation is achalasia, followed by dysfunction of the intestine, including episodes of chronic intestinal pseudo-obstruction. Obstructive episodes have also been observed during acute Lyme disease. A viral etiology was suspected in patients infected with neurotropic viruses from the herpes virus family, including cytomegalovirus, varicella-zoster virus, Epstein-Barr virus, herpes simplex virus type 1, and human immunodeficiency virus (HIV).[85,86] Debinski and colleagues provided the first proof for a viral etiology by identifying Epstein-Barr virus in the myenteric plexus of a patient with chronic pseudo-obstruction.[87] Full-thickness biopsies of the patient showed myenteric inflammatory infiltrates but no evidence for a myopathy. Because the authors did not identify virus material in the tissue of 12 other patients with chronic pseudo-obstruction, they concluded that viral infection is a rare cause of severe intestinal dysmotility. Besnard and colleagues reported a 13-year-old boy with intestinal pseudo-obstrurction, acquired hypoganglionosis, and severe acute dysautonomia related to Epstein-Barr virus reactivation.[88]

Toxic Agents. Abnormal antroduodenal manometry suggestive of enteric neuropathy was reported in five children with fetal alcohol syndrome.[89] All patients presented during infancy with disabling symptoms of gastrointestinal dysmotility, including vomiting, abdominal pain and distention, constipation, and intermittent diarrhea, resulting in failure to thrive. However, prior to referral between the ages of 20 months and 9 years, all patients had undergone multiple operations. Nissan fundoplication, with pyloric emptying procedures, was performed in four children and bowel resection in one. Because no tissue was available from these patients, it remains undetermined whether the observed manometric motility pattern was the direct result of in utero alcohol neurotoxicity on the enteric nerves. In a rat model, ethanol ingestion from the sixth to the twelfth day of pregnancy showed histologic and structural changes in the offspring's colon and bladder wall compared with those of control rats.[90]

Drugs. Drugs may affect gastrointestinal motility as a main target organ by intent (eg, various prokinetics or loperamide) or as unwarranted side effects (ie, opiate analgesics, macrolides, or anticonvulsive drugs). Symptoms such as diarrhea, abdominal cramping, or constipation resolve as soon as the drugs are stopped. Two infants with hypoperistalsis and idiopathic intestinal pseudo-obstruction have been reported who were treated during the perinatal period with zidovudine.[91] In both, symptoms resolved when the drug was discontinued. Nonreversible visceral neuropathy owing to long-term intake of cathartics or chemotherapeutic agents has been reported in adults.

Radiation. Radiation damages all structures of the small and large bowel, including the mucosa, blood vessels, connective tissue, nerves, and smooth muscle. Acute manifestations usually subside within weeks, whereas late complications may appear months to decades after radiotherapy. Most affected patients are adults. Symptoms of the late radiation enteropathy include diarrhea, urge defecation, abdominal pain, nausea, vomiting, bloating, and pseudo-obstructive episodes. Late radiation injury is characterized by vascular degeneration and intestinal wall fibrosis evident in all layers of the gut wall. Both neuronal and muscular structures of the bowel are affected and contribute to the motility disorder. Contrast studies may show dilated loops, hypoperistalsis, and a thickened wall. Antroduodenal manometry showed a wide variety of abnormalities, preferentially in patients with more severe symptoms and malnutrition.[92] The major features were an attenuated postprandial motor response and a reduced intensity of the MMC during the night.

Chronic Inflammation and Autoimmune Disease. Gut dysmotility has been reported in patients with different noninfectious inflammatory diseases. Chronic and acute transmural inflammation as in Crohn disease or post–necrotizing enterocolitis causes fibrosis and ischemia and may damage both enteric nerves and muscular structures of the bowel. Dysmotility in untreated celiac disease is probably due to mucosal atrophy, resulting in disturbed secretion of several gastrointestinal hormones. Neuropathic changes have not been reported. Common complaints are symp-

toms of delayed gastric emptying, abdominal distention, and bloating. Hypoperistalsis of the small and large bowel results in constipation in about 10% of untreated celiac patients in spite of malabsorption. A few celiac patients with intestinal pseudo-obstruction have been described. Symptoms of dysmotility resolve on a strict gluten-free diet. Two patients have been reported with an autoimmune visceral neuropathy (ganglionitis) and acquired progressive aganglionosis as a result of a severe T cell–mediated inflammatory ganglionitis of both enteric plexuses.[93] Both patients became symptomatic during childhood, with severe constipation, anorexia, abdominal distention, and abdominal pain, and later developed pseudo-obstructive episodes. No extraintestinal involvement or autonomic dysfunction was observed. High titers of an immunoglobulin G class autoantibody directed against enteric neurons were found in both patients. There was no evidence of a paraneoplastic syndrome because no tumor was found during a period of up to 8 years. The autoimmune inflammatory nature of this acquired severe neuropathy with secondary aganglionosis is supported by the improvement of symptoms during treatment with prednisone and relapse after withdrawal of steroids.

Autonomic Neuropathy. The autonomic nervous system constitutes one of three levels of control of gastrointestinal motor function and interacts with the ENS and the excitable smooth muscle cells. Therefore, it is not surprising that disorders affecting the extrinsic nervous system of the gut cause intestinal dysmotility, even in the absence of morphologic abnormalities of the ENS. About half of the children with the autosomal recessive inherited familial dysautonomia (Riley-Day syndrome) develop gastrointestinal problems.[94] Attacks of severe vomiting affect children after the age of 3 years and are one of the most disturbing afflictions of the disorder. The crises usually last less than 24 to 72 hours and are associated with hypertension, sweating, and erythematous blotching of the skin. Severe gastric distention and abdominal pain may accompany the attacks. The children are at high risk for profound dehydration and aspiration. Children with triple A syndrome (achalasia-addisonian-alacrimia syndrome or Allgrove syndrome), an autosomal recessive disorder, often suffer from a variety of neurologic features with autonomic dysfunction, including gastrointestinal dysmotility with vomiting, retching, diarrhea, or constipation.[95] The *AAAS* gene has been mapped on chromosome 12q13 and encodes a protein, which is involved in signal transduction, ribonucleic acid processing, and transcription.[96]

An acquired idiopathic autonomic neuropathy was described in 27 patients aged 7 to 75 years from the Mayo Clinic, most of whom had an acute or subacute onset of symptoms.[97] In 16 cases, a presumed viral infection preceded symptoms. Gastrointestinal symptoms, reported in 19 patients, consisted of various combinations of nausea, vomiting, diarrhea, and severe constipation. Most of the patients had a partial recovery without relapse. An immune-mediated mechanism comparable to Guillain-Barré syndrome was considered a possible cause by the authors.

Autonomic neuropathy owing to poorly controlled diabetes mellitus is common in adults but rarely reaches clinical significance in childhood. Gastroparesis and diarrhea are the main manifestations. Celiac disease needs to be excluded because it affects 3 to 5% of children with insulin-dependent diabetes mellitus (see Chapter 44.1, "Celiac Disease").

Endocrine Disorders. Several endocrine disorders with decreased or excessive hormone release may manifest with symptoms of gastrointestinal dysmotility. Severe slow-transit constipation or even pseudo-obstructive episodes may be the presenting symptom of hypothyroidism, whereas diarrhea with or without steatorrhea owing to rapid intestinal transit occurs in hyperthyroidism. Impaired gut contractile activity with small bowel dysmotility and steatorrhea has been observed in children with hypoparathyroidism, especially when it is part of a polyendocrine deficiency syndrome. Tumors producing catecholamines or vasoactive peptides, that is, neuroblastoma, pheochromocytoma, carcinoid, ganglioneuroblastoma, VIPoma, and gastrinoma, may present with dilated small bowel loops and dysmotility in addition to watery diarrhea.[98]

Metabolic Disorders. Several metabolic disorders, with or without electrolyte disturbances, may result in acute or chronic gastrointestinal dysmotility (eg, organic aciduria, end-stage liver disease, or renal disease). In some disorders, material stored within the bowel wall may result in permanent damage of the neuromuscular structures (ie, Fabry disease, amyloidosis).

Anorexia Nervosa and Bulimia. Patients with eating disorders frequently complain of bloating, early satiety, fullness, and constipation. Delayed gastric emptying and slow bowel transit have been documented. Symptoms improve or resolve when the behavioral problem is successfully treated.

Acute Colonic Pseudo-obstruction (Ogilvie Syndrome). This is a severe form of adynamic ileus with massive dilatation of the colon in the absence of mechanical obstruction. It occurs in hospitalized patients with a wide variety of medical and surgical conditions. Most cases respond to conservative management. Colonoscopic decompression is often performed to prevent ischemia and perforation, but it is not without risk. Intravenous neostigmine rapidly decompresses the colon in adult patients and may be tried in children with this condition who do not respond to conservative treatment.[99]

DISORDERS OF THE INTERSTITIAL CELLS OF CAJAL

Throughout the gastrointestinal tract, there are non-neural cells derived from mesenchymal precursors, the ICC, that generate and propagate slow waves. These cells are very important modulators of communication between nerves and muscle, and loss or defects of ICC significantly com-

promise neuronal regulation of gastrointestinal motility.[99,100] ICC can be identified in normal tissue by their immunoreactivity for the tyrosine kinase receptor Kit and by ultrastructural criteria in transmission electron microscopy. However, some limitations and pitfalls are reported with respect to identification of ICC in disease states: The ultrastructural criteria for ICC may not apply to pathologic conditions, and absence of detectable Kit-positive cells may not only indicate loss of ICC but may also be due to artefactual loss of Kit positivity by ICC. For example, Kit positivity is impaired by paraffin embedding, and certain antigen retrieval procedures are mandatory to detect Kit positivity on such material.[99] In addition, long-standing dilatation of the intestine or hypertrophy makes it difficult to quantify the number of both neuronal cells and ICC and may result in an underestimation or overestimation of the cell density. Most important, any changes with respect to ICC observed in tissue from patients with advanced intestinal motility problems may be the cause of the disease or be secondary to the disease process. In animal models, it could be demonstrated that chronic bowel obstruction or chronic inflammation results in defects in ICC networks.[101] Therefore, at this point, we can only summarize the recent knowledge of the role of ICC in human gastrointestinal motility disorders.

Delayed Maturation of ICC

Two infants, one of whom was born prematurely, with neonatal intestinal pseudo-obstruction, have been reported who showed lack of ICC in the intestine at the side of ileostomy.[102] The intestinal motility normalized over the first months of life, and at the time of closure of the stoma, a normal distribution of Kit-positive ICC was documented. The authors speculated that a developmental delay of Kit-positive ICC may have been the underlying mechanism. Their finding was confirmed in six other children with meconium ileus who required ileostomy during the neonatal period. No Kit-positive ICC were detected in the colonic biopsies of two children, and there was a scanty distribution in the remaining four compared with controls. All children showed a normal pattern of ICC when the ileostomies were closed between 39 and 104 days of age.[103]

Reduced Density or an Abnormal Distribution of Kit-Positve ICC

This has been described in patients with children with hypoganglionosis,[104] in a woman with intestinal pseudo-obstruction and megaduodenum owing to myopathy,[105] and in the sigmoid colon of adults with slow-transit constipation.[106] However, the cause/consequence relationship in these cases remains unresolved.

For the diagnostic and therapeutic approaches to motility disorders, the reader is referred to Chapter 46.4 and Chapter 76.3, "Motility."

3. Hirschsprung Disease

Essam Imseis, MD
Cheryl E. Gariepy, MD

Hirschsprung disease is the congenital absence of the enteric nervous system (ENS) extending continuously for a variable distance to the internal anal sphincter. The ENS consists of ganglion cells in the myenteric and submucosal plexuses and associated connecting nerves within the wall of the intestine. Short-segment Hirschsprung disease is restricted to the rectum and sigmoid colon and accounts for nearly 90% of cases. Long-segment Hirschsprung disease generally describes disease that begins proximal to the sigmoid colon. Long-segment disease accounts for approximately 10% of cases. This includes disease that involves the entire colon (total colonic aganglionosis; approximately 5% of cases) and portions of the small bowel.[1] Rarely, aganglionosis includes most or all of the small intestine.[1–4] The existence (and definition) of an "ultrashort" form of the disease is debated.

In recent years, great progress has been made in our understanding of the molecular genetics of this disorder, which appear to be quite complicated. Hirschsprung disease has become a paradigm for multigene disorders because the same basic phenotype is associated with mutations in at least seven distinct genes. This chapter discusses the history, diagnosis, and treatment of the disorder as well as the current understanding of the pathogenesis and genetics of Hirschsprung disease and the potential practical applications of this information.

HISTORY

Harald Hirschsprung provided the first detailed description of the disease that bears his name in 1886 when he reported the autopsy of two infants, age 8 months and 11 months, who presented with constipation and megacolon.[5] In the two centuries prior to Hirschsprung's classic description, more than 13 individuals described a clinical entity suggestive of congenital distal intestinal aganglionosis. The earliest was Frederick Ruysch, a Dutch anatomist, who described a 5 year old with "enormis intestini coli dilatatio" (enormous dilatation of the colon) on autopsy in 1691.

After Hirschsprung's description, great debate ensued regarding the etiology of this disease. It was not until 1948, when Whitehouse and Kernohan and Zuelzer and Wilson independently confirmed an absence of ganglion cells in affected individuals, that this abnormality was widely accepted as the cause of Hirschsprung disease.[6,7] At roughly the same time, Orvar Swenson performed the first successful operation for the disease, involving resection of the aganglionic bowel with anastomosis of ganglionic bowel near the internal anal sphincter.[8]

EPIDEMIOLOGY

The general incidence of Hirschsprung disease is approximately 1 in 5,000 live births.[9–11] Recent studies suggest that incidence rates may vary among different ethnicities, with incidence rates in whites, blacks, Asians, and Pacific Islanders of 1 in 7,000, 1 in 5,000, 1.4 in 5,000, and 3.8 in 5,000, respectively.[12,13] The male-to-female ratio for Hirschsprung disease is 4:1 for short-segment disease and approaches 1:1 as the length of involved segment increases. Overall, 7% of cases have a family history of the disorder. However, the familial prevalence is 21% in individuals with total colonic disease.[14]

Approximately 15% of individuals with Hirschsprung disease present with at least one other congenital anomaly.[15,16] Excluding individuals with Down syndrome, cardiac anomalies are found in 4.5%, central nervous system anomalies are found in 3.9%, genitourinary anomalies are found in 5.6%, and other gastrointestinal anomalies are found in 3.9% of individuals with Hirschsprung disease.[15] In some instances, these anomalies may constitute part of a known syndromic disorder (Table 46.3-1).

Chromosomal anomalies are seen in 12% of individuals with Hirschsprung disease. Trisomy 21 is the most commonly associated chromosomal abnormality and is found in 2 to 8% of individuals with Hirschsprung disease.[1,10,15,17]

PATHOPHYSIOLOGY AND MOLECULAR GENETICS

ENS precursors are derived from the neural crest and colonize the gut in a cranial-to-caudal progression between weeks 5 and 12 of embryogenesis. Hirschsprung disease is caused by failure of the ENS precursors to colonize the distal intestine.[18] Absence of the myenteric and submucosal nerve plexus in the affected bowel results in inadequate relaxation of the bowel and bowel wall hypertonicity (see Chapter 4, "Motility," for further details). The hypertonic bowel causes intestinal obstruction, which can lead to bacterial overgrowth and enterocolitis.

The inheritance pattern of Hirschsprung disease can be autosomal dominant or recessive. The genetics of Hirschsprung disease displays three characteristics: (1) the penetrance of mutations is generally low, (2) there is a

TABLE 46.3-1 ANOMALIES ASSOCIATED WITH HIRSCHSPRUNG DISEASE

SYNDROMES	KEY FEATURES
Chromosomal*	
Down	Mental retardation with characteristic features
Syndromes requiring Hirschsprung disease	
Goldberg-Shprintzen†	Cleft palate, hypotonia, mental retardation, facial dysmorphism
Shah-Waardenburg‡	Pigmentary abnormalities (white forelock, depigmentaton of skin, premature graying, heterochromic irides), and sensorineural deafness
Hirschsprung disease with distal limb anomalies (several syndromes)	Polydactyly, brachydactyly, or nail hypoplasia with other assorted anomalies
BRESHEK	Brain abnormalities, mental retardation, ectodermal dysplasia, skeletal malformation, ear/eye anomalies, kidney dysplasia (ie, BRESHEK with Hirschprung disease)
Syndromes with Hirschsprung disease as an occasional finding	
Mowat-Wilson†	Facial dysmorphic features, mental retardation
Congenital central hypoventilation	Abnormal autonomic control of respiration
Bardet-Biedl	Pigmentary retinopathy, obesity, hypogonadism, mild mental retardation, postaxial polydactyly
Multiple endocrine neoplasia IIA	Medullary thyroid carcinoma, pheochromocytoma, parathyroid hyperplasia
Kaufman-McKusick	Hydrometrocolpos, postaxial polydactyly, congenital heart defect
Smith-Lemli-Opitz	Growth retardation, microcephaly, mental retardation, hypospadias, syndactyly of second and third toes, dymorphic features
Cartilage-hair hypoplasia	Short-limb dwarfism, metaphyseal dysplasia, transient macrocytic anemia, immunodeficiency, fine and sparse blond hair
Syndromes with a possible association with Hirschsprung disease§	
Fukuyama congenital muscular dystrophy	Muscular dystrophy, polymicrogyria, hydrocephalus, mental retardation, seizures
Clayton-Smith	Dysmorphic features, hypoplastic toes and nails, deafness, ichthyosis
Kaplan	Agenesis of the corpus callosum, adducted thumbs, ptosis, muscle weakness
Dermotrichic	Alopecia, ichthyosis, mental retardation, seizures
Okamoto	Hydrocephalus, cleft palate, agenesis of the corpus callosum, familial dysautonomia

Adapted from Chakravarti A and Lyonnet S.[46]

*Hirschsprung disease is also seen in association with the following chromosomal disorders: chromosome 2p deletion syndrome, chromosome 22q11.2 deletion, cat-eye syndrome (supernumerary dicentric chromosome 22q), chromosome 20p deletion, and deletions/duplications of chromosome 17q21-q23.

†Goldberg-Shprintzen and Mowat-Wilson syndromes may or may not be related disorders.

‡Other neurocristopathies are reported in association with Hirschsprung disease that likely share a molecular basis with Shah-Waardenburg syndrome. These include Yemenite deaf-blind hypopigmentation (Online Mendelian Inheritance in Man database [OMIM] #601706), ABCD syndrome (OMIM #600501), familial piebaldism (OMIM #172800), and congenital deafness.

§Hirschsprung disease is also reported in association with the following syndromes: Pallister-Hall, Fryns, Jeune asphyxiating thoracic, frontonasal dysplasia, osteopetrosis, Goldenhar, Lesch-Nyhan, Rubinstein-Taybi, Toriello-Carey, and spondyloepimetaphyseal dysplasia with joint laxity.[46]

sex difference in the penetrance and expression of mutations, and (3) the penetrance of a gene mutation depends on the extent of aganglionosis in affected family members. Most identified gene mutations associated with Hirschsprung disease are best thought of as susceptibility factors. That is, the mutation increases the individual's odds of having Hirschsprung disease but is not predictive of the abnormality.

Multiple Hirschsprung disease susceptibility genes are identified, primarily through studies of animal models (Table 46.3-2). Among the identified gene mutations are two signaling pathways, one involving the RET receptor and the other involving the endothelin B receptor.

The *RET* gene encodes a transmembrane receptor, tyrosine kinase. Mutations of *RET* were the first gene mutations identified in Hirschsprung disease.[19,20] Inactivation of the tyrosine kinase domain of RET is associated with Hirschsprung disease and accounts for up to 50% of familial cases of Hirschsprung disease.[19–22] Mutations in *RET* are more common in long-segment Hirschsprung disease, where they can be identified in up to 75% of individuals.[23] Mutations in the gene encoding the RET ligand, glial cell line–derived neurotrophic factor, are also associated with Hirschsprung disease, and loss of function mutations in its coreceptor, glial cell line–derived neurotrophic factor family receptor α-1 (GFRα-1), cause a similar disease in mice.[24–26]

RET mutations are dominant, with generally low penetrance. In families with low-penetrance *RET* mutations, the *RET* mutation likely represents a weakly expressing allele, and other gene mutations are necessary to express Hirschsprung disease. One possible modifying gene resides at chromosome 9q31.[27] Germline *RET* mutations also cause multiple endocrine neoplasia (MEN) syndrome IIA and IIB, as well as familial and sporadic cases of medullary thyroid carcinoma.[28–32] These mutations are generally activating mutations. Interestingly, some of the same *RET* mutations that cause Hirschsprung disease cause MEN IIA.[33] The pathophysiologic basis for this overlap is unclear, but it suggests that some individuals with Hirschsprung disease and their family members may be at risk for neuroendocrine tumors.[26,34]

RET and GFRα-1 are expressed in ENS precursors as they migrate through and colonize the gut during embryogenesis.[24, 35] Glial cell line–derived neurotrophic factor is expressed by the mesenchyme of the developing gut.[36,37] Mice deficient in ret signaling display an absence of ENS

TABLE 46.3-2 GENE MUTATIONS ASSOCIATED WITH HIRSCHSPRUNG DISEASE

GENE	GENE PRODUCT	HUMAN LOCUS	% OF HIRSCHSPRUNG DISEASE	HOMOZYGOTE PHENOTYPE	HETEROZYGOTE PHENOTYPE	PENETRANCE (%)	ANIMAL MODEL
RET	Receptor tyrosine kinase	10q11.2	Familial, 50; sporadic, 15–35[21]	Long-segment Hirschsprung disease (1 case reported)[4,23]	Hirschsprung disease	51–72[21]	Mouse
GDNF	Glial cell line–derived neurotrophic factor (RET ligand)	5p12–13.1	< 1[26,116]	None reported	Hirschsprung disease	Unknown	Mouse
GFRA1	GDNF family receptor α_1	10q26	None reported	None reported	None reported	Unknown	Mouse
EDNRB	Endothelin B receptor	13q22	5[50,117]	Shah-Waardenburg syndrome (often with total intestinal aganglionosis)[21,43,118,119]	Hirschsprung disease (with or without features of Waardenburg syndrome)[43,120]	30–85[121]	Mouse, rat, horse
EDN3	Endothelin 3	20q13.2-13.3	< 5[122,123]	Long-segment Shah-Waardenburg syndrome[44,45]	Shah-Waardenburg syndrome (1 case reported)[124]	Unknown	Mouse
ECE1	Endothelin converting enzyme 1	1p36.1	< 1	None noted	Hirschsprung disease with cardiac defects, craniofacial defects, and autonomic dysfunction (1 case reported)[51]	Unknown	Mouse
SOX10	Sex-determining region on the Y chromosome–related high-mobility group box gene 10, transcription factor	22q13.1	< 1	None noted	Shah-Waardenburg syndrome often with other neurologic deficits.[62–65,125]	> 80[121]	Mouse
ZFHX1B (SIP1)	Zinc finger homeobox 1B (SMAD interacting protein 1), transcription factor	2q22	< 1	Hirschsprung disease with microcephaly, mental retardation, epilepsy, and characteristic facial features	Hirschsprung disease with microcephaly, mental retardation, epilepsy, and characteristic facial features	Unknown	None

development distal to the stomach along with renal anomalies.[24,25,38–40] Ret-expressing cells are multipotent progenitors of the mammalian ENS.[41] In mice, ret-deficient ENS precursors fail to colonize the gut beyond the gastric cardia and a reduced population of neurons and glia survives in the esophagus.[42]

Endothelins are 21–amino acid peptides that interact with G protein–coupled receptors and play a number of roles in mammalian physiology and development. Mutations in the endothelin B receptor and its ligand, endothelin 3, cause Hirschprung disease that may be associated with pigmentary abnormalities (regional hypopigmentation, white forelock, bicolored irides) and sensorineural deafness.[43–45] This combination of defects is known as Waardenburg syndrome type 4, or Shah-Waardenburg syndrome. Patients homozygous for mutations in the endothelin B or endothelin 3 gene express the complete Shah-Waardenburg syndrome, whereas patients heterozygous for mutations in these genes may have isolated Hirschsprung disease or Waardenburg syndrome.[46] Mutations in endothelin B are found in approximately 5% of individuals with isolated Hirschsprung disease, as are mutations in endothelin 3.[44,45,47–49] In one large, inbred kindred, the penetrance of an endothelin B mutation was greater in males than in females: whereas 85% of males homozygous for the mutation exhibited Hirschsprung disease, only 60% of females homozygous for the mutation exhibited Hirschsprung disease.[43] Unlike *RET* mutations, endothelin B mutations are often associated with short-segment Hirschsprung disease. Hirschsprung disease is reported in one patient with a large deletion near, but not including, the endothelin B gene. This suggests that nearby genomic rearrangements may affect endothelin B expression and may explain why mutations within the gene are not found more commonly in individuals with Hirschsprung disease.[50]

Mutations in the gene encoding endothelin-converting enzyme 1, a protease responsible for the biologic activation of endothelin 3, may also be associated with Hirschsprung disease. An endothelin-converting enzyme 1 mutation is reported in a single individual with Hirschsprung disease associated with cardiac, craniofacial, and other abnormalities.[51]

Endothelin B is expressed by early ENS precursors and endothelin 3 is expressed by the surrounding mesenchyme.[52] Studies in the mouse demonstrate that, in the absence of endothelin B activation, ENS precursors show abnormalities in gut colonization beginning in the region of the cecum. Several lines of evidence suggest that endothelin B activation during this phase of intestinal colonization is critical for complete colonization of the distal gut.[53–56] In vitro evidence indicates that endothelin 3/B signaling inhibits neuronal differentiation.[57,58] It is hypothesized that, by inhibiting differentiation, endothelin B signaling maintains the ENS precursors in a colonization-competent state. Mice and rats with mutations affecting endothelin B signaling are reported to exhibit abnormalities in the ganglia of ENS-containing bowel. These abnormalities are hypothesized to play a role in the prolonged dysmotility observed in some Hirschsprung disease patients after surgical resection of aganglionic bowel.[59–61]

Mutations in *SOX10* also cause Shah-Waardenburg syndrome.[62] Most *SOX10* mutations are dominant and frequently occur de novo. Although the penetrance of the identified mutations is high, some individuals with *SOX10* mutations may have only some of the features of Shah-Waardenburg syndrome.[63] They tend to have short-segment aganglionosis or even hypoganglionosis of the colon. Some of these individuals show other abnormalities involving the central or peripheral nervous system.[63–65] Not all patients with Shah-Waardenburg syndrome have identified mutations in the genes encoding endothelin B, endothelin 3, or SOX10.

SOX10 is a transcription factor that is expressed in early ENS precursors and appears to support their survival. In mice homozygous for *sox10* mutations, ENS precursors undergo apoptosis before they reach the foregut. Mice heterozygous for *sox10* mutations exhibit early delays in ENS precursor migration, although final gut colonization may be complete. This observation has led to the hypothesis that haploinsufficiency for sox10 selectively affects an early subset of ENS precursors.[66,67]

Inactivating mutations in the gene encoding the zinc finger homeobox 1B gene *ZFHX1B* (formerly *SIP1*) cause Mowat-Wilson syndrome (characteristic facial features, microcephaly, mental retardation) with or without Hirschsprung disease.[68] Individuals with Mowat-Wilson syndrome carry dominant de novo mutations in this gene.[68,69] ZFHX1B is believed to be a transcriptional repressor that directly binds promoters and interacts with Smad proteins.[68–70]

Identified gene mutations currently account for only about half of all cases of Hirschsprung disease. Our current understanding of the molecular genetics of Hirschsprung disease comes largely from studies of syndromic or long-segment disease. Much less is known regarding molecular genetics of the most common form of Hirschsprung disease, nonsyndromic, short-segment disease. Recently, three loci were identified as both necessary and sufficient to explain the incidence and recurrence risk of Hirschsprung disease in 49 nuclear families ascertained through short-segment Hirschsprung disease probands. One of these loci appears to be the *RET* gene, although the majority of the significant mutations are apparently in noncoding sequence. The other two loci involve as yet unidentified genes at chromosomes 3q21 and 19q12. Interestingly, this analysis suggests a significant difference in the parent of origin of the abnormal *RET* allele, with 78% of affected individuals carrying the maternally derived *RET* mutation.[71]

Finally, several factors are thought to contribute to the pathophysiology of Hirschsprung disease–associated enterocolitis. The major problem is likely bowel stasis secondary to the aganglionosis, although enterocolitis often occurs after resection of aganglionic bowel. Stasis is thought to lead to bacterial overgrowth and translocation of bacteria into the intestinal wall. Histologically, as the disease progresses, the epithelium becomes ulcerated, and perforation may occur. In addition, defects in intestinal epithelial defense mecha-

nisms are identified in Hirschsprung disease. These include luminal immunoglobulin A deficiency and altered mucin composition.[72,73] How these defects relate to the identified gene mutations in Hirschsprung disease is unclear.

CLINICAL MANIFESTATIONS

The clinical manifestations of Hirschsprung disease depend on the age of presentation and the length of aganglionic bowel. Kleinhaus and colleagues reported in 1979 that 40% of individuals with Hirschsprung disease are diagnosed in the first 3 months of life and 60% are diagnosed in the first year of life.[14] Over the past few decades, the mean age at diagnosis has decreased so that the majority of patients are now diagnosed in the first 3 months of life. Individuals with total colonic disease tend to be diagnosed earlier than individuals with short-segment disease.[74]

The neonate with Hirschsprung disease is usually full term, with normal birth weight. Failure to pass meconium on the first day of life should raise the suspicion of Hirschsprung disease. Approximately 94% of neonates with Hirschsprung disease fail to pass meconium in the first 24 hours of life (as opposed to 10% of neonates without Hirschsprung disease), and 57% of infants with Hirschsprung disease fail to pass meconium in the first 48 hours of life.[75] Abdominal distention, vomiting, constipation, and poor feeding are also commonly seen in neonates with Hirschsprung disease. Diarrhea is seen in approximately one-third of neonates and often indicates the presence of enterocolitis, the most common cause of morbidity and mortality in cases of Hirschsprung disease.

The infant or child with Hirschsprung disease usually presents with constipation that begins in infancy and responds poorly to medical management. Fecal urgency, stool-withholding behaviors, and fecal soiling are usually not noted. Poor weight gain, anemia, hypoalbuminemia, and bouts of diarrhea (associated with enterocolitis) are common. Urinary retention with enlarged bladder, ureter, and hydronephrosis may occur owing to ureteral compression.[76]

Physical examination may reveal a tympanitic distended abdomen with palpable fecal masses, particularly in the older infant and child. A rectal examination is essential to evaluate for imperforate anus, an anteriorly displaced anus, and anal stenosis. The digital rectal examination in Hirschsprung disease will demonstrate a normally placed anus that will easily admit the finger but may remain somewhat tight. Stool is generally not found in the distal rectum, and the rectal mucosa remains snug to the examiner's finger (the "finger in glove" sensation). Often there is an explosive release of air and liquid stool as the examiner's finger is removed. The patient with enterocolitis will have diarrhea and appear ill, usually with fever and lethargy.

DIFFERENTIAL DIAGNOSIS

The clinical history and physical findings are very valuable in differentiating Hirschsprung disease from other disorders. Hirschsprung disease should be considered in any child who has a history of constipation dating back to the newborn period. Suspicion should increase in any child with associated abdominal distention, vomiting, and/or poor growth. Suspicion should also increase in a child with a family history of Hirschsprung disease.

It is important to differentiate Hirschsprung disease from functional constipation (Table 46.3-3). The patient with Hirschsprung disease often has problems that begin in the neonatal period with delayed passage of meconium and poor growth. Stool caliber in Hirschsprung disease is often small and ribbon-like, whereas children with constipation occasionally pass large stools. Rectal examination in Hirschsprung disease generally fails to detect stool in the rectal vault.

In addition to functional constipation, the clinical findings associated with Hirschsprung disease can mimic several other clinical entities. Anatomic causes of intestinal obstruction, endocrine disorders, electrolyte imbalances, sepsis, and drug side effects should all be included in the differential (see Chapter 46.1, "Idiopathic Constipation").

INVESTIGATIONS

Radiographic Studies

Abdominal radiographs frequently show loops of distended intestine and may show a paucity of air in the rectum. Prone films are particularly helpful as this position facilitates the movement of air into the rectum of individuals without an obstruction. The presence of free air indicates a perforation and is more frequently seen in infants.[77]

TABLE 46.3-3 CLINICAL FEATURES DIFFERENTIATING HIRSCHSPRUNG DISEASE AND FUNCTIONAL CONSTIPATION

CLINICAL FEATURE	HIRSCHSPRUNG DISEASE	FUNCTIONAL CONSTIPATION
Age at onset	Under 1 yr of age	Over 1 yr of age
Passage of meconium	Delayed	Normal
Encopresis	Absent	Present
Growth	Poor	Normal
Abdominal pain	Rare	Frequent and colicky
Stool size	Small ribbon-like or pebble-like	Large
Stool-withholding behavior	Absent	Present
Abdominal examination	Distended	Not distended
Rectum	Empty	Filled with stool
Rectal examination	Explosive passage of stool	Stool in rectum

Because the proximal, ganglionic intestine may not be significantly dilated in the first few weeks of life, an unprepared contrast enema is most likely to aid in the diagnosis of Hirschsprung disease in children older than 1 month of age. Similar difficulties arise in interpreting contrast studies in individuals with total colonic aganglionosis (Figure 46.3-1A). Classic findings include a contracted distal colon with an abrupt transition to a widely dilated proximal colon (Figure 46.3-1B). In the absence of this finding, it is important to compare the diameter of the rectum with that of the sigmoid colon. A rectal diameter that is the same as or smaller than the diameter of the sigmoid colon is suggestive of Hirschsprung disease (Figure 46.3-1C). A radiograph taken 24 hours after the study may also be helpful in showing retained contrast in individuals with Hirschsprung disease.[78]

The transition zone demonstrated by the contrast study (and by gross inspection of the intestine) does not necessarily provide reliable evidence regarding the length of aganglionosis.[79] Only histologic analysis can determine how much bowel will need to be resected. Finally, a contrast enema should not be undertaken in a patient with clinical enterocolitis or recent rectal biopsy because the risk of perforation is increased.

Anorectal Manometry

Anorectal manometry is a measure of ENS function. Distention of a proximal colonic segment normally leads to relaxation of the neighboring distal segment. The technique looks for relaxation of the internal anal sphincter in response to distention of the rectum with a balloon (Figure 46.3-2). The reported sensitivity and specificity of the test vary widely.[80–82] In experienced hands, the technique can be quite sensitive.[83,84] However, the procedure generally requires some patient cooperation and can be difficult to perform on young children in the absence of sedation. In addition, the anorectal reflex may not be completely developed in premature or full-term infants less than 12 days of age,[85] and the technique can be technically difficult in very young infants. Anorectal manometery is best done by a very experienced operator.

Rectal Biopsy

Rectal biopsy is the gold standard for diagnosing Hirschsprung disease. The diagnosis is usually established by a rectal suction biopsy, which can be performed at the bedside or in an outpatient setting. Two difficulties most commonly arise with the technique. The first is in obtaining an adequate amount of submucosa to adequately evaluate the ganglion cells. The other difficulty is in getting biopsies from the appropriate location. A segment of hypoganglionosis exists normally in the submucosal plexus just above the dentate line. This ranges from 3 to 17 mm in length.[86] To avoid taking biopsies in this area, the general practice is to obtain suction rectal biopsies no closer than 2 cm above the dentate line. If an adequate specimen is obtained from the correct location, the test is highly accurate. The technique is also quite safe, although perforations and significant hemorrhages are reported.[87] Because the length of normal hypoganglionosis above the dentate line is shorter in the myenteric plexus, full-thickness biopsies can be obtained more distally than rectal suction biopsies. They are generally reserved for difficult cases in which rectal suction biopsies have failed to resolve the clinical question.

In experienced hands, examination of hematoxylin and eosin–stained sections from an adequate biopsy is sufficient to establish a diagnosis of Hirschsprung disease (Figure 46.3-3). Acetylcholinesterase staining on unfixed specimens can aid the diagnosis. Hypertrophied extrinsic nerve fibers in the lamina propria and muscularis mucosa are often, but not always, identified in the aganglionic bowel in Hirschsprung disease (Figure 46.3-4). Acetyl-

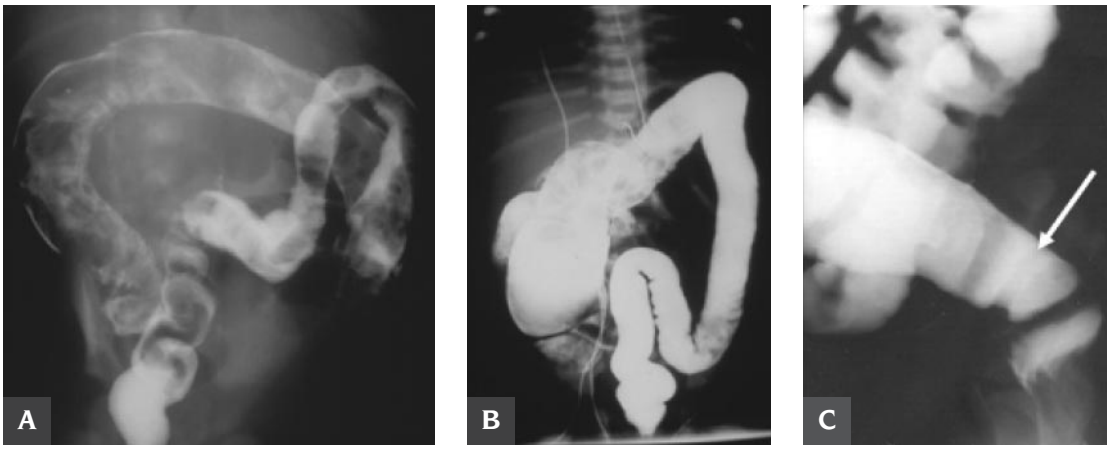

FIGURE 46.3-1 *A*, Contrast enema in an infant with total colonic aganglionosis. Note the consistent small caliber of the colon and the lack of an identifiable transition zone. Reproduced with permission from Teitelbaum D, et al.[89] *B*, Typical contrast enema appearance in long-segment Hirschsprung disease. The transition zone is in the ascending colon. Courtesy of Daniel Teitelbaum, Department of Pediatric Surgery, University of Michigan, Ann Arbor. *C*, Contrast enema of an infant with short-segment Hirschsprung disease. *Arrow* indicates rectum. Note that although the distal sigmoid is not dilated, the rectal diameter is smaller than that of the sigmoid colon. Courtesy of Peter Strouse, Department of Pediatric Radiology, University of Michigan, Ann Arbor.

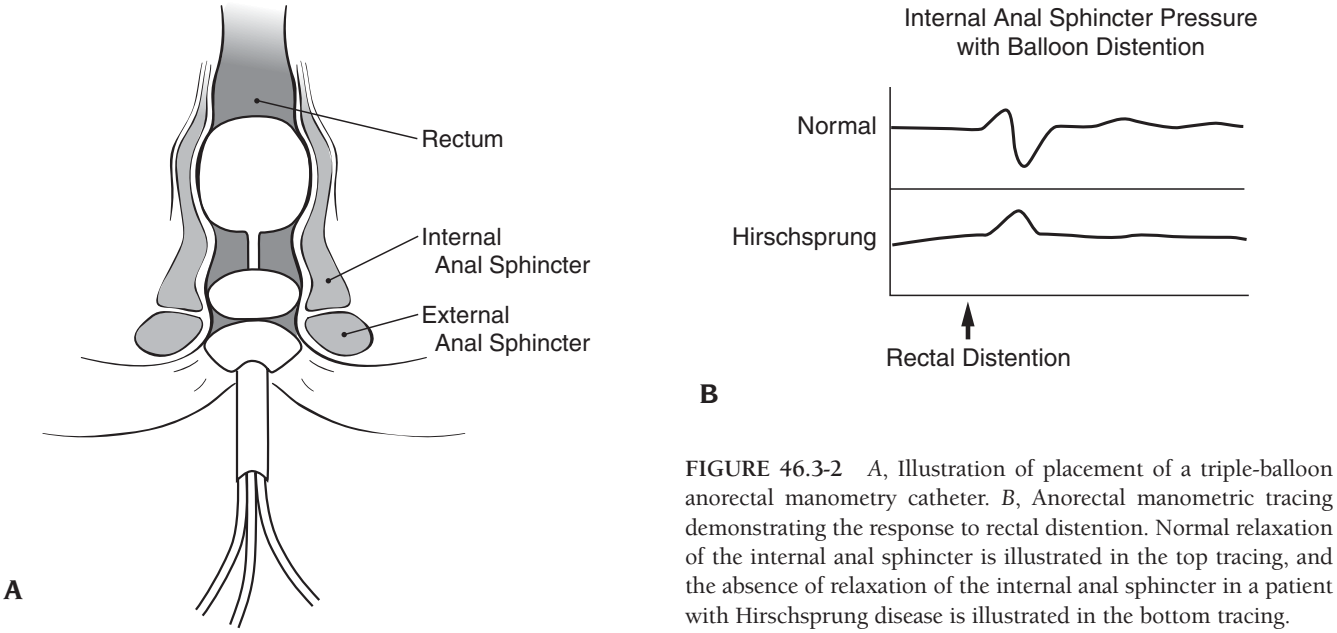

FIGURE 46.3-2 *A*, Illustration of placement of a triple-balloon anorectal manometry catheter. *B*, Anorectal manometric tracing demonstrating the response to rectal distention. Normal relaxation of the internal anal sphincter is illustrated in the top tracing, and the absence of relaxation of the internal anal sphincter in a patient with Hirschsprung disease is illustrated in the bottom tracing.

cholinesterase staining is most useful if the biopsy contains limited submucosa and no ganglion cells are identified. In this case, acetylcholinesterase staining typical for Hirschsprung disease can be diagnostic.[88]

Ultrashort-segment Hirschsprung disease is also referred to as anorectal achalasia and may represent a different pathophysiologic process. The major controversy with this disease entity is that the gold standard for diagnosing Hirschsprung disease (a rectal biopsy 3–5 cm above the dentate line) is normal. In addition, the clinical history is generally consistent with functional constipation (often with encopresis). Only anorectal manometry demonstrates the characteristic abnormality of Hirschsprung disease: failure of reflex relaxation of the internal anal sphincter on distention of the rectum. This disorder may go undiagnosed because many centers do not routinely perform anorectal manometry on patients with this presentation.

TREATMENT

Definitive treatment for Hirschsprung disease is surgical. Medical management is important in stabilizing the patient, especially if the patient has enterocolitis, and to adequately prepare the bowel for surgery.

The treatment of Hirschsprung disease–associated enterocolitis involves the placement of a soft rectal tube to decompress the colon and to allow saline washes. Patients generally need intravenous antibiotics. Rectal tube decompression and washes may not be effective in long-

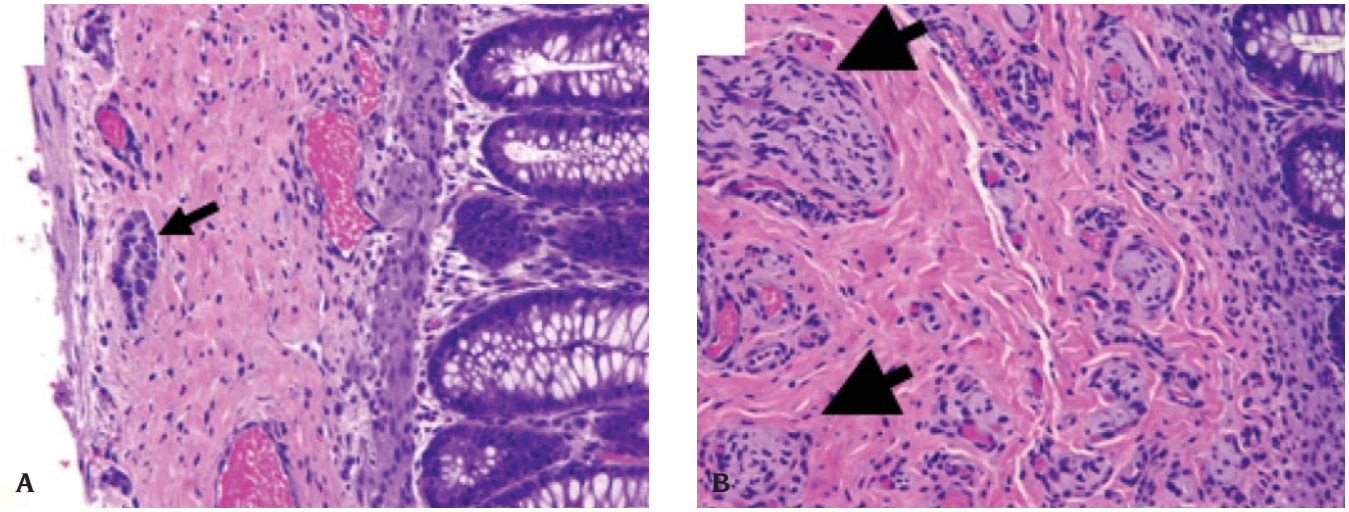

FIGURE 46-3-3 Hematoxylin and eosin–stained sections of a surgically resected specimen from a patient with Hirschsprung disease (×200 original magnification). *A*, Proximal section demonstrating normal myenteric ganglia (*small arrow*). *B*, Distal (rectal) section showing numerous hypertrophic peripheral nerves (*large arrows*). Ganglion cells are not identified. Photograph courtesy of Robert Ruiz, Department of Pathology, University of Michigan, Ann Arbor.

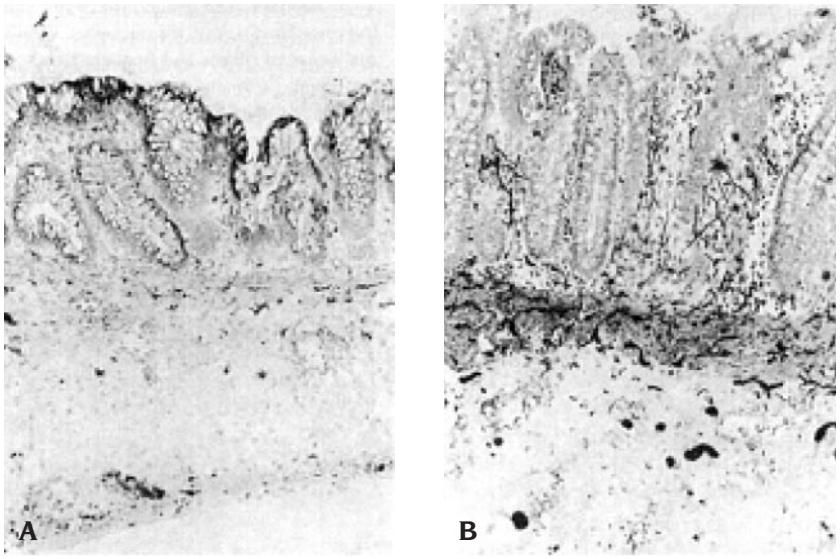

FIGURE 46-3-4 Acetylcholinesterase staining of rectal suction biopsy frozen sections. *A*, In an individual without Hirschsprung disease, staining is limited to a few nerve twigs in the muscularis mucosa. *B*, In Hirschsprung disease, staining reveals more and thicker nerve fibers in the muscularis mucosa and the lamina propria than in normal tissue. segment disease, in which case, a decompressing ostomy may be required.

The bowel should be prepared for surgery with warm saline enemas (10 mL/kg) through a rectal tube. In addition, the patient should be given a clear liquid diet for 2 to 3 days or a polyethylene glycol electrolyte solution (25 mL/kg/h) for 8 hours on the day prior to the procedure.[89] Hypertonic phosphate enemas should never be given to a patient with proven or suspected Hirschsprung disease. Retention of these enemas leads to hyperphosphatemia, hypocalcemia, hypokalemia, and metabolic acidosis. These abnormalities may result in tetany, dehydration, acute renal failure, cardiac arrest, and death.[90]

Four surgical pull-through approaches are commonly used in the treatment of Hirschsprung disease: the Rehbein, Swenson, Soave, and Duhamel procedures. Historically, obstruction was relieved in all infants with the creation of a stoma proximal to the aganglionic segment. Definitive surgery was delayed until the child weighed 9 to 10 kg (20 lbs) or until the dilated proximal segment regained a normal caliber. Currently, many infants undergo a primary pull-through procedure, which is often done laparoscopically. The results with the primary pull-through appear comparable to those with the staged procedure.[91–94]

In the Rehbein procedure (which is more frequently used in Europe than the United States), an anterior approach is used to remove the defective aganglionic tissue. The procedure leaves 3 to 5 cm of aganglionic colon above the dentate line (Figure 46.3-5A).

The Swenson procedure consists of dissection of the rectal wall distally to the level of the internal anal sphincter. The ganglion-containing bowel is pulled through the pelvis and anastomosed end to end to the rectum within 2 cm of the dentate line. Both a muscular and a mucosal anastomosis is created, and no muscular cuff is left in place (Figure 46.3-5B).

In the Soave procedure (endorectal pull-through), the aganglionic intestine is dissected circumferentially in the seromuscular layer distally to within 1.5 cm of the anus in older children and less than 1 cm in newborns. The ganglionic intestine is incised and pulled through the muscular cuff, and an anastomosis is created to the submucosal-mucosal tube close to the anus (Figure 46.3-5C).[89] The Soave procedure has been associated with a higher incidence of postoperative enterocolitis and constipation. This may be related to the length of the muscular cuff. Because of this concern, a muscular cuff that extends no more than 1 to 2 cm above the levator muscle complex is advocated.[89]

The Duhamel procedure involves positioning the proximal ganglionic intestine posterior to the rectum. The ganglionic bowel is anastomosed side to side to the posterior wall of the aganglionic rectum through an incision 1 to 2 cm proximal to the dentate line (Figure 46.3-5D). The Duhamel procedure has been modified by Martin. The Martin-Duhamel procedure involves an extended side-to-side anastomosis of the small intestine to the aganglionic left colon.

LONG-TERM COMPLICATIONS AND RESULTS

Hirschsprung disease–associated enterocolitis remains the major cause of morbidity and mortality in the disease. Enterocolitis may be a presenting complaint in Hirschsprung disease, but it also frequently occurs after pull-through. The published mortality rates range from 6 to 30%[14,95,96] and appear to be decreasing.[97] Individuals with Down syndrome are at increased risk for enterocolitis.[94,98] Patients with repeated episodes of enterocolitis after pull-through may require further evaluation and surgical intervention. Repeat resections and pull-through procedures are not uncommon.[99]

Anorectal stenosis is a frequent occurrence after pull-through and is associated with recurrent enterocolitis. Some patients can be managed by anal dilatations. Twenty to 30% of patients may require anal myectomy or myotomy for relief of constipation.[100]

After resection of aganglionic bowel, some patients are unable to absorb adequate nutrients and are dependent on parenteral nutrition. This includes patients with extensive

aganglionosis involving the small bowel and patients with dysmotility in the remaining bowel. Dysmotility may improve with time, and often no histologic abnormality in the remaining bowel can be identified. Rarely, individuals with Hirschsprung disease also exhibit intestinal neuronal dysplasia (IND B), which is characterized by hyperplastic submucosal ganglia (see Chapter 46.4, "Chronic Intestinal Pseudo-obstruction Syndrome").[101] In addition, Hirschsprung disease is identified in up to 20% of individuals diagnosed with IND B in the proximal intestine.[102] Although specific histologic features of IND B are defined, a recent study demonstrated high interobserver variation in making the diagnosis.[103] No genetic link is established between Hirschsprung disease and IND.[104] Finally, abnormalities in the network of interstitial cells of Cajal in the ganglion-containing bowel of patients with Hirschsprung disease are reported and may contribute to dysmotility.[105]

Fecalomas develop in a small subset of patients. Fecalomas in the rectum are frequently associated with the retention of a septum between aganglionic rectum and the pulled-through intestine in patients who have undergone the Duhamel procedure.

Long-term follow-up with individuals surgically treated for Hirschsprung disease reveals that ongoing difficulties with fecal incontinence and weight gain are not uncommon. Ludman and colleagues found that 7 to 17 years after definitive operation, 60% of patients treated for rectosigmoid aganglionosis were incontinent, whereas 86% of patients treated for total colonic aganglionosis were incontinent.[106] Similarly, Tsuji and colleagues found that, in patients with total colonic disease, the fecal incontinence rates were 82% at 5 years, 57% at 10 years, and 33% at 15 years. [107] With time, most individuals have improved fecal continence, but this may not occur until late adolescence. Yanchar and Soucy surveyed teenage patients who underwent definitive surgical treatment in the first year of life and their parents. They concluded that incontinence significantly impacted the patients' social and family lives. Despite this, most parents were satisfied with their child's outcome.[108] Individuals with Down syndrome appear to have prolonged difficulties with continence, particularly at night.

Few data exist regarding possible damage to pelvic neuronal structures in the process of the pull-through procedure. Most reports fail to mention the subject. Sherman and colleagues found no abnormalities in urinary or sexual function in their review of a large number of adult postoperative patients.[77]

GENETIC COUNSELING

Hirschsprung disease is a sex-modified multifactorial disorder. The generalized risk to siblings is 4% and increases as the length of involved segment increases.[1,17] In Hirschsprung disease associated with known syndromes, genetic counseling may focus more on the prognosis related to the syndrome than on the recurrence risk of Hirschsprung disease. In isolated Hirschsprung disease, a more precise risk table can now be created (Table 46.3-4). Prenatal diagnosis is possible if the mutation within the family is known. However, because the penetrance of single gene mutations is low (except for *SOX10* mutations), the clinical usefulness of genetic testing is limited. Genetic testing in Hirschsprung disease is currently performed as a research tool and is not used in clinical assessments of recurrence risk.

In addition to prenatal evaluation and assessments of recurrence risks, genetic testing in Hirschsprung disease

has the potential to identify significant risks for other diseases in individuals with Hirschsprung disease or their family members. Currently, this is most clearly illustrated in Hirschsprung disease patients with *RET* mutations identical to those observed in individuals with MEN IIA. Mutations of *RET* codons 609, 618, and 620 (within exon 10) are rarely associated with MEN IIA and Hirschsprung disease. In addition, there have been rare cases of Hirschsprung disease with exon 10 mutations identical to those found in hereditary medullary thyroid carcinoma.[109] A family history of thyroid, parathyroid, or adrenal cancer should be sought in all patients with Hirschsprung disease. A recent consensus statement from an international group of endocrinologists recommends *RET* exon 10 mutation analysis in all children with Hirschsprung disease.[110] Although the vast majority of these tests will be negative, the significance of identifying a MEN IIA mutation carrier to that individual and family justifies such testing. If a MEN IIA mutation is identified, first-degree relatives should be screened. Prophylactic thyroidectomy in carriers should be considered before the age of 5 years as well as regular screening for pheochromocytoma and hyperparathyroidism.[110]

Recently, Newby and colleagues assessed the in vivo vasomotor responses to endothelin B stimulation in a group of healthy adults with a history of nonsyndromic Hirschsprung disease, without regard to the length of aganglionosis or genetic mutation. They reported that the individuals with a history of Hirschsprung disease exhibited an abnormal vascular response to the injection of the endothelin B selective agonist and that the pattern of abnormality suggested a defect in endothelin B signaling.[111] This result raises the possibility that children treated for Hirschsprung disease may be at increased risk for cardiovascular disease in adulthood. Endothelin B is normally expressed on the vascular endothelium and smooth muscle, where it appears to be involved in the maintenance of basal vascular tone. Rats genetically deficient in endothelin B exhibit salt-sensitive hypertension.[112] However, no association has yet been made between Hirschsprung disease and noncongenital cardiovascular disease.

FUTURE DIRECTIONS

As our understanding of the molecular genetics of ENS development has improved, so has our ability to identify and isolate ENS stem cells. This allows the pursuit of a new treatment option for Hirschsprung disease: transplant of ENS precursors into the aganglionic gut. Sandgren and colleagues, using the endothelin 3–deficient mouse model of Hirschsprung disease, transplanted myenteric ganglia and smooth muscle from the proximal to the distal intestine with promising results.[113] Recently, Bixby and colleagues and Kruger and colleagues successfully isolated enteric neural crest stem cells (capable of self-renewal and differentiation into neuronal, glial, and myofibroblast phenotypes) from both embryonic and postnatal rats by flow cytometry.[114,115] One day it may be possible to "seed" the aganglionic gut of patients with Hirschsprung disease with these stem cells, creating a distal ENS and minimizing the need for surgical resection.

4. Chronic Intestinal Pseudo-obstruction Syndrome

Christophe Faure, MD

Chronic intestinal pseudo-obstruction (CIP) is a rare disorder in which impaired intestinal and/or colonic motility lead to signs and symptoms of bowel obstruction in the absence of a mechanical obstructive lesion. CIP can result from a variety of disorders of the enteric neuromusculature. Its classification is based on histopathologic data into myopathic, neuropathic, or unclassified forms, with each category occurring as a primary disorder or secondary to a nongastrointestinal disease. The diagnosis of CIP has been controversial and has recently been defined in children as a clinical syndrome "characterized by repetitive episodes or continuous symptoms and signs of bowel obstruction, including radiographic documentation of dilated bowel (except in a few congenital cases), in the absence of a fixed lumen occluding lesion."[1] It is clear that pediatric CIP is distinct from adult forms: children are affected predominantly by primary disorders of enteric neuromusculature, whereas adults present most often with CIP secondary to systemic diseases such as diabetic neuropathy, systemic sclerosis, or paraneoplastic syndromes.[2]

Although knowledge and prognosis of this heterogeneous syndrome have improved in recent years, CIP is one of the most severe intractable problems in pediatric gastroenterology: almost half of pediatric patients never tolerate enteral feeding.[3–5]

PATHOPHYSIOLOGY AND CLASSIFICATION

Gastrointestinal motility is controlled by the intrinsic enteric nervous system, which is modulated by its sympathetic and parasympathetic supply. Transmitters released from the enteric neurons modulate the peristaltic reflex. The intrinsic nervous system includes neurons, glial cells, and the interstitial cells of Cajal (ICC). The latter act as intestinal pacemakers and as modulators of cellular communication between enteric neurons and smooth muscle cells in the delivery of gastrointestinal motility (see Chapter 4, "Motility").[6] Any congenital or acquired abnormality of the enteric neuromuscular system may result in intestinal pseudo-obstruction. The clinical presentation of these disorders is dependent on the localization of the anomaly of the enteric neuromuscular network within the gastrointestinal tract.

The comprehensive histopathologic classification of enteric neuromuscular disorders is available in Chapter 46.2, "Dysmotilities."

Neuropathic Pseudo-obstruction

A neuropathic disorder affecting gut motility may theoretically be confined to either extrinsic innervation, the intrinsic enteric nervous system, or to both levels of neural control. In pediatric patients, most neuropathic forms of CIP involve the intrinsic innervation of the gut. One or more components of the enteric nervous system (ie, neurons, glial cells, and ICC) may be affected. The neuropathy is considered primary if no etiology known to induce such disorders is documented (Table 46.4-1). Most childhood cases of CIP are a result of an alteration in the number of enteric neurons and glial cells: both insufficient (hypoganglionosis)[7,8] and excessive numbers of these elements (hyperganglionosis, multiple endocrine neoplasia [MEN] syndrome type IIB,[7] intestinal neuronal dysplasia[9]) result in severe dysmotility. ICC, which are of mesodermal embryonic origin,[10] can also be affected transiently[11] or permanently.[12]

Most often, the exact mechanisms responsible for the developmental anomalies are unknown. However, recent advances in knowledge on enteric nervous system embryogenesis have provided new tools to understand these disorders.[13] A number of genes and regulatory molecules are involved in the development of the enteric nervous system. In rodents, transcription factors (Sox 10, Pax 3, Phox2a, Phox2b, Hand 2, Mash-1) and growth factors (Gdnf-Gfrα1/Ret, endothelin 3-ednrb, neurotrophin 3 [NT3]-TrkC, BMP2-4-BMPRI, BMPRII-SIP1) have been shown to be involved at various stages in normal enteric nervous system development.[13] All of these factors may be theoretically involved in the pathophysiology of primary enteric neuropathies.[14] In fact, derangement of function of *SOX10* and of the RET-GDNF, ET3-EDNRB, and BMP2-4-BMPRI pathways accounts for some cases of Hirschsprung disease in humans (see Chapter 46.3, "Hirschsprung Disease"). The etiology of other forms of visceral neuropathies is less clear. Germline mutations of the *RET* gene, causing a gain of function, have been reported in MEN type IIB.[15] There are also three reports of *SOX10* mutations in patients with CIP without aganglionosis: one girl with CIP, deafness, and peripheral demyelinating neuropathy[16] and two individuals with CIP, deafness, agenesis of the semicircular canals, developmental delay, white matter changes on magnetic resonance imaging, a white forelock, and blue eyes.[17]

TABLE 46.4-1 CAUSES OF SECONDARY INTESTINAL PSEUDO-OBSTRUCTION IN CHILDREN

TOXIC
Ketamine
Carbamazepine
Clonidine
Atropine, anticholinergics
Theophylline
Fludarabine
Vinblastine and other vinca alkaloids
Neuroleptics
Antidepressants

STRIATED MYOPATHY
Myotonic dystrophy[27,29]
Duchenne muscular dystrophy[28]
Desmin myopathy[34]
Mitochondrial myopathy[90,124]
CENTRAL OR PERIPHERAL GENERALIZED NEUROPATHY
Degenerative process: diabetes, amyloidosis (not reported in children)
Mitochondrial neurogastrointestinal encephalopathy[93]
Familial dysautonomia[83]
Acquired cholinergic dysautonomia or acquired pandysautonomia[81]
MISCELLANEOUS
Angioedema[125]
Postradiation enteropathy[126]
Kawasaki disease[127]

CMV = cytomegalovirus; EBV = Epstein-Barr virus; PCNA = proliferation cell nuclear antigen.

Myopathic Pseudo-obstruction

Myopathic forms of CIP result from smooth muscle cell injury.[18–20] Visceral myopathies may be primary or secondary to a systemic disease (see Table 46.4-1). Attempts to characterize primary visceral myopathies at the molecular level have been difficult because differential expression of proteins critical for contractile function and cytoskeletal integrity of smooth muscle may be secondary to intestinal distention.[21] Further, the histopathology of affected smooth muscle may be normal, even in the presence of a molecular defect. In one individual with CIP and visceral myopathy, complete absence of smooth muscle α-actin was documented in the presence of normal histopathology.[22]

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is an autosomal recessive disorder involving the enteric neuromuscular system associated with multiple deletions and depletion of mitochondrial deoxyribonucleic acid (mtDNA). MNGIE is characterized by a myopathy of striated muscle with ragged red fibers and mixed enteric neuromyopathy.[23] The pathogenic mechanism is related to aberrant thymidine metabolism, which results in impaired replication and/or maintenance of mtDNA.[24] Several mutations have been reported of the gene coding for thymidine phosphorylase, located on chromosome 22q13.32-qter.[25] Duchenne muscular dystrophy (DMD) and myotonic dystrophy are the most frequent skeletal myopathies that may present with severe digestive motor disorders (gastroparesis[26,27] and intestinal pseudo-obstruction[28,29]) owing to smooth muscle involvement. Indeed, dystrophin, the protein product of the DMD locus, has been localized to enteric muscle,[30] and digestive motor abnormalities have been demonstrated in patients with both DMD[31] and myotonic dystrophy.[32] In DMD, the digestive symptoms may occur late in the course, often after orthopedic procedures. In myotonic dystrophy, digestive motor symptoms may herald the disease: neonates with the disorder may present with CIP.[27] CIP with atrophic smooth muscle fibers has also been reported in cases of desmin-related myopathy (characterized by intracytoplasmic accumulation of desmin in skeletal muscle).[33,34]

CLINICAL FEATURES

Prevalence

CIP is a rare condition, and epidemiologic data in children are lacking. According to the American Pseudo-obstruction and Hirschsprung's Disease Society, an estimated 100 new cases of childhood CIP are reported every year in the United States.[35] One recent study reported 105 cases collected over a 19-year period in France and Belgium.[3] Another series of 44 cases collected over a 18-year period was also reported in Great Britain.[4]

Sex

The male-to-female ratio in CIP is thought to be 1:1; however, girls have been found to be more frequently affected in the neonatal forms.[3,4,36,37]

Family History

Familial cases of CIP account for less than 5% of cases in the large pediatric series.[3,5]A variety of myopathic forms and neuropathic forms have been reported in infants and children (see Chapter 46.2).

Prenatal Symptoms

Prenatal signs may be detected in about 20% of cases.[3,4] Megacystis is the most frequently reported sign, whereas dilated bowel is quite rare. This has been noted in megacystis-microcolon–intestinal hypoperistalsis syndrome, in which an antenatally enlarged bladder is seen by ultrasonography

in 88% of cases, hydronephrosis in 53%, increased volume of amniotic fluid in 34%, and gastric distention in only 10%.[37] Although some reports have described the detection of these signs by ultrasonography as early as 16 weeks, more often the abnormalities are noted very late in gestation.[38] Antenatally diagnosed nonobstructive megacystis, with neonatal urologic symptoms, may precede gastrointestinal symptoms of pseudo-obstruction for several months.

Age at Onset

Two-thirds of patients present within the first month of life and 80% by 1 year of age. The remainder are detected sporadically throughout the first two decades of life.[3–5, 39]

Clinical Presentation

Prenatal- or Neonatal-Onset Form. In the neonatal form, CIP presents as severe abdominal distention with bilious vomiting (Table 46.4-2). The abdominal radiograph shows dilated bowel loops with air-fluid levels suggestive of an organic intestinal obstruction. In megacystis-microcolon–intestinal hypoperistalsis syndrome, an obstructed urinary system leading to an abdominal distention may be the presenting feature, with symptoms of intestinal obstruction that may appear within days to 12 months later. To avoid unnecessary surgery, an exploratory laparotomy should be deferred in a neonate with antenatal diagnosis of megacystis. Some affected infants may present with abdominal distention and diarrhea secondary to bacterial overgrowth.

CIP may be mimicked by immaturity of intestinal motility in preterm infants; thus, this diagnosis should be made with caution in this group. For instance, the migrating motor complex does not appear in its mature form until a gestational age of 34 to 35 weeks.[40]

Infantile- or Late-Onset Form. ***Major Forms with Acute Presentation.*** Some patients present with subacute and/or recurrent episodes of gastric, intestinal, and/or colonic obstruction leading to frequent drainage and fluid replacement. The symptoms depend on the regions of the gastrointestinal tract involved. They may be acute or insidious and chronic. They may be persistent but are most often intermittent. Exacerbations may be precipitated by various causes, including intercurrent infections, fever, vaccines, general anesthesia, and stress. Diarrhea owing to bacterial overgrowth is frequent and may alternate with constipation or episodes of partial obstruction. Abdominal pain is often severe enough to lead to feeding difficulties, resulting in malnutrition. Notwithstanding frequently detected esophageal involvement by manometry, dysphagia is rarely reported.[41]

Recurrent episodes of functional partial bowel obstruction may be very difficult to differentiate from true mechanical obstruction in the child who has undergone a prior laporotomy and who may have adhesions.

Urinary tract involvement occurs in 33 to 92% of cases, independent of the type of CIP.[3,42–44] Megacystis with a hypocontractile detrusor, increased bladder capacity, and compliance is the most frequent pattern of urologic abnormality (bladder adynamia). Ureterohydronephrosis is seen in 56 to 68% of cases, but vesicoureteral reflux occurs in less than 10%.[44] Urinary tract infection is frequent but may be asymptomatic. In myopathic forms of CIP without megacystis, urinary tract infection remains a frequent problem.[4] The renal prognosis is generally good provided that careful, active evaluation and management of the adynamic bladder are performed to ensure adequate bladder emptying and to prevent urinary tract infection.[44]

Bladder biopsies show nonspecific fibrotic changes in neuropathic and myopathic forms of CIP and are thus not useful for subtype classification of CIP.

Moderate Forms with Subacute Presentation. Seventy percent of these patients present with progressively severe constipation (ie, less than one stool per 7 to 15 days), abdominal distention, bilious vomiting, and failure to thrive. Following exclusion of Hirschsprung disease and other causes of mechanical obstruction, CIP should be considered, and urinary symptoms should be carefully checked. The colonic form of CIP (colonic inertia) may result in severe intractable constipation without upper digestive tract involvement.[45]

DIAGNOSIS

The diagnosis of CIP is difficult because of the variable clinical presentation and the lack of a specific diagnostic test. The diagnosis should be suspected in children presenting with symptoms of intestinal obstruction without an occluding lesion. The diagnosis of CIP should be also considered when there is persistent vomiting after a Ladd procedure for malrotation,[46] when intestinal obstruction is

associated with bladder dysmotility, or when, in a full-term neonate, there is persistent or recurrent obstruction after exclusion of Hirschsprung disease and hypothyroidism. The differential diagnosis should be carefully considered (Table 46.4-3) because establishing a diagnosis of CIP may be invasive, and the psychological consequences in children and their families are significant.

The diagnosis is made after careful analysis of the clinical course, radiographs, motility testing, and, if available, pathologic data. Diagnosis tests should then be performed in three steps to (1) definitely rule out any fixed, occluding lesion; (2) confirm the abnormal motility of the gastrointestinal tract; and (3) find a treatable systemic cause of secondary CIP.

Definitively Rule Out Any Fixed Obstructive Lesion

The definitive exclusion of intestinal obstruction by a fixed occluding lesion is the first step to affirm the "pseudo" obstruction. Although aganglionosis results in a real "pseudo" obstruction, establishing a diagnosis of Hirschsprung disease is essential because the treatment and prognosis of this condition are well established and different from CIP (see Chapter 46.3).

Specific manometric features such as nonpropagated, prolonged contractions in small bowel differentiate CIP from a partial mechanical obstruction in adults.[47] These manometric features should be interpreted with caution, and, at present, antroduodenal manometry should not be used for differentiating "true" obstruction from "pseudo" obstruction.

Radiographic Studies. Plain abdominal films show signs typical of intestinal obstruction with air-fluid levels, a dilated stomach, small intestine, and/or colon. In neonates, the dilatation may be absent because the digestive tract has never been used.[48] Megacystis may be the main radiographic sign with a gray aspect over the lower half of the abdomen.

Contrast studies should be performed to exclude any intraluminal or extrinsic lesion that could explain the symptoms.[49,50] They should be performed with a nontoxic, water-soluble medium to prevent intraluminal solidification, leading to a true obstruction. Enteroclysis may be necessary to rule out a partial mechanical obstruction. Progression of the contrast medium may be slow with stasis in the stomach and small bowel. Impaired and retrograde peristalsis may occur. Small bowel and/or colonic dilatation are the most frequent signs, present in more than 60% of cases. Contrast enema results may be normal when the process of the disease involves only the upper digestive tract. Sometimes the dilatation may occur only in a segmental part of the small bowel or colon. A microcolon is found in neonates. Diverticulosis of the small bowel or the colon has been reported in some cases, reflecting severe dysmotility.[51–53] Pneumatosis cystoides intestinalis has been reported in children with CIP.[54]

Malrotation is frequent, especially in neonates (up to 40% of cases),[3–5] and has been reported in cases of myopathy, neuropathy, and familial syndromes associating CIP, malrotation, congenital short bowel, and pyloric nonhypertrophic stenosis.[55–57]

TABLE 46.4-3 DIFFERENTIAL DIAGNOSIS OF CHRONIC INTESTINAL PSEUDO-OBSTRUCTION IN CHILDREN

Aerophagia
Gastroparesis
Constipation
Cyclic vomiting syndrome
Severe irritable bowel syndrome
Bacterial overgrowth of various origin (lactase deficiency, disaccharidase deficiency, intestinal duplication)
Aerodigestive fistula
Munchausen syndrome by proxy

Surgery. One of the aims of an accurate diagnosis is to avoid an unnecessary exploratory laparotomy, among other reasons because surgery may cause adhesions rendering difficult the interpretation of subsequent obstructive episodes. However, some patients with an acute presentation undergo emergent exploratory laparotomy. The prevalence of surgery at diagnosis of pediatric CIP approaches 50%.[3,4,8,18,37,39] Laparotomy should be reserved to exclude an organic obstructing lesion in cases in which radiographs, manometry, or the clinical course of the illness suggests that one is likely.

Confirm Abnormal Motility of the Gastrointestinal Tract

Functional Motility Testing. Manometric studies are the most sensitive tools to evaluate the strength and the organization of the smooth muscle contractions at different levels of the gastrointestinal tract and, therefore, its functional motor capacity. Recall that manometry of any part of the gastrointestinal tract should be performed on nondilated segments because tracings from dilated bowel are of poor quality and often noninterpretable. The manometric studies should be performed in cooperative patients in a stable condition, far removed from any acute episode of obstruction or surgery.

Schematically, visceral neuropathies result in contraction of normal amplitude with abnormal propagation and compromised organization.[41] In myopathic forms, the amplitude of contractions is weak but correctly propagated and organized.[58,59]

Esophageal manometry has been found abnormal in 50 to 90% of patients with both forms of CIP, independent of esophageal symptoms.[60] In visceral neuropathies, in addition to the neuropathic manometric signs, the lower esophageal sphincter may fail to relax normally.[41]

The rectoanal inhibitory reflex is found in all patients with CIP and is absent only in Hirschsprung disease.[41] Although there are reports of absence of this inhibitory reflex in some patients with the neuropathic form of CIP, this is likely due to chronic rectal distention rather than to a primary absence of this reflex.

Antroduodenal manometry provides important information in confirming the dysmotility of the upper digestive tract, which is almost always involved in children with CIP.[58,61] Studies are performed in the fasted state and after a

meal if the patient is able to tolerate food. It should be emphasized that, especially after several years of clinical course, the manometric anomalies may be difficult to interpret because chronic distention of the gut may itself induce severe motor disturbances, particularly in postsurgical patients.[62] Stimulation with erythromycin[63] or octreotide,[64] which induces phase III motor contractions arising from the antrum or duodenum, is also used: the lack of response to these powerful prokinetic agents indicates a severe alteration of the enteric neuromusculature. Conversely, normal antroduodenal manometry essentially rules out the diagnosis of CIP.[65] If the clinical symptoms support the possibility of intestinal dysmotility, normal antroduodenal manometry is a strong argument against a motility disorder: this situation should alert the physician to the possibility of psychological or behavioral disorders, as well as Munchausen syndrome by proxy.[66] Antroduodenal manometry allows the characterization of myopathic and neuropathic forms of CIP.[58] In the group of the neuropathies, the abnormalities reported are absence of phase III motor complexes, abnormal configuration or propagation of phase III, bursts of uncoordinated phasic activity, and sustained periods of prolonged phasic activity during fasting. After a meal, the inability to induce a fed motility pattern is also reported.[41,58,67] In some patients with very severe disease, no contractile activity may be seen despite prolonged recording under excellent technical conditions. Nonpropagating prolonged contractions after a meal suggest a partial mechanical obstruction.[47] There are no specific manometric signs that correlate with respect to pathologic types of visceral neuropathies.[41] The prognostic value of antroduodenal manometry has been reported by several groups. The ability to tolerate enteral feeding is more likely when phase III or organized and propagated clusters of contractions in the duodenum-jejunum are present.[41,67,68]

Colonic manometry provides information on the motor activity of the colon during fasting and after stimulation with a meal or a laxative (bisacodyl). Weak basal activity with an absence of gastrocolic response is found in visceral neuropathies involving the colon.[69]

Electrogastrography is noninvasive and may be used in pediatric patients. Unfortunately, the results of this technique are often nonspecific and, at present, do not differentiate CIP from other forms of intestinal dysmotility. Further validation of this technique is needed.[70,71]

Nuclear medicine technetium 99m studies generally show delayed gastric emptying of solids and liquids in affected children. Normal values for scintigraphic transit time have not been established in children for the small intestine and colon.

Histopathology. Histopathologic data may confirm the abnormal aspect of the enteric neuromusculature. Description and classification of the various types of visceral myopathies and neuropathies are provided in Chapter 46.2. Although pathologic features may have a great importance in establishing the diagnosis of CIP, interpretation is often difficult and requires highly experienced pathologists.

Full-thickness intestinal wall specimens should be taken during surgery when an ostomy is needed and performed. When such a surgery is planned, pathologists should be alerted to organize optimal procedures for fixation and staining of the specimens. It is important to obtain large samples (> 1 cm) and to preserve them to permit routine light microscopy, ultrastructural examination (glutaraldehyde fixation), and immunohistochemistry (snap-freezing). Owing to the severe consequences of laparotomy in CIP patients, it is not recommended to perform surgery only to obtain intestinal specimens for histopathologic analysis. A full-thickness rectal biopsy may often be informative and may reflect the neuromuscular pathologic pattern of the colonic or intestinal wall.[7,72] It thus may be performed in patients for whom a pathologic investigation is requested, such as when an inflammatory process is suspected.[52,72]

Find a Treatable Systemic Cause of Secondary CIP

Although much rarer than in adults, finding a secondary cause of CIP is of great importance because the specific treatment of the condition may lead to the total cure of the disease. The causes of secondary pseudo-obstruction that have been described in children are listed in Table 46.4-1. Some of these causes are treatable and should be carefully excluded. Others are related to intractable or degenerative conditions but are important to be characterized for adaptation of symptomatic treatment and for giving a prognosis.

The family history should be explored to identify hereditary neurologic, myopathic, and autoimmune diseases. One should ascertain whether the patient has previously used or is currently using drugs such as anticholinergics, phenothiazines, antihypertensives, tricyclic antidepressants, serotoninergic agents, dopaminergic drugs, opiates, and calcium channel blockers or whether there is any prior exposure to radiation.[73] In atypical cases, with normal manometry, Munchausen syndrome by proxy should be considered.[66]

Any history of travels should be elicited, although Chagas disease develops exclusively in young adults after several years of evolution. The possibility of a viral infection at the onset of disease should be noted, although the demonstration of an active or past infection does not prove causation. Infections with cytomegalovirus[74,75] and Epstein-Barr virus[52,76] have been implicated as causes of CIP because these viruses have been found in enteric neurons[52,77] or involving extrinsic vagal innervation[76] of affected patients. Rotavirus has been described as a cause of both severe and prolonged gastroparesis.[78]

The physical examination should encompass a thorough neuromuscular assessment, including testing for pupillary reactions to light and accommodation and external ocular movements to help identify conditions associated with autonomic neuropathy or mitochondrial diseases. Testing for orthostatic stability should be performed in children because postural dizziness, visual disturbances, and sweating abnormalities suggest the presence of an underlying autonomic neuropathy.[79] Dysautonomia may be familial[80] or acquired.[76,81] In familial cases, reported in Ashkenazi Jewish families, the clinical diagnosis is based on the presence of five signs: lack of axon flare after intradermal injection of histamine, absence of fungiform papil-

lae on the tongue, myosis of the pupil after conjunctival instillation of methacholine, absent deep tendon reflexes, and diminished tear flow.[82] In these cases, chronic vomiting is the main digestive symptom,[83] although small bowel motility disorders have also been reported.[84]

The dermatologic examination should note signs of connective tissue disease (ie, systemic sclerosis, lupus), including Raynaud phenomenon, skin eruption, palmar erythema, telangiectasia, nodules, and scleroderma of the hands, feet, face, and forearms. Digestive symptoms may precede the skin involvement in these disorders.[85,86]

Laboratory investigations should include electrolytes, thyroid-stimulating hormone, free thyroxine, antitransglutaminase antibodies, urinary catecholamines, plasma vasoactive intestinal peptide, erythrocyte sedimentation rate, fraction of complements 3 and 4, and antinuclear antibodies. Carnitine and vitamin E levels should be checked in cases with possible fat malabsorption or maldigestion because their deficiency has been reported to be involved in enteric myopathic disorders with deposition of lipofuscin in smooth muscle cells.[87–89] Metabolic screening for mitochondrial diseases—that is, plasma lactic acid and pyruvate—should be performed when the physical examination shows external ophthalmoplegia.[90]

Neural crest–derived tumors and pheochromocytoma should be suspected and ruled out in children and infants with CIP: appropriate computed tomographic and ultrasonographic studies should be considered to exclude the presence of thoracic or abdominal tumors.[91]

Audiologic assessment is important to rule out deafness, seen in patients with a *SOX10* gene mutation.[16,17] External ophthalmoplegia associated with deafness suggests a MNGIE defect. The onset of symptoms (gastrointestinal, ocular, or both) generally occurs during adolescence, although very-early-onset disease has been reported (5 months of age).[92] Peripheral neuropathy and diffuse muscle weakness are the predominant manifestations, although almost all patients have indices of leukoencephalopathy on magnetic resonance imaging of the brain.[93] Thymidine phosphorylase activity and plasma thymidine should be measured when suspecting such a diagnosis.[24,92]

Cardiac function should be evaluated by echocardiography because involvement should lead one to suspect muscular diseases such as desmin myopathies.[33]

Full-thickness biopsies of the rectal wall or of other parts of the digestive tract may be of interest in seeking an inflammatory process of the smooth muscle cells[94,95] or of the enteric ganglia,[96] which may be amenable to anti-inflammatory or immunomodulatory therapy. Indeed, autoimmunity may directly affect either muscular cells or enteric neurons via a cytotoxic effect[96] or via circulating antienteric neuronal antibodies.[97] Inflammation may also occur in connective tissue disorders.

TREATMENT

Treatment of CIP is always supportive and, when possible, curative. Steroids have been successfully used in cases of immune-mediated myositis[95] and ganglionitis,[97] although full recovery may not be achievable in the setting of advanced neuroenteric or myopathic injury. Supportive treatment is a major objective in pediatric CIP because recovery may be protracted even in secondary forms and because curative therapy is not available for the primary forms of CIP. Supportive care is provided to bridge the gap until intestinal adaptation occurs or, if indicated, to intestinal transplant. The aims of supportive care include maintaining an adequate nutritional status, preserving growth and development, avoiding life-threatening episodes of sepsis originating from intestinal bacterial translocation or from infection of a central venous catheter, and maintaining an acceptable quality of life.[98]

Symptomatic Treatment

Acute episodes of bowel pseudo-obstruction and exacerbations in children with chronic bowel distention may benefit from bowel decompression using nasogastric suction. In children with frequent exacerbations, the placement of a venting gastrostomy may be of great benefit to avoid the recurrent placement of nasogastric tubes.[99] Normal electrolyte and acid-base balance should be restored by intravenous fluid replacement. Fever suggests the possibility of a urinary tract infection, bacterial overgrowth, bacterial translocation from the gut, or catheter sepsis, necessitating treatment with intravenous antibiotics.

Nutritional Support

Artificial nutritional support should be considered as soon as malnutrition occurs in the course of the disease because failure to thrive is reported in about 60% of untreated CIP patients.[3] Normalization of the nutritional status may also lead to improvement of intestinal dysmotility.

Enteral feeding should always be preferred to using parenteral nutrition. When possible, the intragastric route is preferred over the jejunal route because of the technical difficulties found in the placement and maintenance of the gastrojejunal tube position because the tubes may migrate if the child vomits. In the case of severely impaired gastric emptying and intractable vomiting, continuous intragastric feeds should be tried, and on failure, a surgical jejunostomy should be placed.

When enteral feeding is not possible or when malnutrition is too severe, parenteral nutrition should be employed. About two-thirds of pediatric patients with CIP require parenteral nutrition during the course of their disease. Total parenteral nutrition (TPN) is one of the main therapeutic modalities in children with CIP. Unfortunately, TPN is also the major cause of morbidity and mortality owing to infectious, thrombotic, and TPN-associated hepatic disorders.[3–5] It appears that when TPN is required, every effort should be made to establish some tolerance of enteral feeding and, ultimately, weaning off TPN.

Prokinetics and Antibiotics

Bacterial overgrowth can be treated with nonabsorbable antibiotics to prevent bacterial translocation and hepatic complications of TPN. However, the use of antibiotics leads to the development of resistant bacterial strains, ren-

dering the treatment of bacteremia owing to translocation more difficult.

Almost all prokinetic drugs have been tried in CIP, usually without any proven benefit in terms of improvement of clinical symptoms. Cisapride,[100,101] erythromycin,[63,102] octreotide,[64] and trimebutine[103] have been shown manometrically to induce and to enhance duodenal motility in children with CIP but are often less effective in providing clinical benefit.

Erythromycin (3 mg/kg intravenously every 8 hours), a motilin receptor agonist that induces strong and powerful phase III–like antral contractions, has been used in combination with octreotide, which induces duodenal phase III–like contractions. This combination has been tested with success in adults with systemic sclerosis and pseudo-obstruction.[104]

Bethanechol, a muscarinic agonist acting on both the digestive and the urinary tract, may be useful in some patients with megacystis. Metoclopramide, domperidone, misoprostol, trimebutine, naloxone, and leuprolide have been tested sporadically and may be useful in selected cases.

Several new agents are being tested in adults and could potentially help children with CIP. Tegaserod is a 5-hydroxytryptamine$_4$ receptor partial agonist shown to enhance gastric and colonic motility.[105] Two neurotrophins (NT3 and brain-derived neurotrophic factor) have been reported to accelerate the colonic transit time in constipated patients. They may act as neurotransmitters as well as on the neuronal plasticity of the enteric nervous system.[106]

Surgery

As previously stated, gastrostomy and/or jejunostomy are often required, representing the most effective intervention in many cases of CIP children. The Malone procedure can also help patients, improving bowel movements.[107]

When attacks of intestinal obstruction are frequent or life threatening or when tube feeding is not possible, enterostomy (ileostomy or colostomy) should be performed to bypass the functional obstruction and obtain digestive decompression. Bowel decompression may prevent or cure severe dilatation, which itself impairs and reduces effective motility of the gut. Intestinal motility may improve as the bowel dilatation is reduced. Symptom relief, sometimes dramatic, may occur in 50% of cases in some series, making possible withdrawal of parenteral nutrition.[3,4] Closure of the stoma may be considered when a clear improvement is observed, with weaning off TPN, and prolonged (for at least 2 years) effectiveness and tolerance of enteral feeding are obtained, without exacerbations. Ileorectal anastomosis with the Duhamel procedure has been suggested as effective in some cases.[4] Patients for whom surgery is ineffective in terms of dependence on artificial feeding methods may nevertheless benefit from venting ostomies, which may decrease bacterial overgrowth, translocation, chronic distention, abdominal pain, and vomiting.

Surgery has been reported to result in dense adhesions in these patients, and any further laparotomy performed to exclude mechanical obstruction may add to them. This is reflected in the small number of patients in the published series who underwent a single laparotomy during their illness, suggesting that others underwent further surgery because occlusive episodes recurred, raising the possibility of adhesions.[3–5,8] Laparotomy should always be avoided at diagnosis (see above). If necessary, laparotomy should be planned for bowel decompression and not undertaken only for obtaining biopsies. During the course of the disease, exploratory laparotomies for obstruction should be performed only when a clear mechanical obstruction has been demonstrated or when focal signs suggest a likely obstruction.

Intestinal transplant is the only definitive curative treatment for patients with CIP. Isolated small bowel or multivisceral transplant in such patients is challenging, however, because of the possible associated esophageal (achalasia) and gastric dysmotilities that may be unmasked after the transplant. Also, previous surgeries that patients have undergone prior to the transplant make procedures more difficult.[108–110]

Sympathetic plexus neurolysis, by interrupting sympathetic efferent (and inhibitory) activity on the upper digestive tract, has been shown to improve symptoms in two CIP patients.[92,111]

Urinary Tract

In children with urinary tract involvement, the management of megacystis and prevention of long-term renal complications are of great importance. Intermittent urethral catheterization to aid in bladder emptying and to decrease the frequency of urinary tract infections is the mainstay of treatment. Surgery to construct an alternative catheterizable channel or vesicostomy may be required in intolerant patients. Prophylaxis of urinary tract infections should be undertaken.[44]

Overall Strategy

The overall strategy is summarized in Figure 46.4-1.

OUTCOME AND PROGNOSIS

Complications

Stoma prolapse, recurrent pancreatitis,[112] diversion colitis,[113] and excessive fluid losses with high ileostomy output[114] have been reported in CIP patients. In patients with gastric and upper digestive tract motor involvement, gastric perforation and gastric bezoars may occur.[3] Medullary thyroid carcinoma associated with MEN type IIB and neurogangliomatosis should be searched for by measuring serum calcitonin levels, and early prophylactic thyroidectomy may be considered.[7]

Outcome

In secondary and acquired forms of CIP, outcome is dependent on the underlying disease responsible for the dysmotility. In cases of destruction of enteric innervation or musculature, deterioration may occur rapidly without specific treatment.[97]

Most often, viral infections resolve spontaneously,[52,74] but some chronic cases have been reported.[77,115]

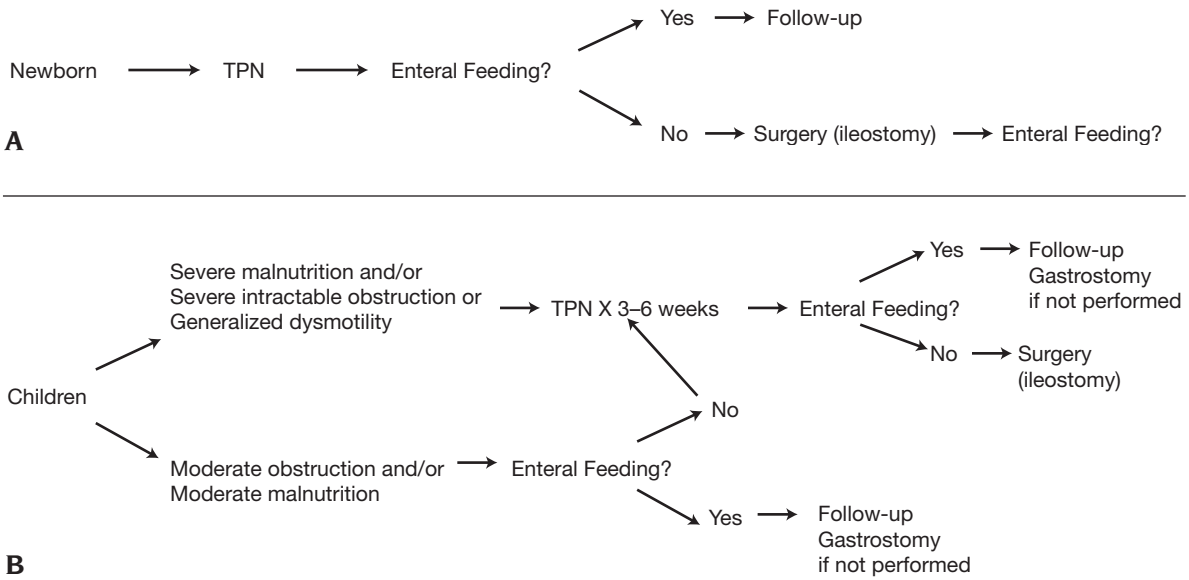

FIGURE 46.4-1 Overall therapeutic strategy for *A*, newborns and *B*, children. Enteral feeding: When possible, the intragastric route is preferred over the jejunal route. In the case of intractable vomiting, continuous gastric feeds should be tried, and on failure, a jejunostomy should be placed. TPN = total parenteral nutrition.

In primary forms of CIP, the prognosis is poor. In one series of 105 patients, two-thirds required parenteral nutrition, and 41% could not be enterally fed. More than half of the patients were TPN dependent for periods ranging from 2 months to 16 years. Eleven patients received TPN for more than 10 years. Twenty-four of the 58 patients who underwent bypass surgery were able to eat normally, and 20 of those eventually had their stoma closed.[3] Heneyke and colleagues reported that if TPN is required for more than 6 months, the child will probably be TPN dependent for at least 4 years.[4]

Mortality

Progress in the management of parenteral nutrition and the use of bowel decompression have modified the high mortality rate reported in historical series in neonates, for whom up to 90% of patients died before 1 year of age.[36,37] In series published more recently, mortality varied from 10 of 105 patients[3] to 14 of 44[4] and 22 of 85 patients.[5]

Underlying CIP is rarely the cause of death except in cases with MEN type IIB and medullary carcinoma. In pediatric series reported to date, the high mortality rate is almost always due to iatrogenic complications. Long-term TPN-related complications, including central venous catheter–associated sepsis and liver failure, and post-transplant complications are the major contributing factors to mortality and morbidity in CIP patients.[3–5] Sudden cardiac arrest has been reported in two patients with CIP.[116]

Prognostic Factors

In the large pediatric series published to date, comparison between patients requiring and those no longer requiring artificial feeding shows significant clinical differences in terms of the likelihood of neonatal onset, urinary tract involvement, requirement for surgery during the course of the disease, and myopathic disorders, all features that are more frequent in cases with a poor prognosis.[3–5] The presence of phase III of the migrating motor complex on antroduodenal manometry has been reported by several groups to be a good prognostic indicator for tolerance of enteral feeding,[41,68] response to cisapride,[117] and mortality.[67]

CHAPTER 47

SECRETORY TUMORS

Praveen S. Goday, MB, BS
Mitchell B. Cohen, MD

Amine precursor uptake and decarboxylation cells are postulated to be of neural crest origin and to have migrated during embryogenesis to a variety of organs, including the pituitary gland, thyroid, parathyroid, adrenal medulla, lung, pancreas, and gut. These cells, which are capable of making a variety of hormones and neurotransmitters, have been divided into enterochromaffin and nonenterochromaffin cells according to the products they secrete. Enterochromaffin cells secrete one or more neurotransmitters, including serotonin, substance P, histamine, kallikrein, motilin, prostaglandins, and kinins. Nonenterochromaffin cells secrete one or more of the peptide hormones, including gastrin, glucagon, insulin, somatostatin, vasoactive intestinal polypeptide (VIP), and pancreatic polypeptide. Sporadic tumors of these cells arise, secreting one or more and, frequently, several of these hormones or neurotransmitters in pharmacologic quantities.[1] All tumors of the enterochromaffin cells used to be known as carcinoids. The term carcinoid tumors is now reserved for classic midgut tumors secreting serotonin. Other types of carcinoid tumors are called neuroendocrine tumors of the lung, thymus, and so on. The release of transmitters from large carcinoids produces what is referred to as "malignant carcinoid syndrome." This syndrome is extremely rare in childhood, and carcinoids are discussed here only briefly.[2] Islet cell tumors in adults and ganglioneuromas and ganglioneuroblastomas in children are among the most common tumors to secrete peptide hormones affecting the gut. Figure 47-1 shows the computed tomographic (CT) scan of the abdomen, gross pathology of the surgical resection, and immunohistochemistry with neuron-specific enolase and VIP of a child who presented with explosive watery diarrhea and was found to have elevated levels of gastropancreatic hormones. Although tumors may secrete several hormones, the clinical syndrome produced generally reflects the action of only one of the hormones. Syndromes that have been identified include gastrinoma (Zollinger-Ellison) syndrome, VIPoma (Verner-Morrison) syndrome, somatostatinoma syndrome, and glucagonoma syndrome. The first two of these syndromes have been described in children

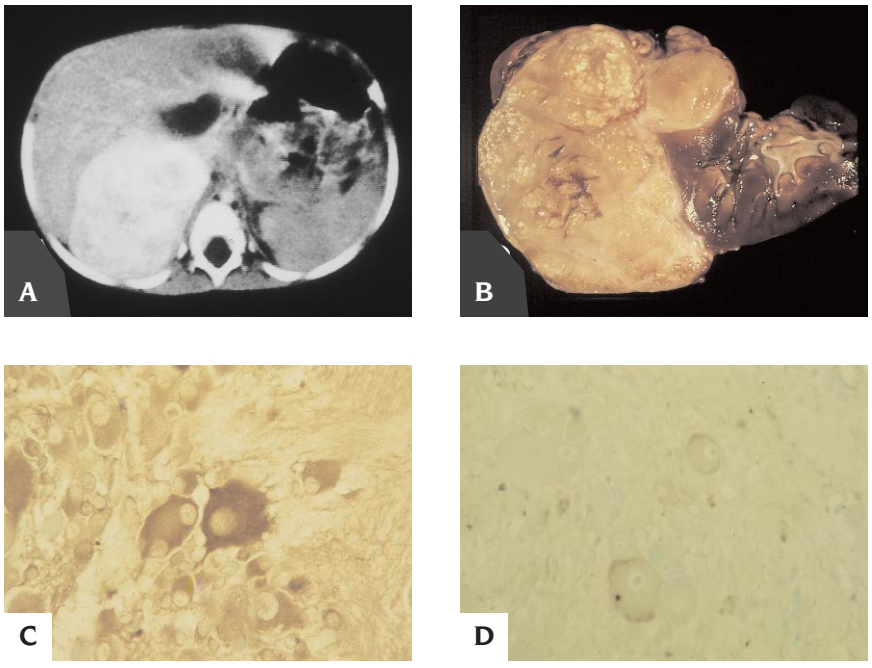

FIGURE 47-1 Child with vasoactive intestinal polypeptide (VIP)-secreting ganglioneuroblastoma. A 20-month-old child presented with a 10-month history of watery, explosive diarrhea, and abdominal distention. She was found to have elevated serum levels of norepinephrine, epinephrine, VIP, dopamine, vanillylmandelic acid, and homovanillic acid. Evaluation by computed tomography demonstrated a suprarenal mass (*A*) consistent with the tumor found at resection (*B*). Staining of the tumor revealed neuron-specific enolase, a neuroendocrine enzyme marker (*C*), and VIP (*D*) immunoreactivity. Courtesy of Dr. Philip M. Sherman, FRCP, Departments of Pediatrics and Microbiology, and Dr. Ernest Cutz, Department of Pathology, Hospital for Sick Children, University of Toronto, ON.

and are discussed here in some detail. Somatostatinoma syndrome and glucagonoma syndrome have been reported only in adults; they are discussed briefly on the assumption that they will be recognized in childhood eventually.

GENETIC INSIGHTS

Knudson initially proposed that cancers in affected individuals require two gene mutations, and this model has subsequently been confirmed and expanded.[3–5] This "two-hit" hypothesis suggests that such susceptible individuals are born with a mutation that predisposes them to acquire the cancer and that a second mutation allows the cancer to appear (the presence of both mutations in utero would be expected to be lethal). This model has been used to explain why certain families are predisposed to endocrine tumors, and three distinct types of multiple endocrine neoplasia (MEN) have been identified: I, IIA, and IIB. There is now clear evidence that "two hits" occur in MEN I[4] and II.[6] In MEN I, mutations occur in the putative tumor suppressor gene, menin, on chromosome 11q13.[7,8] Menin is a nuclear protein that interacts with several proteins involved in transcription and cell growth regulation.[9] Menin inactivation also antagonizes transforming growth factor-β–mediated cell growth inhibition.[10] The *MENI* gene is also frequently mutated in many sporadic tumors, including parathyroid adenomas, gastrinomas, insulinomas, and bronchial carcinoids.

Both patients with MEN IIA (which is associated with medullary carcinoma of the thyroid, parathyroid hyperplasia, and pheochromocytoma) and patients with MEN IIB (multiple mucosal and alimentary tract neuromas [Figure 47-2], medullary carcinoma of the thyroid, and pheochromocytoma) have a mutation in the region of chromosome 10 coding for the *RET* proto-oncogene.[11] The mutation in MEN IIA involves the extracellular portion of the molecule, whereas the mutation in MEN IIB involves the intracellular portion of the molecule. Mutations in the same gene are associated with the development of Hirschsprung disease.[12] It appears that loss of function mutations of the *RET*-encoded tyrosine kinase result in Hirschsprung disease,[13] whereas overexpression (gain of function) mutations result in MEN IIA and MEN IIB.[14] Rarely, overexpression mutations of *RET* have been associated with both MEN IIA and Hirschsprung disease.[15] Clinical aspects of the MEN tumors are discussed in more detail under the specific syndromes described below.

Genetic changes have also been described in sporadic pancreatic neuroendocrine tumors. Mutations in the *DPC4/SMAD4* gene, a tumor suppressor gene located in pancreatic cancer locus 4, have been seen in nonhormone-secreting pancreatic neuroendocrine tumors but not in

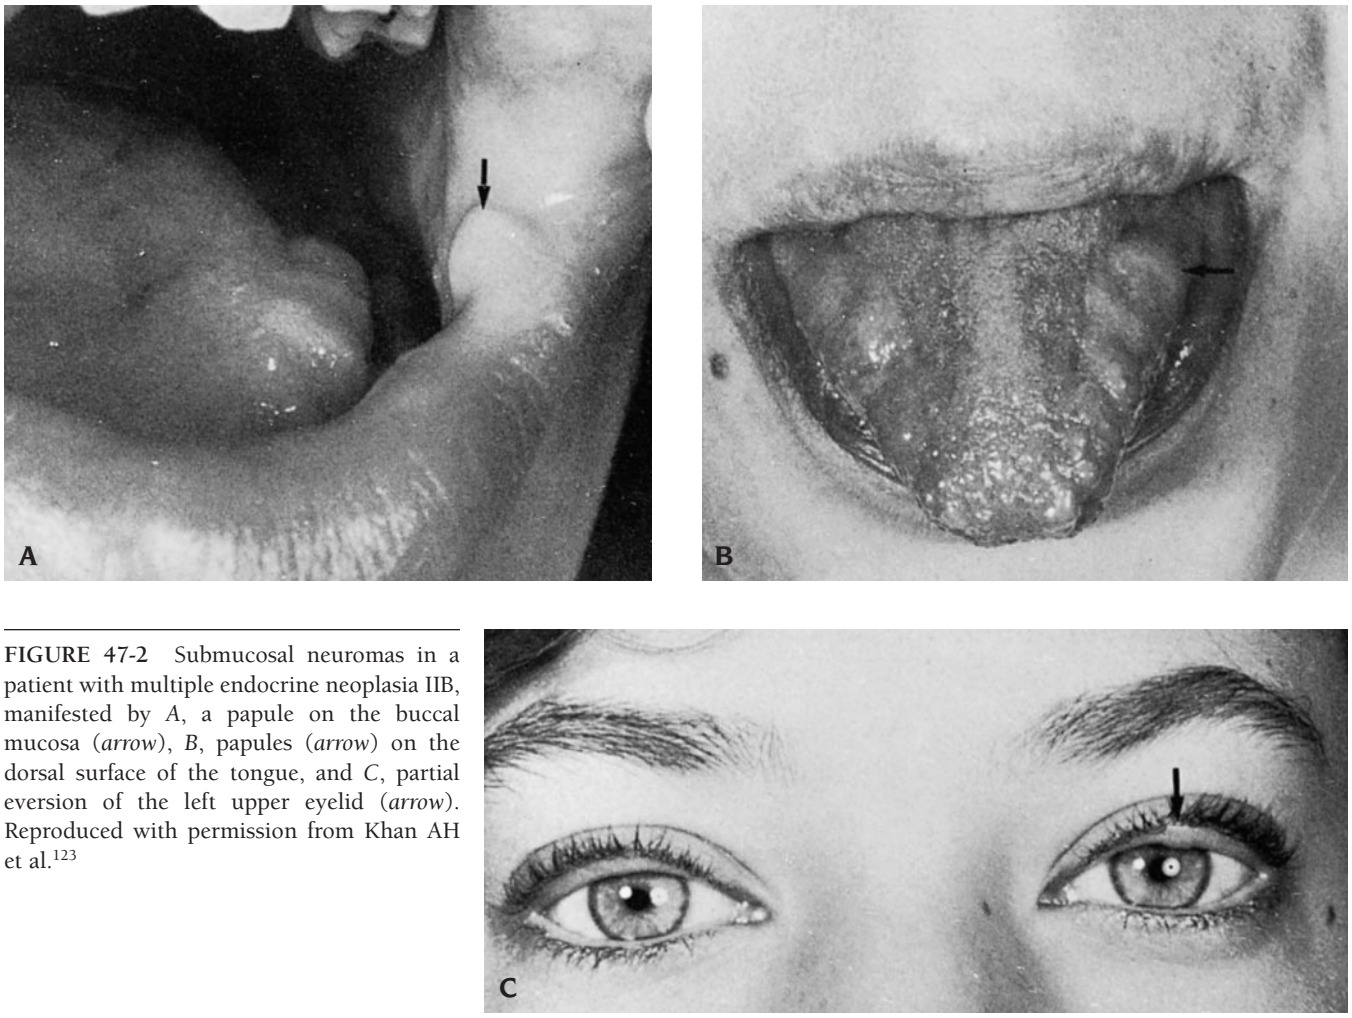

FIGURE 47-2 Submucosal neuromas in a patient with multiple endocrine neoplasia IIB, manifested by *A*, a papule on the buccal mucosa (*arrow*), *B*, papules (*arrow*) on the dorsal surface of the tongue, and *C*, partial eversion of the left upper eyelid (*arrow*). Reproduced with permission from Khan AH et al.[123]

their hormone-secreting counterparts.[16] Inactivation of the *p16/MTS1* tumor suppressor gene has been described in both secreting and nonsecreting tumors.[17] Anomalous overexpression of *p27(Kip1)*, a tumor suppressor, has been described in pancreatic endocrine tumors.[18] Mutations of *Reg*, a gene that encodes a secretory protein proposed to regulate islet beta cell and gastric mucous cell growth, have been associated with enterochromaffin-like (ECL) cell carcinoids in rats.[19]

GENERAL DIAGNOSTIC CONSIDERATIONS

Neuroendocrine tumors affecting function of the gastrointestinal tract are uncommon and present many clinical, diagnostic, localization, and therapeutic challenges. The clinical syndromes caused by these neoplasms are due to the systemic effects of their secretory products. Their diagnosis rests on the identification of humoral factors rather than on tissue biopsy. Their small size—often less than 1 cm—and frequent occult location can make diagnosis and localization difficult. These tumors, with the exception of insulinomas, often possess high concentrations of the somatostatin receptor *SSTR2*, which has a very high affinity for octreotide.[20] This receptor lends itself to imaging with the labeled somatostatin analog octreotide ([^{111}In-diethylenetriamine pentaacetic acid–DPhe^{1}] octreotide). Thus, octreotide can be used in the diagnosis and treatment of tumors that express the *SSTR2* receptor, and somatostatin receptor scintigraphy (SRS) is helpful in tumor detection.[21] Surgical resection of localized neuroendocrine tumors leads to a complete cure. Where complete resection is not possible, debulking helps by reducing humoral levels of the offending hormone and facilitating medical management. In addition, medical therapies can help control symptoms in patients with unresectable tumors.

GASTRINOMA SYNDROME (ZOLLINGER-ELLISON SYNDROME)

In 1955, Zollinger and Ellison described a syndrome of peptic ulcerations in the jejunum, associated with islet cell tumors of the pancreas.[22] They postulated that this represented secretion by the islet cells of a substance that stimulated gastric acid secretion. This factor was subsequently demonstrated to be gastrin.[23] The major features of the syndrome (gastric acid hypersecretion, peptic ulceration, diarrhea, and steatorrhea[24]) are understandable as responses to excessive levels of gastrin.

Pathogenesis

Under physiologic conditions, G cells in the gastric antrum secrete gastrin,[25] a peptide that mediates 90% of meal-related acid release. The release of gastrin is affected by elevation of gastric pH, the presence of peptides in the stomach, mechanical distention, and a direct effect of the vagus nerve. A negative feedback exists between the H^+ concentration and the secretion of gastrin. In addition to stimulating gastric acid secretion, gastrin stimulates ECL cell growth. Indeed, high circulating gastrin levels in some disease states are associated with ECL carcinoid-like tumors.[26] Gastrin also appears to stimulate growth of acid-producing tissue and appears to do this independently of histamine. Vagal tone also supports both ECL cell mass and parietal cell mass independently of gastrin.[27]

Normally, a number of systemic and local mechanisms operate to limit or decrease gastric acid secretion. In addition to gastric acid, secretin, released in response to acid delivery to the duodenum, inhibits gastrin secretion.[28] Somatostatin reduces gastrin release by G cells and exerts suppressive effects on both histamine release by ECL cells and acid secretion by parietal cells.[29] Histamine exerts negative feedback on its own secretion via the H_3 receptor on ECL cells.[30] Prostaglandins also suppress the effect of histamine on parietal cells and inhibit histamine release by ECL cells.[31,32] This carefully balanced regulation is important for normal homeostasis. Zollinger-Ellison syndrome (ZES) results from the unregulated secretion of gastrin from an ectopic source, and excessive acid secretion causes most of the features of the disease. Peptic ulcers in ZES resolve when acid secretion is reduced below 10 mEq/h.[33] The diarrhea and steatorrhea seen in patients with this syndrome are also acid related. The mechanisms of diarrhea include the delivery of large volumes of acid into the duodenum, resulting in jejunitis owing to acidification and hypermotility of the intestine secondary to high gastrin levels. Steatorrhea may result from inactivation of pancreatic enzymes or from precipitation of bile salts.

Clinical Features

The age at onset of reported cases of ZES has been from 7 to 90 years of age, with a peak incidence between 30 and 50 years of age.[23] Approximately one-third of adult patients with ZES have the familial MEN I, in which are found (in decreasing order of frequency) tumors of the parathyroids, pancreatic islets, and pituitary gland.[34] Only 5% of patients with MEN I and 2.5% of patients with sporadic disease had the onset of ZES below 20 years.[35] Most patients present with signs of recurrent peptic ulcer disease or unexplained diarrhea.[35] Three-quarters of the patients present with abdominal pain or diarrhea. Heartburn is seen in 42%, whereas vomiting and gastrointestinal bleeding are each seen in roughly one-quarter of patients. Approximately 18% of patients present with weight loss. A sign that is observed in 94% of ZES patients is prominent gastric folds on endoscopy. Uncommonly, patients have esophageal strictures (3%) or pyloric/duodenal scarring (10%). Nearly 75% of the patients have confirmed peptic ulcer disease.[35] Although multiple ulcers in unusual locations are considered pathognomonic of ZES, nearly 75% of the ulcers in ZES patients are solitary and located in the duodenal bulb.[36]

Clear-cut criteria for undertaking detailed diagnostic studies for ZES in children have not been established. Most children present with abdominal pain; symptoms of typical ulcer disease, such as hematemesis, vomiting, and melena, are less frequent. Patients with unusual presentations of peptic ulcer disease, patients with a family history of ZES, or symptoms in a patient with a family history of MEN I

and other conditions listed in Table 47-1[37] should stimulate an evaluation. Persistent diarrhea with an abnormal small bowel biopsy, steatorrhea, and a negative workup for infection, celiac disease, or allergy should lead to an evaluation for gastrinoma. Patients with ulcer disease and kidney stones should also be evaluated for ZES because excessive acid secretion interferes with bile salt action, causing calcium to combine with fats to form soaps in the gut lumen; oxalate is then free to go into solution and form oxalate calculi in the kidney.

Diagnosis

The sign of gastrinoma is the unregulated and excessive secretion of gastrin. Figure 47-3 shows an algorithmic approach to the diagnosis of a gastrinoma. The best screening test is a fasting serum gastrin level, which, in children with at least an 8-hour fast, should be less than 125 pg/mL.[38] Often patients with a gastrinoma have levels more than 5- to 10-fold higher. An elevated serum gastrin may be seen in other conditions (listed in Table 47-2)[39] and should be further investigated with a provocative test, the easiest and most specific of which is the secretin stimulation test.[40,41] For this test, 2 U/kg of pure secretin are injected intravenously over 30 seconds. Blood samples are taken for gastrin measurement 5 minutes before injection, just before injection, and at 5-minute intervals for 30 minutes after injection. Secretin has no effect on the gastrin level in normal patients and patients with benign G-cell hyperplasia but results in at least a doubling of the gastrin level in patients with gastrinoma (it usually increases by more than 200 pg/mL). A negative result in a patient with recurrent ulcer disease should be investigated with a study of gastric acid secretion, using pentagastrin. Normal basal acid secretion in children has been estimated at 0.04 ± 0.01 mEq/kg/h.[42] Some important diagnostic criteria for ZES in adults with reference to a pentagastrin-stimulated gastric acid secretion test are as follows: (1) basal acid output ≥ 15 mEq/h (highest sensitivity and specificity); (2) basal acid H^+ concentration/maximal acid H^+ concentration ≥ 0.6; and (3) in a patient with hypergastrinemia, gastric pH > 2 rules out ZES.[43] A positive secretin stimulation test or, where secretin is unavailable, an elevated fasting gastrin level in association with an elevated basal acid secretion (if available) should trigger an intensive search for a gastrinoma.[41]

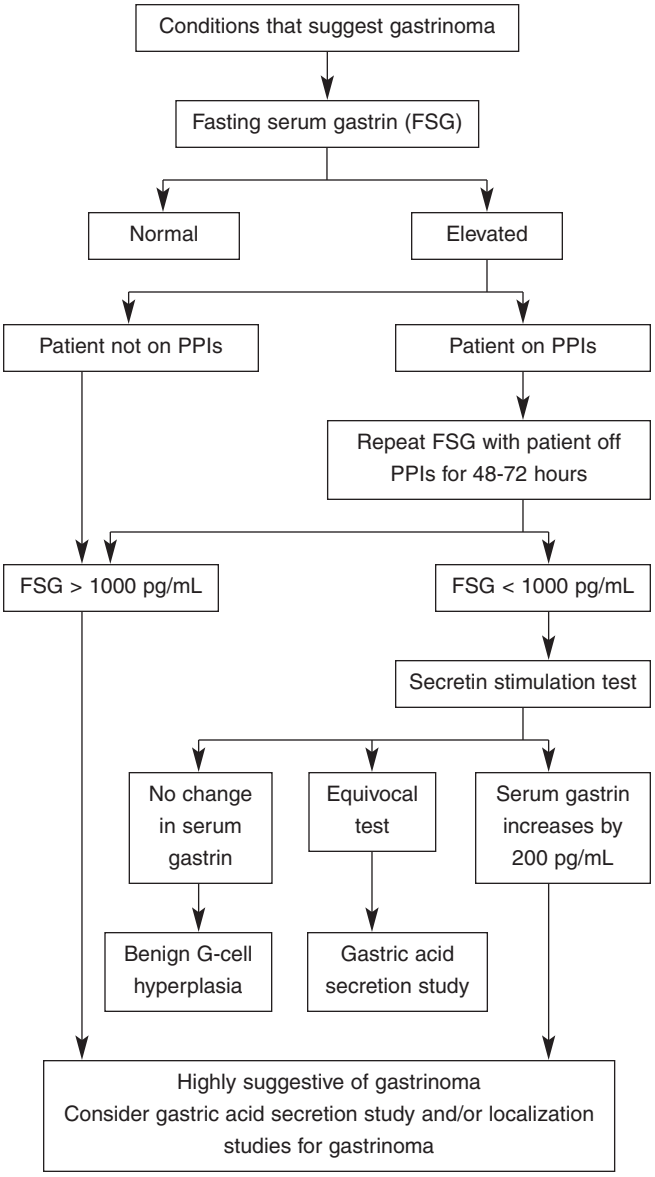

FIGURE 47-3 Elevated fasting gastrin level or positive secretin stimulation test in the setting of elevated basal acid secretion strongly suggests the presence of a gastrinoma. PPI = proton pump inhibitor.

TABLE 47-1 CONDITIONS IN CHILDREN THAT SUGGEST TESTING FOR GASTRINOMA

SYMPTOMS
Peptic ulcer disease and weight loss
Long history of peptic ulcer disease (> 5 yr)
Peptic ulcer disease unresponsive to standard medical therapy
Peptic ulcer and diarrhea
Strong family history of peptic ulcer
Personal or family history of MEN I
Peptic ulcer disease and urinary tract calculi
Recurrent peptic ulcer disease negative for *Helicobacter pylori* and without a history of NSAID use
Unexplained secretory diarrhea
SIGNS
Prominent gastric folds
Multiple upper gastrointestinal tract ulcers
Ulcers distal to the first portion of the duodenum
Gastric acid hypersecretion, hypergastrinemia, or both
COMPLICATIONS OF PUD
Bleeding, perforation, esophageal stricture, gastric outlet obstruction

Adapted from McGuigan JE[37] and Roy PK et al.[35]
MEN = multiple endocrine neoplasia; NSAID = nonsteroidal anti-inflammatory drug; PUD = precursor uptake and decarboxylation.

Localization

Gastrinomas are frequently very small (3 cm or less in size), and multiple tumors are common.[41] Typically, they are found in the "gastrinoma triangle," which lies between the cystic duct, the third portion of the duodenum, and the neck of the pancreas and includes the head of the pancreas, the duodenum, and the porta hepatic.[44] In children, gastrinomas

TABLE 47-2 CAUSES OF HYPERGASTRINEMIA

HYPERGASTRINEMIA WITHOUT GASTRIC HYPERSECRETION
Achlorhydria or hypochlorhydria associated with
Pernicious anemia
Atrophic gastritis
Gastric ulcer
Prior vagotomy
Helicobacter pylori infection
Therapy with proton pump inhibitors
HYPERGASTRINEMIA WITH GASTRIC HYPERSECRETION
Gastrinoma
Renal failure
Retained antrum
Antral G-cell hyperplasia
Pheochromocytoma
Hypercalcemia
Duodenal ulcer
Pyloric obstruction

have been reported in the liver and kidney.[45,46] At least 60% of gastrinomas are malignant, and many have already metastasized by the time they are found. The most common sites of metastases are local lymph nodes and the liver.

The algorithm delineated in Figure 47-4 presents a useful approach to the localization of a gastrinoma.[47] Various studies have shown that the sensitivity of SRS is better than any single conventional imaging study, whether ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), or selective angiography, and is at least equal to or better than all other imaging modalities combined.[48,49] The specificity of SRS appears generally excellent. This and the ability to image the entire body make SRS the initial imaging modality of choice in gastrinomas and other neuroendocrine tumors (with the exception of insulinomas). If liver metastases are seen on SRS and are extensive, as is the case with 80 to 90% of liver metastases, then surgery is generally not a consideration. The diagnosis of gastrinoma can then be confirmed using CT- or US-guided biopsy. In the case of extensive metastases, an MRI study can be used to estimate tumor size and facilitate ongoing assessment of tumor growth. If metastases are limited and cytoreductive surgery is considered, then selective angiography and MRI can be performed to delineate the exact location and size of the metastases and their relationship to surrounding vessels. Hepatic arterial injection of secretin followed by hepatic venous sampling changed the clinical decision-making process in 22% of patients with limited hepatic metastases.[50] As SRS detects more than 90% of all hepatic metastases, and other studies add very little to this figure, additional investigations are unnecessary to rule out hepatic metastases if SRS is negative. However, 40% of extrapancreatic primary tumors may be missed by SRS; thus, the primary lesion may need to be localized using endoscopic ultrasonography (EUS). EUS localizes almost all pancreatic endocrine tumors, although it may miss 50% of duodenal neuroendocrine tumors.[51,52] Combining EUS and SRS provides 93% sensitivity in preoperative localization of gastrinomas.[53] If EUS and SRS are negative, selective intra-arterial injection of secretin followed by hepatic venous sampling should be performed.[54] At surgery, intraoperative US is essential, and duodenal exploration with a duodenotomy should be performed. Intraoperative gastrin levels with and without an intraoperative venous secretin stimulation test have been used to demonstrate completeness of resection.[55] This test depends on a very rapid turnaround time for gastrin measurement, a feature not available in most centers.

Surgical Management

The only potential cure for gastrinoma is complete surgical resection (Table 47-3). Because the tumors are small, preoperative efforts to localize them with radiographic and selective sampling techniques should be aggressive. Careful surgical exploration with the assistance of duodenal transillumination and intraoperative US of the pancreas is most likely to localize a tumor.[56] Aggressive resection of local lymph nodes and resectable metastases is recommended. On rare occasions, pancreaticoduodenectomy is required. Reported short-term cures in patients with sporadic gastrinomas without metastases on imaging studies approach 80%. Aggressive surgical intervention in MEN I patients is controversial because the disease has virtually a 100% recurrence rate. In unresectable cases and in MEN I, a highly selective vagotomy at the time of surgery may make subsequent medical management easier.[57] Proton pump inhibitors have practically obviated the need for gastrectomy.

If it is possible to safely resect the primary tumor and the liver metastases, surgery should be performed. Even if complete resection is not possible, selected patients may still benefit from debulking.[58] When liver debulking is not

possible, selective hepatic embolization is another consideration to control symptoms related to excess hormone secretion or pain.[59]

MEDICAL MANAGEMENT OF ACID SECRETION

Acid secretion can be controlled with high doses of proton pump inhibitors given twice daily (adults need 60 to 120 mg/d of omeprazole, although higher doses may be used).[60] Therefore, proton pump inhibitors are the cornerstone of medical therapy in ZES. Intravenous pantoprazole (160–240 mg/d) effectively controls acid production in > 90% of patients with ZES.[61,62] The object of therapy is to keep acid secretion rates below 10 mEq/h by using an adequate dose and monitoring its effect on gastric pH. Acid secretion can be medically controlled in virtually all patients with ZES.

CHEMOTHERAPY

In patients with extensive metastatic disease, significant tumor regression has been achieved with streptozocin, used either alone or in combination with 5-fluorouracil. The morbidity of these agents has been reduced by new antiemetics. The addition of α-interferon and octreotide to chemotherapy produces a more pronounced antiproliferative effect, overcomes resistance developing to chemotherapeutic agents,[63] and has extended the median survival of patients with liver metastases to 50 months.[64] Chemotherapy may be used for palliation when ablative techniques have failed or when significant extrahepatic disease is present. Because of the modest success of current chemotherapeutic regimens, patients with advanced disease in need of treatment may be encouraged to enrol in clinical trials testing newer agents or treatment strategies.[65] The results have generally been dismal when liver transplant has been performed in disease metastatic to the liver.[65]

PROGNOSIS

With an aggressive diagnostic and surgical approach, about 30% of patients can be cured of sporadic gastrinomas by tumor resection.[66] Even when they cannot be cured, patients have a 15-year survival rate of 83% for ZES-related deaths.[67] The correlates of a poor prognosis are primary pancreatic (not duodenal) lesions; metastases to lymph nodes, liver, and bone; ectopic Cushing syndrome; and a highly exaggerated gastrin level.[67] Patients with MEN I who have apparently localized gastrinomas can rarely be cured of the disease. Only 5% of patients with MEN I and ZES were biochemically cured at 5 years after diagnosis. In a significant subset of patients with MEN I and ZES, aggressive tumor growth occurs and can lead to decreased survival. The identification of prognostic factors that identify this group will be important clinically.[68] Although only a small proportion of these patients can be cured of their disease, long-term survival is usual.

All patients with potentially resectable ZES who do not have MEN I should undergo exploration because surgical outcome is not related to preoperative testing.[69] A normal fasting serum gastrin or secretin stimulation test immediately postoperatively predicts a long-term cure. Limited data in children indicate that 25- to 30-year survival rates are possible.[70]

VIPOMA SYNDROME (VERNER-MORRISON SYNDROME; WATERY DIARRHEA, HYPOKALEMIA, ACHLORHYDRIA SYNDROME; PANCREATIC CHOLERA)

In 1958, Verner and Morrison described a syndrome of refractory watery diarrhea and hypokalemia associated with islet cell tumors of the pancreas.[71] In 1970, Said and Mutt described a polypeptide, isolated from the small intestine, that caused systemic vasodilatation, hypotension, and hyperglycemia.[72] Bloom and colleagues in 1973 demonstrated that patients with watery diarrhea, hypokalemia, achlorhydria (WDHA) syndrome have markedly elevated levels of this VIP.[73] It was subsequently shown that the major features of WDHA syndrome resulted from the actions of VIP.[74]

PATHOGENESIS

VIP is widely distributed through the gut and the central nervous system. It stimulates adenylate cyclase activity, raises intracellular levels of cyclic adenosine monophosphate, and initiates a signal transduction cascade that results in intestinal secretion.[75] Intravenous infusion of VIP, both in humans and in animals, stimulates cyclic adenosine monophosphate production by enterocytes, producing effects very similar to those of cholera toxin. The combination of VIP-induced active secretion of chloride (water and sodium follow passively) by crypt cells and decreased passive absorption of water and salt by villous cells results in copious watery diarrhea of an isotonic solution of electrolytes. Passive potassium absorption in the small bowel is reduced when bulk absorption of water and sodium is reduced. Studies in patients with WDHA syndrome show that most potassium losses in this disease are colonic.[76] The VIP stimulation of adenylate cyclase activity in the colon causes potassium secretion. It has been suggested (but not proven) that aldosterone released in response to vascular volume contraction also stimulates potassium secretion in the colon. The results of this increased potassium secretion are hypokalemia and acidosis.

Vasodilatation, manifested by facial flushing, was one of the earliest reported effects of VIP. This symptom has been reproduced in humans by the infusion of VIP, producing

blood levels seen in WDHA syndrome.[72] Hyperglycemia, which has been reported in animals, has been seen in some patients with WDHA syndrome but has not been reproduced by VIP infusion.[74,77] Hypercalcemia has been reported in patients with VIPoma, but the mechanism is not known.[77]

Clinical Features

WDHA syndrome has been reported in all age groups. Virtually all patients have presented with watery diarrhea and hypokalemia, and several have been incontinent. Fecal losses while fasting have been at least 20 mL/kg/d and in most cases exceed 50 mL/kg/d. Fecal osmolality is entirely accounted for as twice the sum of the concentrations of sodium and potassium. Notably, steatorrhea is not a feature of the syndrome. Hypochlorhydria occurs in about 70% of patients, hyperglycemia in 20 to 50%, and hypercalcemia in 20 to 50%. Flushing is present in about 20% and is frequently intermittent, indicating that hormone release by the tumor is also sporadic.[77,78]

In children, most reported VIPomas are ganglioneuromas or ganglioneuroblastomas found in the neck, thorax, or suprarenal or pelvic areas.[78] Neuroblastomas may also uncommonly secrete VIP and may mature to the ganglioneuroblastoma or ganglioneuroma phenotype. There are two reports of VIP-secreting pancreatic tumors (the most common VIPomas in adults) in children.[79,80] There has been a case report of islet cell hyperplasia associated with VIP hypersecretion and villous atrophy and another report of villous atrophy with VIP hypersecretion with no evidence of tumor or hyperplasia.[81,82] The relationship between VIP and villous atrophy in these cases is not clear. As opposed to pancreatic tumors, ganglioneuromas and ganglioneuroblastomas tend to metastasize less frequently (30% versus 56%) and exhibit characteristics of malignancy less often (one-third versus two-thirds). Almost 90% of the neurogenic tumors can be resected as opposed to ~ 70% of pancreatic VIPomas.[83]

Extrapancreatic lesions have been located in the usual areas of neurogenic tumor occurrence, including the adrenal gland and the paravertebral sympathetic tissues in the abdomen, chest, and neck. These tumors have been associated with hypercalcemia, hypophosphatemia, hyperglycemia, and increased urinary catecholamines. The symptoms of WDHA syndrome precede the recognition of a neural crest tumor in most cases.[84–86] They usually cause hypochlorhydria as opposed to the traditional achlorhydria.[82] In contrast to individuals with VIP-secreting pancreatic tumors, patients with neurogenic lesions have normal levels of pancreatic polypeptide, gastrin, insulin, and somatostatin.

Diagnosis

Diarrhea that persists during fasting in amounts greater than 20 mL/kg/d should suggest VIPoma as a possible diagnosis.[87,88] Table 47-4 lists a variety of causes of secretory diarrhea. Common causes include infection and laxative administration. Stool electrolytes and osmolality should be measured in initial investigations. If twice the sum of the sodium and potassium concentrations is significantly less than the osmolality, a search should be initiated for an osmotic agent (eg, magnesium or lactulose). Stool should be screened for phenolphthalein, senna, and other stimulant laxatives. If true secretory diarrhea is found, cultures should be obtained for toxigenic organisms. These include *Clostridium difficile* and toxigenic *Escherichia coli*, which are not recognized on routine stool cultures. These toxigenic strains can be identified by reference laboratories. In the absence of a positive stool culture, a small bowel biopsy should be examined for adherent *E. coli* organisms. If vomiting is present, a screen for emetine (which does not appear on routine toxic screens) should be obtained because secretory diarrhea has been seen with ipecac intoxication. If all of these steps do not yield a cause for secretory diarrhea, hormone-secreting tumors should be considered. Secretory diarrhea is seen with VIPoma, tumors secreting prostaglandin E_2,[77,89] ZES, and carcinoid syndrome. If the level of suspicion is high, gastrin, 5-hydroxyindoleacetic acid, prostaglandin E_2, and serotonin levels should be checked. Chromogranin A is a standard probe for immunohistochemical analyses of some neuroendocrine tumors, including gastrinomas and carcinoid tumors, and elevated serum chromogranin A levels are diagnostic of these neoplasms. Measurement of chromogranin A levels in blood can also be used to monitor the progression or regression of neuroendocrine tumors during treatment.[90]

Hormone levels should be measured in an experienced reference laboratory, and abnormal values should be repeated. Although VIP levels are usually considerably elevated in this condition, VIPomas should be considered in patients with values just above the upper limit of normal.[91] "Falsely" elevated VIP levels may be seen in neurofibromatosis, small bowel resection, chronic renal failure, and prolonged fasting.[91] The incidence of false-negative tests is not known. If blood tests support the diagnosis of VIPoma, a vigorous search for the tumor must begin, remembering that in childhood, most of the tumors are ganglioneuromas or ganglioneuroblastomas and may be found anywhere from the pelvis to the neck. They are frequently identified on chest radiography, US, EUS,[92] CT, MRI, or preoperative angiography. However, SRS is again the procedure of choice.[93] Because these tumors may secrete a variety of hormones, preoperative screening with a broad panel of

TABLE 47-4 DIFFERENTIAL DIAGNOSIS OF SECRETORY DIARRHEA

Infection with toxigenic organisms (eg, *Escherichia coli*, *Vibrio cholerae*, *Salmonella* spp, *Clostridium difficile*)
Mucosal necrosis or atrophy

5-Hydroxyindoleacetic acid
Serotonin

hormones, including somatostatin, pancreatic polypeptide, insulin, and adrenocorticotropic hormone, is often performed in adults because metastases may eventually secrete only one of them.

Therapy and Prognosis

Operative tumor resection offers the only possible cure for VIPoma. In childhood, in which 70 to 80% of VIPomas are resectable, the outlook is good.[78,94] The overall survival in children with neuroblastomas has been relatively poor (35–40%). However, children with neuroblastomas that secrete VIP do better than other children with non–VIP-secreting tumors.[84]

Preoperative stabilization of fluid and electrolyte balance is critical. Intraoperative US may provide additional help in locating tumors not seen on preoperative imaging. It has been shown that with successful resection, VIP levels fall to normal within hours postoperatively.[95] When the tumor is not resectable, a long-term symptomatic remission may be achieved with medication, although management has been very difficult. Supportive therapy includes intravenous fluid and oral glucose electrolyte solutions. A variety of agents have been used to reduce the diarrhea. Prednisone has been effective in reducing diarrhea temporarily in many patients, but it has no effect on the circulating level of VIP.[77,78] Somatostatin inhibits the release of VIP from pancreatic tumors, and a long-acting somatostatin analog octreotide has been very useful in controlling diarrhea from pancreatic VIPomas.[96–98] Long-acting preparations of octreotide and lanreotide have been effective in adults, but the role of these somatostatin analogs in the treatment of unresectable tumors causing VIPoma syndrome in childhood, in which most of the tumors are ganglioneuromas, has not yet been fully explored. Somatostatin has been used in one patient with a VIP-secreting neuroblastoma, with reduction in VIP levels but without cessation of diarrhea.[99] Good control was obtained in an infant with an enlarged pancreas and elevated VIP levels.[100] The dose of octreotide should be titrated to achieve normal stooling with improved fluid and electrolyte balance without necessarily normalizing VIP levels.[101] Streptozocin, 5-fluorouracil, α-interferon, and octreotide have been used in isolation and in combination[102] with success in the treatment of pancreatic tumors, but their effectiveness in treating ganglioneuroblastoma has not been reported.

SOMATOSTATINOMA

Somatostatin is a potent inhibitor of the release of a variety of hormones, including gastrin, cholecystokinin, insulin, and secretin.[103] The symptoms of somatostatinoma, therefore, are diabetes, gallstones, steatorrhea, and hypochlorhydria.[104] Somatostatinoma has not yet been recognized in a patient younger than 18 years of age.

GLUCAGONOMA

Excessive secretion of glucagon induces a catabolic state, glucose intolerance, hypoaminoacidemia, and a characteristic dermatitis. The most striking clinical features of glucagonoma syndrome are weight loss, rash, and diabetes.[105–107] The rash begins as red scaly lesions on the extremities, in the creases, and about the mouth. These become bullous and, finally, crusty and confluent. Dystrophy of the nails and alopecia are also seen. All of these findings are probably manifestations of the severely catabolic state. Glucagonoma has not yet been described in a patient younger than 18 years of age. Diagnosis is suggested by diabetes and a characteristic rash; it is confirmed by finding an elevated level of circulating glucagon.

MEN Syndromes

Several familial groupings of multiple endocrine tumors have been classified according to the pattern of organ involvement as MEN I (hyperparathyroidism, islet cell tumors of the pancreas, and nonfunctional adenomas of the pituitary), MEN IIA (medullary carcinoma of the thyroid, parathyroid hyperplasia, and pheochromocytoma), and MEN IIB (multiple mucosal and alimentary tract neuromas, medullary carcinoma of the thyroid, and pheochromocytoma).[108] A patient may be considered to have MEN I if two of the three principal MEN I–related tumors affecting the parathyroids, pancreatic islets, or anterior pituitary gland have occurred.[109] Patients with MEN I comprise approximately one-sixth of all patients with hyperparathyroidism, one-third of all patients with ZES, 4% of all patients with insulinoma, and a small fraction of patients with VIPoma, somatostatinoma, and glucagonoma syndromes.[110] The extent of organ involvement tends to increase with the patient's age, and the parathyroid glands are most frequently involved. In one extensively studied kindred, the frequency of parathyroid involvement was essentially 0% at 15 years of age and 100% at 40 years of age.[111] In that kindred, hyperparathyroidism always preceded hypergastrinemia. In another kindred, ZES in a child was the first manifestation.

Screening recommendations for first-degree relatives of patients with MEN I are shown in Table 47-5. To test for MEN I, molecular genetic testing using direct deoxyribonucleic acid (DNA) screening strategies is the preferred method of screening. Whereas screening family members in a MEN I family with a known mutation can be fast and inexpensive, screening for a mutation in a new MEN I family or proband is an expensive and laborious task.[112] Neuroendocrine tumors in these patients are frequently extrapancreatic (duodenum and lymph nodes) and multiple and are therefore rarely resectable. However, they are late to metastasize, and long survival is the rule.[110] The surgical management of ZES in MEN I is controversial. Some suggest annual screening of gastrinomas with SRS and resection when tumors attain 3 cm in size because metastases rarely occur when tumors are < 3 cm.[113] However, once the primary tumor is > 3 cm in MEN I, surgery does not prevent the development of metachronous liver metastases.[114] Therefore, most groups do not require such substantial tumor burdens, and many recommend operation if the imaged lesion is 1 cm.[115,116] Several believe that the goal in MEN I is cancer prevention and that surgery

TABLE 47-5 TEST SCHEDULES TO SCREEN FOR TUMOR EXPRESSION IN A HIGHLY LIKELY CARRIER OF MEN I MUTATION

TUMOR	AGE TO BEGIN (YR)	ANNUAL BIOCHEMICAL TESTS	IMAGING TESTS EVERY 3 YR
Parathyroid adenoma	8	Calcium (Ca^{++}), Parathyroid hormone	None
Gastrinoma	20	Gastrin*	None
Insulinoma	5	Fasting glucose, insulin	None
Other enteropancreatic	20	Chromogranin A, glucagon, proinsulin	SRS, CT scan or MRI
Anterior pituitary	5	PRL, IGF-I	MRI
Foregut carcinoid	20	None	CT scan

CT = computed tomography; IGF = insulin-like growth factor; MEN = multiple endocrine neoplasia; MRI = magnetic resonance imaging; PRL = prolactin; SRS = somatostatin receptor scintigraphy.
*Gastric acid output measured if gastrin is high; secretin-stimulated gastrin measured if gastrin is high or if gastric acid output is high.

should be performed if the biochemical diagnosis is unequivocal, even without other signs.[117] There may also be other benefits to more global treatment of MEN I; there is evidence that hypergastrinemia is significantly ameliorated by parathyroidectomy.[118]

Major morbidity from MEN I is rare in children. The earliest reported major morbidity in MEN I has been a pituitary macroadenoma in a 5 year old.[119] Clinically evident hyperparathyroidism in MEN I has been reported between the ages of 5 and 8 years. MEN I–associated prolactinomas have been reported in children ages 10 to 13 years. Gastrinoma, the other defining feature of MEN I, has not been seen earlier than age 12 years in MEN I.[35] MEN I–associated insulinoma has been described as early as age 6 years.[119] WDHA syndrome has not been reported in a patient with MEN I who is younger than 18 years of age. All or most of these prior reports of early-onset endocrinopathy have been anecdotal.

Patients with MEN II develop tumors of the thyroid (medullary carcinoma of the thyroid), adrenal medulla (pheochromocytoma), and, sometimes, parathyroid glands. The MEN II group has been divided into two subcategories, depending on the presence (B) or absence (A) of mucosal and intestinal neuromas. MEN IIA accounts for over 75% of MEN II.[120] The MEN IIB subcategory, also known as Sipple syndrome and on occasion referred to as MEN III, is particularly important to pediatric gastroenterologists because children with this disorder present with gastrointestinal symptoms and have a very high risk of developing malignant thyroid tumors. Early identification by regular monitoring of serum levels of calcitonin or thyroidectomy permits early intervention, the only hope of curing medullary carcinoma of the thyroid.

Infants with MEN IIB have feeding problems, including poor suck, colic, and constipation.[121] Severe constipation in the first year of life is common, and mistaken diagnoses of Hirschsprung disease or segmental dilatation of the colon have been made. Rectal or colonic biopsies show ganglioneuromatosis of the colon, which should suggest the diagnosis[122] and may also be seen in Cowden disease. Less common gastrointestinal manifestations have included vomiting and diarrhea; the diarrhea is felt to be the result of calcitonin secreted by the thyroid tumor. Patients usually do not develop hyperparathyroidism. As MEN IIB patients get older, they develop overt mucosal neuromas that appear as nodules on the buccal mucosa, lips, tongue, and eyelids, giving an everted appearance to the eyelids.[123] Photographs of these lesions are shown in Figure 47-2. A decreased upper-to-lower body ratio and corneal neuromas may also be seen. Older patients generally have a marfanoid habitus, and skeletal abnormalities, including pes cavus, slipped capital femoral epiphysis, scoliosis, and pectus excavatum, are very common. The tumors themselves may stain positive for cytokeratin, carcinoembryonic antigen, calcitonin, bombesin, chromogranin, serotonin, and Leu 7.[124]

All patients affected by MEN IIB develop medullary carcinoma of the thyroid, which responds poorly to therapy. The tumor is frequently multifocal and can develop at a very early age. Medullary carcinoma of the thyroid has been seen in a 2-year-old child with MEN IIA and in a 1-year-old child with MEN IIB.[125] Screening for *RET* mutations must be performed in patients suspected of having MEN IIA and IIB and has been suggested in all patients with Hirschsprung disease (for the rare possibility of identifying a *RET* overexpression mutation). Mutations of *RET* occur predominantly in one of six codons in MEN IIA and can be detected with a high likelihood of success.[126] Ninety-nine percent of MEN IIB patients have one of two mutations that can be detected by polymerase chain reaction and single-strand conformational polymorphism.[122,127] Children with MEN IIB should have a prophylactic thyroidectomy certainly by 4 years of age,[128,129] and some have proposed thyroidectomy within the first 6 months and preferably within the first month of life.[15] For all other conditions associated with *RET*-activating mutations, the precise mutation determines the age at which thyroidectomy must be performed.[15]

CARCINOID SYNDROME

The symptoms of carcinoid syndrome include episodic flushing, facial swelling, palpitations, abdominal pain, and explosive diarrhea.[130] Late accompaniments of the syndrome may include mesenteric fibrosis and endocardiac and cardiac valvular fibrosis. The syndrome is caused by tumors of enterochromaffin cells, and symptoms do not appear until the tumors are metastatic. The symptoms appear to be mediated primarily by serotonin, bradykinin, and histamine secreted by the tumor. The fibrosis appears

to be induced by serotonin. Mesenteric fibrosis can cause severe abdominal pain. The secretory diarrhea is thought to be mediated via various neurotransmitters, including serotonin and histamine.

Carcinoid tumors in children are usually seen as an incidental finding at appendectomy,[131] and malignant carcinoid syndrome in a child has only rarely been reported.[132,133] Appendiceal carcinoids less than 1 cm in diameter are treated by simple excision and are thought to have little or no risk of metastasis. Tumors larger than 2 cm in diameter are at risk of metastasis.[134] Right hemicolectomy is recommended for tumors > 2 cm to remove the regional lymph nodes to which these tumors metastasize.[134] Once the tumors are metastatic, some patients appear to have very indolent courses; others have rapidly progressive courses. Poor prognostic indicators include multiple liver metastases, the presence of carcinoid syndrome, and high levels of tumor markers. Diagnosis is made by measurement of 24-hour urine 5-hydroxyindoleacetic acid.[130] SRS is sensitive and can be used to localize primary and metastatic carcinoid tumors.[135] Positive SRS scans also predict the clinical response to somatostatin analogs.[136] Surgical resection and embolization of liver metastases can offer effective palliation and can prolong survival in selected patients.[137] The treatment of choice in metastatic disease is a somatostatin analog,[138] and octreotide has been particularly helpful in relieving the symptoms of carcinoid syndrome.[139] Depot preparations—octreotide (given every 4 weeks) and lanreotide (given every 2 weeks)—are also effective. These somatostatin analogs cause symptomatic improvement, biochemical improvement, and temporary cessation of tumor growth[140] and may rarely cause complete tumor regression.[141] Chemotherapy for carcinoids is confined to patients with metastatic disease who are symptomatic and when other treatments are ineffective.[63] In these cases, chemotherapy with streptozocin, 5-fluorouracil, doxorubicin (Adriamycin), and α-interferon, among other chemotherapeutic agents, has been useful.[142] Tumor-targeted treatment with radioactive somatostatin analogs has also been developed.[143]

SUMMARY

Neuroendocrine tumors affecting gut function are fascinating but rare; they manifest themselves through the products they secrete. Diagnosis requires an understanding of the special clinical features of these tumors and a focused and timely evaluation. Diagnosis should be followed by accurate localization of the tumor because resection of a localized tumor is usually curative. Where disease is advanced, debulking and a variety of potent drugs facilitate medical management.

CHAPTER 48

SYSTEMIC ENDOCRINOPATHIES

Jonathan E. Teitelbaum, MD

Systemic endocrinopathies have effects on multiple organ systems, including the gastrointestinal (GI) tract. Effects on the GI system are secondary to shared genetic susceptibilities (eg, diabetes and celiac disease [CD]), as well as altered homeostatic and metabolic functions (eg, hyperthyroidism and diarrhea). The pathophysiologic basis for these alterations is often poorly understood. In part, the effects can be meditated through the effects of the endocrinopathies on other organ systems, such as the enteric nervous system. Finally, because the endocrine system plays a vital role in organ development and growth, endocrinopathies have effects on both the developing gut and the mature intestine.

DIABETES MELLITUS

Previously called juvenile-onset diabetes, type 1 diabetes mellitus (DM) is a common, serious disease of childhood and adolescence. These patients are insulinopenic and require exogenous insulin to prevent ketosis and preserve life. The prevalence of type 1 diabetes in the United States among children and adolescence is between 1.2 and 1.9 cases per 1,000 members of this age group.[1]

Type 2 diabetes is most commonly found among adults and obese persons. Previously called adult-onset diabetes, this type of diabetes is the result of insulin resistance without adequate compensatory insulin secretion. Thus, a relative, not absolute, insulin deficiency occurs. Affected patients are not dependent on insulin for survival but may require exogenous insulin for metabolic control.

The diagnosis of diabetes in a child is rarely subtle. Most children present with classic symptoms of polyuria, polydipsia, polyphagia, weight loss, and lethargy. GI manifestations are well described (Table 48-1), although many adult studies will combine the data obtained from both type 1 and type 2 patients. Thus, one must be cautious in applying these findings to pediatric patients in whom type 1 disease is the most prevalent. Mechanisms leading to these GI disturbances include autonomic neuropathy, microangiopathy, hyperglycemia, electrolyte disturbances, and abnormalities in plasma insulin, glucagon, and other hormones, such as motilin and gastric inhibitory polypeptide.[2]

Infants of Diabetic Mothers

Gestational diabetes is defined as carbohydrate intolerance resulting in hyperglycemia of variable severity with onset during pregnancy irrespective of whether or not insulin is used for the treatment or if the condition persists after pregnancy. The frequency of gestational diabetes is variable and mirrors the frequency of type 2 diabetes in the population. In China and South India, the rate is 0.6%; in Australia, 15%; and in the United States, 4%.[3] A normal glucose tolerance test early in pregnancy does not exclude the development of this condition later in gestation. There are significant morbidities and mortality associated with children born to diabetic mothers. Indeed, an early description of these parents read, "They gave birth astride a grave, with a grave awaiting both the mother and fetus."[3] The mother is also at risk for preterm labor, pylonephritis, and hypertension.

Infants of diabetic mothers have been documented to have a large number of associated anomalies. The fetus carries an increased risk of abortion, congenital malformations, macrosomia, intrauterine growth retardation, trauma, asphyxia, respiratory distress syndrome, hypoglycemia, hypocalcemia, jaundice, and cardiomyopathy. Most important among these is the marked increase in perinatal mortality, with an incidence of up to 30% in those who have poorly controlled diabetes. This can be decreased to 2 to 4% with strict glycemic control throughout the pregnancy.[4] Thirty to 40% of these deaths are associated with congenital malformations. Overall, the incidence of such malformations is 6 to 13%, which is 2 to 4 times that seen in the general population.[4] In the Diabetes Control and Complication Trial, 1,441 type 1 diabetics had 270 births. If there was excellent glucose control (hemoglobin [Hb]A_{1c} 4.7 SD above the mean) during pregnancy, then the rate of congenital malformations and abortions was similar to that of the general population (0.7%).[3] Also in this group, the incidence of small for gestational age babies was 20% versus 11% in healthy controls.[5] However, conventional controls (HbA_{1c} 6.3 SD above the mean) had a rate of malformations of 5.9%. These results suggested that the goal should be to maintain a HbA_{1c} less than 5 SD above the mean.[3] The exact teratogen remains unknown, with the major candidates being hyperglycemia, hypoglycemia, increased ketones, effects of increased glycosylation products, changes in amino acid or prostaglandin profiles, and increased free radical production.

The children of diabetic mothers can demonstrate an increase in organ size, specifically the heart and liver, whereas the brain and kidney do not demonstrate visceromegaly. The etiology of hepatomegaly is based on the

TABLE 48-1 EFFECTS OF DIABETES MELLITUS ON THE GASTROINTESTINAL SYSTEM

ABNORMALITY/ASSOCIATION	GASTROINTESTINAL MANIFESTATION
Diabetic ketoacidosis	Nausea, anorexia, vomiting
Esophageal dysmotility	Dysphagia, reflux esophagitis
Esophageal candidiasis	Odynophagia, dysphagia
Gastroparesis/gastritis	Nausea, vomiting, gastric outlet obstruction
Small intestine dysmotility	Malabsorption, diarrhea, bacterial overgrowth
Impaired intestinal fluid reabsorption	Diabetic diarrhea
Celiac disease	Diarrhea, steatorrhea
Steatohepatitis	Abnormal transaminases, hepatic fibrosis
Hepatocellular carcinoma	Twofold increased risk
Cholelithiasis	Biliary sepsis

Adapted from Weber JR and Ryan JC.[86]

increase in maternal blood glucose. This increase causes a similar rise in fetal blood glucose. The fetus, therefore, has an appropriate increase in insulin production to obtain euglycemia. Insulin is the primary anabolic hormone in the growing fetus and results in visceromegaly. Macrosomia is the result of increased adipose tissue, and birth weight correlates with blood insulin levels.[6] Ultrasound monitoring of the fetus can be helpful in predicting fetal well-being. Measurements of fetal abdominal circumference (AC) between 29 and 33 weeks gestation can identify those infants with an AC greater than the 75th percentile. If these women are then treated with insulin, the rate of macrosomia is decreased from 45 to 13%. Those children who have a greater than 1.1 cm increase in their AC per week appear to be at risk for macrosomia. Vohr and colleagues reported that previously macrosomic infants who were followed up at the ages of 4 and 7 years had increased body size and adiposity compared with controls and those infants born to gestational diabetics who were born at the appropriate weight.[7]

Infants of diabetics are also noted to have increased levels of bilirubin. Whereas some suggest that prematurity, ABO incompatibility, red blood cell life span, or osmotic fragility accounted for this increase, other studies do not support a difference in these parameters between infants of diabetic mothers and normal infants.[4] Stevenson suggested that the delayed clearance of bilirubin was a factor.[8] However, polycythemia is felt to be the most important factor accounting for elevated levels of indirect bilirubin in this population.[4]

Neonatal small left colon was first described by Davis and colleagues in 1974. It results in a low obstruction of the large bowel, which clinically is manifest by failure to pass meconium in a timely fashion, tympanic abdominal distention, or bilious vomiting. Barium enema reveals smooth narrowing of the sigmoid and descending colon with proximal dilatation (Figure 48-1). An early series of 20 patients revealed that 17 did well after diagnostic or therapeutic enema.[9] Eight of the 20 (40%) had diabetic mothers. Perforation, typically of the cecum, also has been reported. The etiology is still unclear; theories include disorders of fetal colonic motility perhaps secondary to temporary ganglionic dysfunction.[10] Treatment is typically conservative, with initial parenteral nutrition and nasogastric decompression. At times, the barium enema has been therapeutic and allowed for a graded approach to feeding. The condition commonly resolves within the first 1 to 2 weeks of life.

Diabetic Ketoacidosis and GI Tract

Diabetic ketoacidosis (DKA) is commonly associated with GI symptoms such as nausea, anorexia, and vomiting. At times, the abdominal presentations are severe and raise concerns about coexistent appendicitis or other causes of an acute abdomen. Clinicians should recognize that the symptoms can be solely due to the associated metabolic derangements and will resolve with correction of the acidosis. The patient should be closely observed and correction of the metabolic disturbances undertaken prior to any invasive interventions.

Elevations of amylase may be present and raise concerns about pancreatitis. However, isoenzyme analysis often shows that the amylase is of salivary origin.[11] Marked dilatation of the stomach during DKA has been reported and resolves with nasogastric tube decompression.[12] Acute hypermagnesemia can also contribute to the dysmotility seen with DKA.[12] Upper GI hemorrhage has also been reported, typically secondary to erosive esophagitis,[13] and responds to acid blockade therapy.

Diabetes and GI Neuropathy

Because the motility of the GI tract is dependent on the enteric nervous system, neuropathic changes can adversely affect function. Neuropathic changes within the GI tract of diabetics are typically thought to occur over prolonged periods of time with poor diabetic control. Accordingly, diabetic neuropathy among diabetic children is a rare event. However, studies of neuropathic changes, as documented by alteration in nerve conduction and parasympathetic nerve function (R-R variations), have shown that 25% of children have evidence of low sensory nerve conduction and autonomic dysfunction at the time of diagnosis prior to achieving remission.[14] After 2 years of disease, deterioration in function was common, with a correlation between nerve conduction and glycemic control.[14]

Studies in adults suggest that over 75% of diabetics have GI symptoms related to neuropathy. Among this population, many have documented motility abnormalities, although such abnormalities correlate poorly with symptoms. Many explain this discordance as a possible underreporting of complaints, such as dysphagia or fullness.

The neuropathy associated with DM appears to be the result of altered sympathetic function and cholinergic denervation. Although there is damage to the vagus nerve resulting in vagal nerve dysfunction, most alterations are thought to be in the postganglionic nerves, sympathetic ganglia, and intramural adrenergic plexus. The sympathetic nerve dysfunction is particularly implicated in anal sphincter dysfunction. Others suggest that neurotransmitters (ie, an increase in vasoactive intestinal polypeptide) are the etiology of such dysfunction.[12] One must also consider the effects of polypharmacy and electrolyte disturbances on nerve function.

Histologically, nerves in patients with diabetic neuropathy can appear swollen, with irregular processes and vacuolization, and there can be fragmentation of dendrites or Schwann cells.[15]

Diabetes and Nonspecific Abdominal Pain

Owing to the altered intestinal motility associated with the autonomic neuropathy of long-standing diabetes, there has been an assumption that nonspecific abdominal pain is more common among patients with diabetes. Studies evaluating the prevalence of chronic dyspepsia and chronic constipation among diabetics are somewhat conflicting. Among children with diabetes, one uncontrolled study indicated that the prevalence of gastroesophageal reflux disease (GERD) was 7%.[16] Those affected had poor linear growth and more frequent hospital admissions. In contrast, a larger study of 118 children and adolescents with type 1 diabetes was unable to demonstrate a significant difference in the frequency of recurrent abdominal pain, chronic constipation, or chronic dyspepsia between those with diabetes and controls.[17]

A study of adult diabetics found no significant difference in the presence of upper and lower GI tract symptoms among 75 patients with type 1 diabetes compared with controls.[18] However, among 68 patients with type 2 diabetes, there is more constipation (22.1% vs 10.3%; $p < .05$) and nausea (11.8% vs. 2.9%; $p < .5$). The difference among those with type 2 diabetes is not likely to be due to autonomic neuropathy because diabetes duration and glycemic control did not influence the frequency of symptoms. It seems more likely that these changes are due to an altered pathophysiology in obese patients because obesity has been reported to result in increased amounts of GERD[19,20] and constipation.[21] A larger study by Xia and colleagues surveyed 429 diabetic patients (both type 1 [$n = 49$] and type 2 [$n = 380$]) and compared them with 170 controls. There was no difference in the percentage of patients with GI complaints such as epigastic pain, bloating, distention, early satiety, heartburn, nausea, or vomiting between diabetics and the controls (51% vs 44.7%).[22]

It is unclear if pancreatic transplant can reverse preexisting intestinal damage. However, in a study of 32 patients who underwent transplant, 24 of whom had GI symptoms, almost all (96%) had fewer GI complaints after transplant. One must be aware that with the transplant, the patients had correction of multiple metabolic derangements, so the underlying etiology of the improvement is unclear.[23]

Diabetes and the Esophagus

Alterations in esophageal function in children with diabetes are rare. The majority of reported abnormalities described are limited to case reports, including that of one child with a 4-year history of DM who presented with dysphagia and was found to have manometric features of a nutcracker esophagus.[24]

Although many adult patients with peripheral neuropathy secondary to DM have documented alterations in esophageal motility or gastric emptying, only 30% have clinical symptoms of chest pain, heartburn, or dysphagia. Motility disturbances documented by esophageal manometry reveal few alterations in upper esophageal sphincter function. However, the length of the esophagus can demonstrate a decrease in the amplitude of contractions, aperistaltic contractions, and prolonged contractions, as well as decreased lower esophageal sphincter tone.[12] Such peristaltic alterations can result in a prolonged esophageal transit time. This, along with possible alterations in the immune system,[25]can result in *Candida* esophagitis in this population, with resulting odynophagia.[26]

Diabetes and the Stomach

Gastroparesis in DM was first described in 1945.[27] Alterations in gastric emptying among pediatric diabetics are uncommon and mainly limited to case reports and small case series. Reid and colleagues described three children 1

to 7 years after the onset of diabetes with delayed gastric emptying and postprandial antral hypomotility.[28] Oduwole and colleagues described an adolescent with severe gastroparesis that developed despite good glycemic control and a HbA_{1c} of 7.4%, which normalized after 2 months of treatment with metoclopromide.[29]

Studies have documented delays in gastric emptying in up to 58% of adult diabetics. The onset of symptoms is typically insidious, with early satiety, decreased weight, anorexia, postprandial nausea and vomiting, and epigastric distress. A sense of fullness or bloating correlates with a delay in gastric emptying, whereas nausea and vomiting do not.[30] Physical examination may reveal a succession splash and gastric distention.

The gold standard of diagnosis is scintigraphy. The study should be done during a period of euglycemia, preferably using solids. The development of scintigraphic breath tests likely will be a useful screening tool in the future.[30] Alterations can be documented with a gastric emptying scan, and endoscopy or contrast radiography can rule out pathologic narrowing or obstruction.

The etiology of delayed gastric emptying appears to be due to vagal dysfunction. This dysfunction can be documented by a rise in serum gastrin and a fall in acid secretion during sham feeding.[31] Nerve dysfunction may be related to the direct effect of hyperglycemia on nerves. For instance, experimentally, neurons in the small intestine of rats are responsive to glucose concentration.[32] In diabetics, as well as normal subjects who experience acute hyperglycemia with serum glucose concentrations above 200 mg/dL, one can observe a marked delay in gastric emptying.[33,34] Motility studies reveal a decrease in the frequency of migrating motor complexes in patients with gastroparesis. This may account for the observed increase in motilin in these patients, perhaps as a compensatory change. These changes are reversed with the use of prokinetics.[35] In diabetic mice, interstitial cells of Cajal, which provide pacemaker activity for the stomach, are greatly depleted in the antrum. Accordingly, these mice have delayed gastric emptying.[36] However, such histologic changes have not been reported in humans.

Alteration in the fasting and fed pattern of these patients reveals that there are postcibal alterations in antral rhythm and poor receptive relaxation. Electrogastrography reveals alterations in the normal 3 counts per minute (cpm) electrical pace of the stomach such that one sees bradyrhythmias (1–2.5 cpm) and tachyrhythmias (3.7–10 cpm). Also, the perception of normal patients with nausea, fullness, and distention is more intense with increased levels of serum glucose.[30] Delaying emptying of a solid in the fasting state can contribute to bezoar formation.[12] In the postprandial state, antral contractions are decreased in number and amplitude. In addition, the pylorus exhibits prolonged high-amplitude contractions.[12]

Treatment of these motor disorders begins with better glycemic control. Dietary changes, with the introduction of smaller, more frequent meals and liquid supplements, can be beneficial. In addition, patients should be advised to consume diets with low amounts of residue to avoid bezoar formation.[12] Alternative treatments include gastric pacemakers and *Clostridium botulinum* toxin injection into the pylorus to improve gastric emptying.[37]

Pharmacotherapy is also helpful as adjunctive therapy. Antiemetics do not appear to help to any great degree. Prokinetics coordinate pyloric relaxation and duodenal peristalsis with smooth muscle contraction in the stomach, thus promoting improved gastric emptying.[38,39] Erythromycin, which stimulates the motilin receptor,[40] has had some effect, although some patients develop tachyphylaxis to the drug. A study in DM children with dyspepsia and delayed gastric emptying revealed that domperidone is superior to cisapride in reversing delayed gastric emptying and relieving clinical symptoms.[41] Rarely, recalcitrant patients require parenteral nutrition or transpyloric enteral tube feeding.

Other gastric alterations that have been described in DM include hemorrhagic gastritis, acute and chronic gastritis, atrophic gastritis, and pernicious anemia. The incidence of pernicious anemia among diabetics is 10.5 in 1,000 versus 2 in 1,000 in the general population.[12] Peptic ulcers among diabetics appear to occur at a lower rate compared with those of the general population. It is hypothesized that this is due to the increase in glucagon in response to the hyperglycemia, which subsequently decreases the production of gastric acid.[12]

Diabetes and Helicobacter pylori

Simon and colleagues were the first to suggest that *Helicobacter pylori* infection is more prevalent among patients with DM.[42] Some have hypothesized that the immune dysregulation associated with DM, coupled with the autonomic neuropathy that can lead to gastroparesis, places diabetics at increased risk for *H. pylori* infection. However, a large study by Xia and colleagues, including 429 patients with DM, found no difference in the incidence of *H. pylori* infection between the diabetic patients and controls (32.9% vs 31.7%).[22] Smaller studies of children with diabetes also found no difference in the overall rate of infection between the diabetics and controls.[43]

A study by Jones and colleagues comparing diabetic adults with *H. pylori* infection and those without found no difference in the number with GI symptoms, rate of gastric emptying, glycemic control, or autonomic function.[44] Indeed, the overall rate of infection with *H. pylori* was identical to that of the population without diabetes, indicating that DM is not a risk factor for infection. A study in Bangladesh of 520 DM patients came to the same conclusion.[45] This is in contrast to other studies, which report that DM patients with *H. pylori* have slower gastric emptying[46] or increased numbers of upper GI symptoms and subsequent improvement after eradication of the infection.[47,48]

It has been suggested that eradication of *H. pylori* among those with diabetes can result in better glycemic control; however, the evidence for such a change is weak. The proposed mechanism of this improvement is based on the ability of *H. pylori* to cause an increase in the production of various cytokines, including tumor necrosis factor-α, interferon-γ, and interleukins 1, 6, and 8.[49] In such studies, Begue and colleagues found no change in insulin require-

ments over the 2 years after eradication of *H. pylori*, but there was a modest decrease (2%) in their HbA_{1c} levels.[50] This is similar to another study, which found no difference in glycemic control after *H. pylori* eradication.[17]

Diabetes and Autoimmune Gastritis

Fifteen to 20% of DM patients have parietal cell antibodies (PCAs) compared with 2 to 10% of nondiabetic patients.[51,52] Thus, diabetic patients account for 20 to 40% of all PCA-positive patients. Such antibodies target the gastric proton pump (H/K adenosine triphosphatase) and are a serologic marker for autoimmune atrophic gastritis. This, in turn, is associated with iron deficiency anemia and pernicious anemia and may predispose the patient to gastric cancer and carcinoid tumors. A study of 229 diabetic patients found 69 to be PCA positive.[53] The presence of PCA was associated with human leukocyte antigen (HLA)-DQA1*0501-B1*0301. In those patients with PCA, there is a higher prevalence of iron deficiency anemia, pernicious anemia, autoimmune gastritis, and hypochlorhydria. Signs of preatrophic gastritis are also more common and documented by histologic features, including pronounced lymphocytic infiltration in the corpus mucosa and parietal atrophy of oxyntic glands. The presence of concomitant *H. pylori* infection does not represent a separate risk factor for these findings.[53] Similar studies in pediatric patients with DM are lacking.

Diabetes and Small Bowel Motility

Like other portions of the gut, small intestinal motility can be affected by the neuropathic changes of long-standing DM. Delayed intestinal transit can be seen in up to 33% of diabetics, as demonstrated by the breath hydrogen test.[54] This is due to decreases in the amplitude of contractions and alterations in migrating motor complexes.

Diabetes and Celiac Disease

In 1969, Walker-Smith and Grigor described an 8-year-old with DM who developed CD.[55] CD is associated with HLA-DQ2 and -DQ8; diabetes is also linked to the same DQ2 molecule.[56] In diabetes, it is the DQ molecule that influences the selection and binding to autoantigenic peptides.[56] The prevalence of CD in DM is 10 to 30 times that of the general population, with an incidence of 2 to 8.5%. The wide variation is based on how CD is defined, where using clinical symptoms and histology, the incidence is at the lower end, 2%. If, however, seropositivity is the defining characteristic, then the incidence is 8 to 9%.[57] Among children of type 1 diabetics, 3.5% have CD.[58] CD does not appear to be increased among patients with type 2 diabetes.[58]

A meta-analysis of 20 studies evaluating the incidence of a dual diagnosis of CD and DM found rates in children between 1 in 6 (16.4%) and 1 in 103 (0.97%).[57] If one excludes the study from Algeria, which accounted for the highest prevalence, the remainder of the studies reported a prevalence between 0.97 and 6.2%. In adults, a meta-analysis of 10 studies revealed rates ranging from 1 in 16 (6.4%) to 1 in 76 (1.3%).[57]

A large study by Pocecco and Ventura evaluated 4,500 type 1 diabetics and found two subgroups of patients.[56] The first group included those with type 1 DM who were later found to have "silent CD"; this represented 88% of the dual-diagnosis cases. The second group was those with prediagnosed CD who were later found to have type 1 DM, representing 12% of the cases. Group 1 had minimal GI symptoms and was diagnosed with CD between 11 and 17 years of age. Group 2, however, experienced numerous GI symptoms and was diagnosed with CD at younger ages (between 6 and 10 years). It is thought that the later age at which CD was diagnosed among the group 1 patients was due to the minimal GI symptoms they exhibited. Indeed, in some studies, short stature is the only sign, accounting for up to 33% of the patients.[57] Maki and colleagues screened 238 DM patients with immunoglobulin A antireticulin antibodies (ARAs), and 16 were positive.[59] However, of these, 11 were negative at first screening. CD was confirmed in 9, with typical changes on small bowel histology. Of note, 2 children had a negative ARA and normal small intestinal biopsy at the time of DM diagnosis. One then developed rising ARA titers and after 2 years had flat villi on biopsy. The other child had a positive ARA, but after 8 years, villi were still normal even though there were increased numbers of intraepithelial lymphocytes. The authors recommend that DM patients undergo yearly CD screening.[59]

If the patient had clinical symptoms of CD, then the gluten-free diet typically results in improved diabetic control.[57] However, in those patients who were diagnosed by routine screening alone, studies are varied, with some revealing no improvement in glycemic control, whereas others show better control or fewer hypoglycemic events.[57]

Similarities in peptide sequences can result in a cross-reaction of epitopes at the T-cell level. However, it is unclear whether such similarities exist between gliadin and tissue transglutaminase and glutamic acid decarboxylase or insulin. If such cross-reactivity does exist, then the coexistence of DM and CD can be explained by "molecular mimicry."[56] A study of nonobese diabetic rats provided regular chow versus a gluten-free diet for 320 days decreased the incidence of type 1 diabetes from 64 to 15%.[60]

Diabetes and the Liver

The most common cause of elevated transaminase levels or hepatomegaly among patients with diabetes is steatosis. This is the result of deposition of large, macronodular fat droplets within the parenchyma of the liver. When the fat deposition is associated with an inflammatory infiltrate, one can make a histologic diagnosis of nonalcoholic steatohepatitis, which, in some instances, can progress to fibrosis and cirrhosis.[61] The predominant lipid deposited is the triglyceride, but fatty acids also contribute to the toxic effects. The accumulation is the result of fatty acids brought to the liver at a rate greater than the liver can either metabolize the fatty acid or secrete very-low-density lipoprotein. Furthermore, the increase in liver size can be secondary to increased glycogen stores.[62] Overall, fatty liver is diagnosed in 4.5 to 17% of type 1 diabetics. It typically reflects poor glycemic control and resolves with better control of the diabetes. In type 2 diabetics, the incidence of fatty liver is 45%. This suggests that the increase in inci-

dence among type 2 diabetics is likely secondary to obesity rather than the diabetes itself. However, some studies suggest that histologic evidence of steatosis is even more common than appreciated by transaminase elevation or imaging alone. For example, one study of 68 insulin-treated children found evidence of increased glycogen in the cytoplasm and nucleus of hepatocytes in 58%.[63]

Imaging of the liver with computed tomography or ultrasonography can be helpful in identifying the respective enhancement or echogenicity associated with fatty liver. The degree of transaminase elevation does not correlate to the degree of liver injury. Treatments include weight loss, better glycemic control, and, possibly, vitamin E supplementation.[64] Rapid weight loss can be detrimental, and it is therefore suggested that the loss be no faster than 1.6 kg/wk.

Mauriac syndrome refers to hepatomegaly associated with increased glycogen stores, hypoglycemia, dwarfism, and a cushingoid appearance. Previously, it was described in patients classified as brittle diabetics.[65] This is less frequently seen owing to advances in insulin preparations and glucose monitoring. The disease results from increased serum glucose leading to moderate hepatic glycogen accumulation, which subsequently inactivates glycogen phosphorylase. This inactivation leads to an inhibition of glycogenolysis and increased glycogen synthase and a subsequent increase in glycogen stores. Treatment with insulin results in continued activation of glycogen synthase and further glycogen accumulation. Hypercortisolism is thought to be responsible for the growth retardation and delayed puberty. Better glycemic control results in resolution of the syndrome.

Among diabetics receiving peritoneal dialysis with added insulin, there is a risk of developing subcapsular fatty changes.[62] Also, hepatocellular carcinoma is twice as prevalent in diabetic patients.[12]

Diabetes and Biliary Function

An increase in the frequency of cholecystitis and cholelithiasis is seen in adult diabetics, with the risk of cholelithiasis being twice that of the general population.[12] These increases in prevalence are thought to be secondary to decreased motility and a lithogenic bile composition.[12] Despite these increases in risk, the routine practice of cholecystectomy among diabetics has fallen out of favor.

A study of 20 diabetic children found that the fasting gallbladder volume in these children was greater than that in controls. However, there was no difference in ejection fraction or maximal contraction between the two groups.[66] It is questioned whether the dilation of the gallbladder heralds future autonomic neuropathy and an increased risk for gallstone formation. In addition, there is an increased risk of ascending cholangitis. Reports of organisms, such as *Yersinia enterocolitica*,[67] have rarely been found to be causative.

Diabetes and the Exocrine Pancreas

Thirty percent of adult diabetics have decreased exocrine pancreatic secretion, although this is typically not associated with clinical symptoms. The decrease is likely due to glucagon excess, malnutrition, vagal nerve dysfunction, and a decrease in insulin effects. Among those diabetics who consume alcohol, there is a two- to fourfold risk of adenocarcinoma of the pancreas compared with that of the general adult population.[12]

Diabetic Diarrhea

Diabetic-associated diarrhea can occur in up to 20% of patients with DM. It is typically worse at night and more common among males. The etiology is likely multifactorial and can be associated with rapid intestinal transit or a defect in adrenergic stimulation of colonic water reabsorption. One should consider confounding causes such as drugs, including sorbitol found in sugar-free foods,[68] and small bowel bacterial overgrowth.[69] Some studies suggest that clonidine can aid in increasing water reabsorption. Octreotide has also been used to decrease the diarrhea.[15] Among those with diarrhea, 40% suffer from fecal incontinence. This is hypothesized to be secondary to decreased anal sphincter tone and decreased sensation to rectal distention. Although diarrhea is a relatively common complaint among young diabetics, the disabling form of autonomic diabetic diarrhea rarely begins before middle age. One should thus consider other causes, including those confounders mentioned above, routine enteric infections, and CD in DM children with persistent diarrhea.

AUTOIMMUNE POLYGLANDULAR SYNDROME

Autoimmune polyglandular syndrome type I (Online Mendelian Inheritance in Man [OMIM] #240300), also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, is typically an autosomal recessive disease. The disease is characterized by a combination of the following:

1. Failure of parathyroid, adrenal cortex, gonads, beta islet cells, parietal cells, and thyroid and/or hepatitis
2. Chronic mucocutaneous candidiasis
3. Dystrophy of dental enamel, nails, alopecia, vitiligo, and/or keratopathy[70]

Patients are typically of Iranian, Jewish, Finnish, or Scandinavian descent.[71] A multicenter review of patients with chronic mucocutaneous candidiasis demonstrated that 50% later developed disease components typical of autoimmune polyglandular syndrome.[72] Finland has published the largest cohort of these patients,[70]encompassing a group of 68 patients, with a mean follow-up of 11.2 years between 1910 and 1988. Owing to a founder effect, one major mutation accounts for approximately 90% of these cases. Linkage studies identified a gene at chromosome 21q22.3. This gene, likely a transcription regulator, has been cloned and named autoimmune regulator 1.[71]

Within the Finnish group, the number of endocrine organs involved varied between 1 and 8, with most having 4.[70] Hypoparathyroidism is the most common (79%) and was diagnosed between 19 months and 44 years of age. Adrenocortical failure is second at 72%, being diagnosed between 4.2 and 41 years. Cortisol and aldosterone deficiency occur at the same time in 38 of 49 patients. Gonadal failure occurs in 60% of females and 14% of males, all by

age 30 years. Diabetes is diagnosed in 12% and vitamin B_{12} deficiency in 13%. Rarely, patients have been documented to have coexistent CD[73] or intestinal lymphangiectasia.[74]

The majority of patients (78%) have documented nonendocrine manifestations prior to the first endocrinopathy. In 60% of cases, this includes oral candidiasis, 9% malabsorption, 4% keratopathy, and 1 case of hepatitis. Endocrine problems arose at mean ages of 8.7 years for the first endocrinopathy, 13.3 years for the second, and 16 years for the third. In those patients with adrenal failure as their first endocrinopathy, they had fewer additional organs involved. However, those patients with malabsorption or keratopathy as their first manifestation often had five subsequent organs involved.

All patients have oral candidiasis, the onset of which varies between 1 month and 21 years. Nail involvement is seen in 71% and dermal involvement, typically the hands and face, in 9%. Four patients have had documented esophageal candidiasis, one with a stricture. However, an additional 11 patients had retrosternal pain that resolved with antifungal treatment. Malabsorption was documented in 18% at 4 months to 21 years from onset of disease. All but one of these patients had decreased parathyroid function, and decreased serum calcium appears to correlate with the malabsorption. Of the 43 patients evaluated, 33 had evidence of dental enamel hypoplasia unrelated to hypoparathyroid status. Patients also appear to be at a greater risk for developing carcinoma of the oral mucosa, likely owing to the chronic candidiasis.

Overall, autoimmune hepatitis appears to be a component of the disease in 10 to 18% of patients.[70] Indeed, there are reports in which a sudden onset of hepatitis resulted in death. The first hepatic autoantigen in these patients was identified as cytochrome P-450 1A2.[75] A second autoantigen was identified as aromatic-L-amino acid decarboxylase (AADC).[76] This enzyme, active in the biosynthesis of neurotransmitters, is expressed in the cytosol and was originally described as a beta-cell autoantigen. Among the Finnish cohort, 50% of those tested had AADC autoantibodies. However, up to 92% of autoimmune polyglandular syndrome type I patients with vitiligo and autoimmune hepatitis had such antibodies.[71]

HYPERPARATHYROIDISM

Primary hyperparathyroidism (PHPT) is a rare condition in childhood and often goes undiagnosed. The disease is identified in those patients with hypercalcemia, low-normal phosphate level, and elevated parathyroid hormone. Since its initial description in 1939, approximately 100 cases have been reported among children and adolescents less than 16 years.[77] The etiology of the disease is similar to that of adults, with sporadic adenomas being causative. Rarely, the hyperparathyroidism is a manifestation of a systemic disease such as multiple endocrine neoplasia type I or II. Fewer than 40 neonatal cases have been reported. Here the etiology involves hyperplasia of the parathyroid chief cells. The clinical manifestations of hypercalcemia include muscle weakness, paralysis, and hyporeflexia. GI symptoms (Table 48-2) may be absent or nonspecific, including fatigue, poor appetite, weight loss, abdominal pain, nausea, constipation, peptic ulcer disease, and vomiting.[77] A case report of an adolescent with hyperparathyroidism revealed that hypercalcemia was the etiology of his acute pancreatitis.[78] Abdominal symptoms appear to be seen more frequently among children affected by PHPT than adults, 8% versus 1%, respectively.[79] Nephrocalcinosis has been described in 30 to 70% of PHPT children. Severe pancreatitis immediately following parathyroidectomy for PHPT may occur in as many as 3% of patients.[80]

HYPOPARATHYROIDISM

Hypoparathyroidism among children is rare, although it can be part of other systemic syndromes such as autoimmune polyglandular syndrome, Pearson marrow pancreas syndrome, and DiGeorge syndrome. Biochemically, there is hypocalcemia, hyperphosphatemia, and decreased parathyroid hormone levels. The clinical manifestations of hypocalcemia predominate and result in neuromuscular instability with seizure, tetany, paresthesias, laryngospasm, bronchospasm, or prolonged Q–Tc. Idiopathic hypoparathyroidism is also associated with malabsorption, pernicious anemia, and Addison disease. Indeed, approximately 11% of those with decreased parathyroid function have chronic diarrhea or steatorrhea.[81]

The mechanisms by which parathormone is involved in intestinal absorption are unknown, but symptoms of malabsorption may be the earliest sign of hypoparathyroidism. The diarrhea typically ceases with vitamin D therapy.[81] It has been noted that magnesium deficiency must be ruled out in patients who present with malabsorption and findings of hypoparathyroidism because functional hypoparathyroidism occurs in patients with severe and prolonged hypomagnesemia.[82] Intestinal lymphangiectasia with protein-losing enteropathy also has been reported in association with malabsorption and hypoparathyroidism.[83]

TABLE 48-2 EFFECTS OF HYPERPARATHYROIDISM ON THE GASTROINTESTINAL SYSTEM

ABNORMALITY/ASSOCIATION	GASTROINTESTINAL MANIFESTATION
Increased serum calcium	Constipation, nausea, vomiting
Peptic ulceration	Bleeding, abdominal pain, perforation
Pancreatitis	Acute pancreatitis
Multiple endocrine neoplasia type I	Gastrinoma, VIPoma

Adapted from Weber JR and Ryan JC.[86]
VIPoma = vasoactive intestinal peptide–secreting tumor.

TABLE 48-3 EFFECTS OF HYPOTHYROIDISM ON THE GASTROINTESTINAL SYSTEM

ABNORMALITY/ASSOCIATION	GASTROINTESTINAL MANIFESTATION
Altered colonic function/transit	Constipation, pseudo-obstruction
Impaired esophageal motility	Reflux esophagitis
Liver test abnormalities	Normal histology, prolonged neonatal jaundice
Celiac disease	Diarrhea, steatorrhea

Adapted from Weber JR and Ryan JC.[86]

GI problems similar to but less severe than those found in hypoparathyroidism are found in pseudohypoparathyroidism, but plasma parathyroid hormone levels are high.

HYPOTHYROIDISM

Hypothyroidism is defined as a state in which the thyroid gland fails to secrete sufficient quantities of thyroid hormone. Congenital hypothyroidism has been associated with GI manifestations (Table 48-3), including constipation, feeding difficulties, and prolonged neonatal jaundice. The frequency of CD in patients with autoimmune thyroid disease is 4.3% compared with 0.4% for nonautoimmune hypothyroid controls.[56] The association is likely due to a common genetic predisposition, namely the DQ2 allele.

Among hypothyroid adults, studies show that affected patients have an average of three bowel movements a week (range of 1–7/wk).[84] Studies to determine the pathophysiologic basis of the constipation include anorectal manometry studies, which reveal that hypothyroid individuals have normal maximal resting and squeeze pressures. However, sensation threshold for impending evacuation is greater than that for controls. There is no change in whole-gut transit time.[84] Although there is evidence of increased vasoactive intestinal peptide expression from the anterior pituitary of hypothyroid rats, it is unlikely that these changes play a pathophysiologic role in GI disorders seen with hypothyroidism.[85]

Myxedema has also been associated with decreased esophageal peristalsis and impaired lower esophageal sphincter function, resulting in reflux esophagitis. Hypothyroidism can also cause severe gastric hypomotility and secondary pseudo-obstruction.[86]

Studies of hypothyroid murine models reveal that hypothyroidism decreases the deoxyribonucleic acid (DNA) and protein content of the intestinal mucosa. Villi in the jejunum appear shorter, as does crypt depth. In addition, hypothyroidism decreases the rates of glucose and glutamine use by epithelial cells of the small intestine and colon.[87]

Liver transaminases are mildly abnormal in 50% of hypothyroid patients; however, liver histology is typically normal.[88] Hypothyroidism can cause exudative ascites in the absence of overt liver disease.[86] Rarely, one can have associated chronic active hepatitis, diabetes mellitus, or Cronkhite-Canada syndrome. Hashimoto thyroiditis has also been associated with ulcerative colitis.[86]

HYPERTHYROIDISM

Hyperthyroidism occurs when excessive amounts of circulating thyroid hormone are present. Hyperthyroidism (Table 48-4) has been associated with diarrhea, with some studies showing that such individuals pass an average of 14 bowel movements per week (range 7–21/wk).[24] Attempts at discerning the etiology of the diarrhea include anorectal manometry studies, which reveal that hyperthyroid individuals have a lower maximal resting pressure and maximal squeeze pressure compared with those of controls.[84] In addition, they have a lower threshold sensation for impending evacuation.[84]

Studies of intestinal motility reveal no difference in gastric emptying between controls and hyperthyroid adults. However, hyperthyroid individuals have accelerated small bowel and colonic transit. Small bowel transit time appears to be inversely related to triiodothyronine (T_3) concentrations.[89] Indeed, increased small intestinal myoelectric activity has been reported.[90] This presumably accounts for the GI symptoms and diarrhea exhibited by hyperthyroid individuals. However, there is also evidence for a secretory component to the diarrhea because thyroid hormone can cause increased intestinal secretion via an increase in intracellular levels of cyclic adenosine monophosphate.[86] Changes in intestinal transit appear to normalize once patients are rendered euthyroid.[91]

Hyperthyroidism may cause myopathy, resulting in dysfunction of the striated muscles of the pharynx and proximal esophagus. Decreased propulsive force of the muscles and abnormal closure of the upper esophageal sphincter can result in dysphagia and aspiration. Esophageal peristalsis is increased in thyrotoxic patients.[86]

Appreciation of the GI disturbances in thyroid disease is often overshadowed by other organ dysfunction, including that of the cardiovascular, neuromuscular, and ocular systems. Of note, Graves disease is associated with ulcerative colitis.[86] Also, hyperthyroidism is associated with minor histologic changes in the liver. One can detect mildly ele-

TABLE 48-4 EFFECTS OF HYPERTHYROIDISM ON THE GASTROINTESTINAL SYSTEM

ABNORMALITY/ASSOCIATION	GASTROINTESTINAL MANIFESTATION
Accelerated intestinal transit	Diarrhea
Myopathy of the upper esophagus	Dysphagia
Liver test abnormalities	Minor histologic changes
Ulcerative colitis	Bloody diarrhea

Adapted from Weber JR and Ryan JC.[86]

vated transaminases in approximately 33% of patients, and 5% have an unconjugated hyperbilirubinemia.[86]

PITUITARY HORMONES

Pituitary hormones have important effects on the gut. Adrenocorticotropic hormone stimulates cortisol secretion and enhances brush border enzyme activity, and thyrotropin-stimulating hormone causes thyroxine secretion, with major effects on gut motility.[92] Growth hormone causes intestinal villus growth and enhances absorption.[93] Infants with intrauterine hypopituitarism may present at birth with hypoglycemia, prolonged jaundice,[94] and, in males, micropenis and undescended testes. Excessive secretion of pituitary growth hormone results in acromegaly, which is associated with an increased incidence of adenomatous colonic polyps and cancers of the colon and stomach.[86]

HYPOADRENOCORTICISM

The adrenal cortex secretes glucocorticoids and mineralocorticoids. Glucocorticoids bind to specific cytoplasmic receptors on the enterocyte, and the activated receptor-steroid complex is translocated to the nucleus, where it triggers the synthesis of messenger ribonucleic acid. The net effect is to increase the absorptive capacity of the small intestine and enhance brush border membrane digestive capacity without increasing the number of cells.[95] The dominant GI effect of adrenal gland disorders is related to abnormalities of aldosterone metabolism. Although the effect of increased aldosterone production in increasing sodium absorption in the colon is overshadowed by its effect on the kidney, lack of aldosterone production and end-organ failure to respond to aldosterone are often associated with marked intestinal salt wasting in addition to urinary losses.[96] Thus, in salt-losing states associated with hyperadrenocorticism, the intestinal losses contribute to dehydration.

Some patients with Addison disease have steatorrhea with normal jejunal histology,[97] which resolves with hormone replacement. GI symptoms can include anorexia, weight loss, vomiting, and abdominal pain. There is a high incidence of associated anomalies in children with Addison disease, including autoimmune polyglandular syndrome, adrenoleukodystrophy, and AAA syndrome (Addison disease, achalasia, and alacrimation).

DIENCEPHALIC SYNDROME

Diencephalic syndrome is a complex of signs and symptoms related to hypothalamic dysfunction. The association between brain tumors of the anterior hypothalamus and severe failure to thrive is almost exclusively seen in infants and young children, with 85% occurring at ages less than 2 years.[98] Most patients have space-occupying lesions in the region of the optic chiasm, typically a low-grade, slow-growing glioma or a juvenile pilocytic astrocytoma.

Three major features include failure to thrive in spite of normal energy intake, motor hyperactivity, and apparent euphoria. Autonomic disturbances include skin pallor, profuse sweating, and erratic temperature control. Rotatory nystagmus may be the only neurologic sign.[98]

At the time of diagnosis, length is typically maintained and head circumference is normal, except in the 33 to 58% with hydrocephalus. Vomiting occurs in 68% of affected patients.[98] The etiology of the extreme loss of subcutaneous fatty tissue is unclear. Some suspect increased lipolysis secondary to elevated growth hormone excretion, whereas others feel that it is the effect of the tumor on the satiety center.[98] There is some evidence that these patients have a 30 to 50% increase in resting energy expenditure.[99] Optimal treatment involves complete tumor resection, although this is not always possible. Chemotherapy and radiation have also proven effective.

CHAPTER 49

APPROACH TO NEONATAL CHOLESTASIS

Valerie A. McLin, MD
William F. Balistreri, MD

Cholestasis, defined physiologically as a reduction in canalicular bile flow, is primarily manifested as conjugated hyperbilirubinemia. The major clinical consequences, however, are presumably related to retention of other substances, such as bile acids, which are dependent on bile flow for excretion. The attendant histopathologic features often reflect the nature and degree of the physiologic disturbance and imply the pathophysiologic basis.

There are multiple causes of cholestasis in early life, related either to the response of the neonatal liver to exogenous agents or to specific congenital pathologic conditions. Immature hepatic excretory function creates a milieu wherein infants are susceptible to further impairment of biliary excretion owing to infectious or metabolic insults. Although recognized disorders associated with neonatal cholestasis are numerous, the majority of cases fall into a few discrete and overlapping categories, one of the more frequent ones being the generic "neonatal hepatitis."

Efforts are being made to alert generalists and specialists worldwide to recognize the neonate with cholestasis at the earliest opportunity. Nevertheless, evaluation of the infant with cholestasis remains a difficult task owing to the diversity of cholestatic syndromes, to their obscure pathogenesis, and to the often nonspecific clinical and pathologic presentation. Prompt identification and diagnostic assessment of the infant with cholestasis are imperative to recognize disorders amenable either to specific medical therapy (eg, galactosemia, sepsis) or to early surgical intervention (eg, biliary atresia) and to institute effective nutritional and medical support to allow optimal growth and development. Although the advent of pediatric liver transplant has saved many, early intervention may avoid the need for organ replacement in some of these patients. For example, in tyrosinemia, a nontransplant option is now readily available and efficacious.

DEVELOPMENTAL PHYSIOLOGY OF HEPATOBILIARY FUNCTION

Although comprehension of liver and biliary development is still at the embryonal stage, it is known that the extrahepatic biliary tree develops from an outgrowth of the ventral foregut, whereas the intrahepatic tree differentiates from the multipotent hepatoblast in a centrifugal fashion.[1] Furthermore, the physiology of bile flow in the adult is well described, and its understanding may assist in the approach of the cholestatic infant and the interpretation of laboratory tests. However, it is paramount to remember that the liver of the term infant is "immature" both in its metabolic and excretory functions. With the increased survival of very premature infants, pediatricians, neonatologists, and gastroenterologists are more likely to be confronted by cholestasis and abnormal liver tests. Thus, a basic understanding of physiology, together with prompt recognition and management, should help improve the outcome of these patients. Our goal is to discuss the expeditious and cost-effective approach to the infant with conjugated hyperbilirubinemia, allowing recognition of those who need specialized care.

Bile flow has traditionally been divided into two components: (1) bile acid–dependent flow, which involves active canalicular transport of bile acids, accompanied by osmotic water flow and diffusion of other solutes, and (2) bile acid–independent flow, which is thought to be mediated by active transport of other anions and cations.[2] The primary motive force in the generation of bile flow in early life is the hepatocytic secretion of bile acids; there is little contribution of the bile acid–independent component during the neonatal period.[3] The hepatobiliary excretory system is both functionally and anatomically underdeveloped at birth, leaving the neonate with a unique propensity toward cholestasis.[4–6]

Substantial evidence supports the existence of a period of "physiologic cholestasis" associated with immature or altered metabolism and transport of bile acids at birth (Table 49-1). Serum bile acid concentrations, which reflect the net efficiency of intestinal absorption and hepatobiliary function, are maintained at low levels in the fetus by carrier-mediated transplacental transport to the mother.[7–9] Postnatally, in the normal infant, both fasting and postprandial serum bile acid concentrations are significantly higher than those found in older children. These levels are similar to those attained in adults with cholestatic disease[10,11] and persist through the first several months of life. Factors contributing to decreased bile flow and inefficient enterohepatic cycling of bile acids in the neonate include (1) inefficient intestinal and hepatic bile acid uptake owing to the pace of ontogenic expression of bile acid transport proteins, (2) qualitative and quantitative deficiencies of bile acid synthesis, (3) immature hepatic bile acid metabolism, and (4) inefficient hepatocellular secretion.[12]

The suckling rat model has been used extensively in studies of the developing hepatobiliary system.[13,14] Lower rates of hepatic uptake of bile acids have been demonstrated in experimental systems such as isolated hepatocytes[15] and purified basolateral (sinusoidal) membrane vesicles of developing rats,[16,17] reflecting immaturity of sodium-coupled bile acid transport. This appears to be secondary to reduced expression of specific transport proteins.[18] In the adult rat, avid extraction of bile acids by periportal hepatocytes results in a decreasing periportal to central lobular gradient for bile acid uptake.[19,20] Using similar radioautographic techniques, no acinar gradient could be demonstrated in the 14-day-old rat liver,[21] further supporting the concept of inefficient uptake of bile acids. There is enhanced efflux of taurocholate from suckling rat hepatocytes, which may represent back-diffusion across the sinusoidal membrane; this also contributes to the inefficient hepatic bile acid transport.[22] In the ileum, a similar developmental pattern for the transport of bile acids can be demonstrated, with decreased active bile acid uptake during the suckling period.[23,24] There is significant passive absorption of bile acids in the jejunum of suckling rats, which may combine with decreased hepatic uptake to lead to decreased intraluminal concentrations of some bile acids.[25] A recent study in rats looked at the correlation between intestinal resection length and expression of the apical sodium bile acid transporter. The authors reasoned that there may be an intestinal length "threshold" that determines whether the apical sodium bile acid transporter is up- or down-regulated in response to ileal resection. In parallel, hepatic synthesis of bile acids increases to compensate for decreased absorption up to a certain level, later decreasing when the bile acid pool is severely reduced. These findings are important for two reasons: they illustrate the plasticity of infant bile acid physiology and they offer a hypothesis for the pathogenesis of cholestasis in patients with short bowel.[26]

TABLE 49-1 MANIFESTATIONS OF UNDERDEVELOPED BILE ACID TRANSPORT AND METABOLISM IN EARLY LIFE

Increased serum bile acid levels (physiologic cholestasis)
Decreased hepatic uptake of bile acids from portal blood
Absent lobular gradient
Qualitative and quantitative differences in bile acid synthesis
Decreased conjugation, sulfation, and glucuronidation of bile acids
Enhanced bile acid efflux from hepatocyte
Decreased bile acid secretion rate
Decreased bile acid pool size
Low intraluminal concentrations of bile acids
Decreased ileal active transport of bile acids

Quantitative and qualitative differences in bile acid synthetic pathways are also apparent during early life. Bile acid synthesis begins on day 11 of the 21-day gestation in the rat[27] and near week 12 in the human fetus.[28] A decreased cholate-to-chenodeoxycholate ratio has been observed in the human fetus compared with that of the adult, indicating immaturity of hepatic α-hydroxylation.[29–31] It is believed that a "threshold"' concentration of cholic acid, the primary bile acid, is needed to initiate and maintain bile flow. Cholic acid may be trophic to the developing hepatic excretory system. In the absence of sufficient quantities of cholic acid, there is decreased bile flow.

The immaturity of bile acid synthetic function is also reflected in the presence of "atypical" bile acids found in the fetus and normal neonate.[30,31] Certain of these atypical bile acids, such as the monohydroxylated compound 3-β-hydroxy-5-Δ-cholenoic acid, which has been detected in amniotic fluid[32] and meconium,[33,34] are thought to directly impair bile acid excretion. Significant amounts of nonsulfated tetrahydroxylated bile acids have been identified in the urine of healthy neonates[35] and in the urine of older children and adults with cholestatic liver disease.[33] This polyhydroxylation may increase bile acid solubility, providing a potential alternative pathway for excretion of "toxic" bile acids at a time when transformation and biliary secretion are not fully developed.

Although the mechanisms of intracellular biotransformation of bile acids are not well defined, there is evidence that both the conjugation and sulfation of these organic anions are underdeveloped in early life.[36,37] Conjugation of bile acids with the amino acids taurine and glycine provides a potential mechanism for detoxification and allows efficient intestinal fat digestion and absorption. In isolated hepatocytes obtained from fetal and suckling rats, the rate of conjugation of a radiolabeled bile acid was shown to increase with postnatal age.[37]

The development of effective bile acid secretion from the hepatocyte appears to lag behind the onset of bile acid synthesis, as would be expected if cholic acid truly plays a trophic role. This is suggested by studies of the distribution of the bile acid (taurocholate) pool in fetal and newborn rats.[38] In the fetus, more than 85% of the bile acid pool is localized in the liver, with only 10% found in the intestinal lumen. By postnatal day 5, this distribution is reversed, with more than 85% of the bile acid pool localized in the intestine. Canalicular excretion of bile acids appears to be the rate-limiting step. Reduced canalicular excretion of bile acids in the fetus appears to be related to an immaturity of the canalicular membrane transport sys-

tems for bile acids. The potential-dependent transport protein is not detected in rat liver until postnatal day 7, and transport does not occur until day 14.[39] The adenosine triphosphate–dependent portion of the transport system, however, appears to be functional in the neonatal period and may play a role in bile acid secretion.[40] It has been recognized recently that the regulation of bile acid synthesis occurs by a feedback mechanism involving the nuclear receptor farnesoid X.[41] One can speculate that as these feedback loops mature, they may participate in the imbalance between the hepatocellular bile acid pool and canalicular excretory function. Furthermore, the same ontogenic principles apply to other metabolic pathways and transporters localized on hepatocytes and biliary epithelial cells. Thus, metabolism and excretion of xenobiotics (eg, bacterial toxins, maternal drugs) into bile are likely to be both modified by and potentially exacerbate cholestasis by imposing further demand on the immature liver, especially in the sick newborn. Thus, when investigating an infant with cholestasis, especially a preterm infant, one must look beyond the liver because cholestasis is a nonspecific response to a wide variety of insults in the infant.[42]

During fetal development, canaliculi differentiate from simple intracellular invaginations of two adjacent cell membranes into well-defined structural lumina filled with microvilli.[43] Specific changes in the pericanalicular cytoskeleton, which has been implicated in promotion of bile formation, are also noted during development. Compared with adult cells, cultured fetal hepatocytes have a decreased frequency and force of canalicular contractions, which appear to be related to a lack of pericanalicular cytoplasmic actin.[44] Structural immaturity of both the canaliculi and the pericanalicular cytoskeleton may be significant factors in impaired bile acid secretion during development. Furthermore, studies in both preterm humans and newborn piglets suggest that gallbladder contractility and response to cholecystokinin are also slow to mature, adding an extrahepatic factor to the long list of intrahepatic mechanisms responsible for the increased susceptibility to cholestasis in the infant, in particular the patient dependent on total parenteral nutrition.[45,46]

Despite abundant data suggesting structural and functional immaturity of hepatic excretory function, the clinical and physiologic implications of "physiologic cholestasis" are unclear. However, a reasonable hypothesis could be advanced: in the presence of lower rates of bile flow, compounds destined for biliary excretion would accumulate in the hepatocyte.[11] Certain of these compounds, such as atypical bile acids, are damaging to the membrane or organelle, making hepatic injury likely. Exogenous factors, such as infusion of parenteral nutrition solutions, prolonged fasting, sepsis, or hypoxia, will perturb this already precarious situation and result in the anatomic and clinical manifestations of cholestasis.

DIFFERENTIAL DIAGNOSIS OF CHOLESTASIS

The causes of neonatal cholestasis are diverse (Table 49-2). These include structural anomalies of the biliary tract, both intrahepatic and extrahepatic, which result in obstruction of bile flow, and infectious, metabolic, hemodynamic, or toxic insults, which cause functional impairment of the hepatic excretory process and bile secretion.

Although the differential diagnosis of cholestasis in the neonate is varied, the clinical presentation is similar, reflecting the underlying decrease in bile flow. Specifically, infants with cholestasis present with variable degrees of jaundice, dark urine, light stools, and hepatomegaly. Synthetic dysfunction and hepatocellular necrosis may be present. In certain patients with rapid progression of hepatocellular disease, fibrosis occurs, with signs of decompensation, such as ascites, appearing early in life. Failure to thrive is not always manifest early in the course; normal development may be falsely reassuring and should not detract the clinician from initiating a workup. Similarly, although premature infants are at increased risk for cholestasis, gestational age and side effects of neonatal intensive care should remain a "default" diagnosis once surgical and medical emergencies have been ruled out. The diagnosis of "transient neonatal cholestasis," the most frequent form, may be a more limited subset of the generic "idiopathic" neonatal hepatitis.

Jacquemin and colleagues used the term "transient neonatal cholestasis" to describe a group of 92 patients with early-onset neonatal cholestasis, identifiable perinatal complications incriminated in cholestasis, and a spontaneously favorable outcome.[47] In 85% of the patients, there was a history consistent with acute or chronic perinatal distress. Mean gestational age was 37 weeks, and birth weight was 2,705 g, with one-third of the patients being small for gestational age. Histology was consistent with the previous description of "neonatal hepatitis." The authors did not identify a correlation between histologic findings and perinatal events. Jaundice resolved in all patients, together with normalization of liver biochemical markers and, importantly, growth. The mean duration of jaundice was 3.5 months, and hepatomegaly resolved at a mean age of 13 months. Most had a biphasic progression of their cholestatic markers, with γ-glutamyl transpeptidase reaching its peak as conjugated bilirubin levels normalized. The importance of this study lies in its description of a subset of patients with early-onset neonatal cholestasis and hepatomegaly, perinatal distress, and a characteristic pattern of biochemical markers, in whom it is appropriate to defer liver biopsy and offer supportive care only. It is all the more important that the population of premature babies is increasing, with numerous perinatal hypoxic and toxic insults. Special attention should be paid to those infants who do not have a clearly identifiable cause of prematurity and develop cholestasis or intrauterine growth retarded infants with cholestasis; together, these problems may be indicative of primary liver disease or of an underlying metabolic defect.

DIAGNOSTIC APPROACH

Because of the severity of many of the conditions leading to neonatal cholestasis, early recognition of cholestasis in an infant and prompt diagnosis of the underlying disorder are imperative to identify disorders that will respond to a specific treatment and to institute general supportive care that

TABLE 49-2 CLASSIFICATION OF DISORDERS ASSOCIATED WITH CHOLESTASIS IN THE NEWBORN

EXTRAHEPATIC DISORDERS
- Biliary atresia
- Bile duct stricture/neonatal sclerosing cholangitis
- Choledochal cyst
- Anomalies of the pancreaticoduodenal junction
- Spontaneous perforation of the bile duct
- Inspissated bile
- Mass
  - Intraductular: stone, rhabdomyosarcoma
  - Extraductular: hepatoblastoma, neuroblastoma

INTRAHEPATIC DISORDERS
- Idiopathic
  - "Idiopathic" neonatal hepatitis
  - Intrahepatic cholestasis, *persistent*
    - Severe intrahepatic cholestasis with progressive hepatocellular disease (see Chapter 55.6, "Biliary Transport")
    - Alagille syndrome (syndromic paucity of the intrahepatic bile ducts, arteriohepatic dysplasia)
    - Nonsyndromic paucity of the intrahepatic bile ducts
  - Intrahepatic cholestasis, *recurrent*
    - Benign recurrent intrahepatic cholestasis
    - Hereditary cholestasis with lymphedema (Aagenaes syndrome)
- Anatomic
  - Congenital hepatic fibrosis or infantile polycystic disease (liver and kidney)
  - Caroli disease
- Metabolic or endocrine disorders
  - Disorders of amino acid metabolism
    - Tyrosinemia
  - Disorders of lipid metabolism
    - Cholesterol ester storage disease (Wolman)
    - Niemann-Pick disease
    - Gaucher disease
  - Disorders of carbohydrate metabolism
    - Galactosemia
    - Fructosemia
    - Glycogen storage disease type IV
  - Disorders of bile acid metabolism, primary
    - 3β-Hydroxysteroid Δ^5-C_{27} steroid dehydrogenase/isomerase
    - Δ^5–3-Oxosteroid 5β-reductase (multiple mutations)
  - Disorders of bile acid metabolism, secondary
    - Zellweger syndrome (cerebrohepatorenal syndrome)
    - Peroxisomal enzymopathies
  - Disorders of bile acid transport
    - Rotor syndrome
    - Dubin-Johnson syndrome
  - Mitochondrial hepatopathies
  - Other metabolic defects
    - α_1-Antitrypsin deficiency
    - Cystic fibrosis
    - Hypopituitarism
    - Hypothyroidism
    - Neonatal iron storage disease
    - Infantile copper overload (Menkes syndrome)
    - Hemophagocytic lymphohistiocytosis
    - Arginase deficiency
  - Toxic
    - Total parenteral nutrition–associated cholestasis
    - Fetal alcohol syndrome
    - Other drugs (maternal or used in neonatal intensive care)
- Cholestasis associated with infection
  - Sepsis with possible endotoxemia (urinary tract infection, gastroenteritis)
  - Syphilis
  - Toxoplasmosis
  - Listeriosis
  - Congenital viral infections
    - Cytomegalovirus
    - Herpesvirus (herpes simplex and human herpesvirus 6)
    - Cocksackievirus
    - Echoviruses
    - Rubella virus
    - Hepatitis B virus
    - Other hepatitis viruses: C? nonAnonB?
    - Human immunodeficiency virus (HIV)
    - Parvovirus B19
- Chromosomal
  - Trisomy 18
  - Trisomy 21 (Down syndrome)
  - Donohue syndrome (leprechaunism)
- Vascular disorders
  - Budd-Chiari syndrome
  - Perinatal asphyxia
  - Multiple hemangiomata
  - Cardiac insufficiency
- Miscellaneous
  - Congenital disorders of glycosylation
  - Shock, hypoperfusion
  - Intestinal obstruction
  - Neonatal lupus
  - ARC syndrome (arthrogryposis, renal tubular dysfunction, and cholestasis)

may ameliorate the clinical course. The majority of infants with prolonged cholestasis will be found to fall into the diagnostic category of either biliary atresia or "neonatal hepatitis" (Table 49-3); the latter is a "default diagnosis." As research progresses in pediatric liver disease, the number of cases falling into the "default" category are decreasing. However, at the present time, because of the preponderance of these disorders and the clinical importance of differentiating between them, this chapter focuses on neonatal hepatitis as we know it today; biliary atresia is covered elsewhere in this text. Other specific disorders associated with neonatal cholestasis are discussed in subsequent chapters.

IDIOPATHIC NEONATAL HEPATITIS VERSUS BILIARY ATRESIA

Extensive evaluation of the infant with cholestasis leads to a diagnosis of either idiopathic neonatal hepatitis or biliary atresia in approximately 40% of infants (see Table 49-3). These terms are descriptive and imply a clinical phenotype rather than an etiology. The precise etiology and mechanism of injury in the majority of cases of neonatal hepatitis and biliary atresia remain obscure. The term "idiopathic obstructive or obliterative cholangiopathy" has been used to include disorders that manifest a range of pathology from predominantly hepatocellular injury to predominantly extrahepatic biliary tract injury.

Several overlapping hypotheses attempt to conceptually unify the pathogenesis of these disorders:

1. The ductal plate malformation theory, proposed initially by Jorgensen,[48] suggests that altered embryogenesis may be partially responsible for clinically apparent disorders of cholestasis in the neonate. During normal embryogenesis, the earliest form of the bile duct is a cylindric ductal plate, which is remodeled through an

TABLE 49-3 ESTIMATED FREQUENCY OF VARIOUS CLINICAL FORMS OF NEONATAL CHOLESTASIS

CLINICAL FORM	CUMULATIVE PERCENTAGE
"Idiopathic" neonatal hepatitis	15
Extrahepatic biliary atresia	25–30
α_1-Antitrypsin deficiency	7–10
Intrahepatic cholestasis syndromes (eg, Alagille, PFIC type I)	20
Bacterial sepsis	2
Hepatitis	
Cytomegalovirus	3–5
Rubella, herpes	1
Endocrine (hypothyroidism, panhypopituitarism)	1
Galactosemia	1
Inborn errors of bile acid biosynthesis	2–5

PFIC = progressive familial intrahepatic cholestasis.

interaction between the ingrowing mesenchyme and disappearing ductal plate. Defective remodeling or incomplete dissolution, with failure of recanalization, has been postulated to lead to malformation of the ductal plate and subsequent anatomic abnormalities such as biliary atresia or cystic diseases of the hepatobiliary system. Desmet has suggested that ductal plate malformation is a basic morphologic lesion that occurs at different levels of the biliary tree and may be seen in a variety of disorders in addition to biliary atresia, including congenital hepatic fibrosis.[1]

On a molecular level, it was recently proposed by Clotman and colleagues that intra- and extrahepatic biliary tract development is regulated in part by a cascade involving hepatocyte nuclear factor (HNF) 6 and HNF1 and that ductal plate malformations are visible in knockout models of these transcription factors.[49] Similarly, McCright and colleagues created a mouse model of Alagille syndrome, which suggests that Notch-Jagged interactions are necessary for normal intrahepatic biliary development.[50]

2. Landing set forth the concept of infantile obstructive cholangiopathy, suggesting that these cholestatic disorders represent the pathophysiologic continuum of a single, underlying, obliterative process.[51] According to this hypothesis, an initial insult leads to inflammation at various levels of the hepatobiliary tract. The clinical sequelae represent a static or a progressive inflammatory process at the specific site of injury. If the site of injury is predominantly the bile duct epithelium, the resulting cholangitis could lead to progressive sclerosis and obliteration of the bile duct, clinically manifest as biliary atresia. If, on the other hand, the inflammation is primarily hepatocellular, the clinical picture may be one of neonatal hepatitis. The interrelation between these two processes is further supported by evidence of intrahepatic ductal injury in patients with biliary atresia.[52,53]

Although no specific virus has been consistently identified in patients with "obstructive cholangiopathies," there has been much interest in several specific potential pathogens in these disorders. The majority of studies dealing with viral etiologies in these conditions are related to biliary atresia and thus are discussed in that section. Inborn errors of bile acid synthesis associated with the clinical picture of neonatal hepatitis have also been identified.[6,54,55] As our understanding of immune dysregulation and autoimmunity evolves, it appears that in some cases, the primary insult directed against the hepatocyte or cholangiocyte may be (auto)immune,[56] not unlike diseases found in older subjects (autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis). Immunohistochemical analysis of the "giant cell" reveals that these cells likely result from hepatocellular fusion. However, these observations have not shed light on the underlying insult or trigger for this idiosyncratic cellular response.[57] These studies and others support the contention that the neonatal liver is uniquely susceptible to injury, which, in turn, is manifest in a unique fashion. The initial stereotypic histologic reaction and perpetual injury in infantile obstructive cholangiopathy may result from a wide variety of insults at any level of the hepatobiliary system or beyond in another organ system.

Distinguishing between the intrahepatic, hepatocellular process of neonatal hepatitis and the extrahepatic or mixed injury in biliary atresia is achieved through cholangiography and biopsy and is discussed below.

IDIOPATHIC NEONATAL HEPATITIS

Idiopathic neonatal hepatitis represents the third most common diagnosis in infants with neonatal cholestasis, accounting for 15% overall.[11,58,59] This relative percentage has steadily decreased since the initial description by Stokes and colleagues.[60] This shift is attributable to identification of specific disorders (such as α_1-antitrypsin deficiency and bile acid transport and synthesis defects, which present with a clinical picture of neonatal hepatitis) that were previously included in this category. This diagnosis should be restricted to cases of prolonged neonatal cholestasis in which the classic histologic changes described by Craig and Landing[61] are present on liver biopsy and known infectious or metabolic causes of neonatal hepatocellular disease have been excluded (see Table 49-2). Based on epidemiologic data, two categories of neonatal hepatitis have been proposed: sporadic and familial.[11] The increased incidence within certain families suggests that, at least in these cases, hereditary or metabolic factors are operant. In fact, recent studies have suggested that specific forms of intrahepatic cholestasis, previously included in the "idiopathic neonatal hepatitis" category, can be further subdivided based on the observed pathology and presumed pathophysiology (Table 49-4).[11] It is from this latter group that future discoveries related to the genetic and molecular basis of bile acid synthesis and transport are likely to be made. As research continues to make progress in these areas, the number of identifiable diseases will increase, and the category of idiopathic neonatal hepatitis will proportionately decrease.

TABLE 49-4 PROPOSED SUBTYPES OF INTRAHEPATIC CHOLESTASIS

Bile duct paucity
Syndromic (Alagille)
Nonsyndromic
Progressive (familial) intrahepatic cholestasis
Disorders of canalicular transport
Bile acid transport
Phopholipid transport
Disorders of bile acid biosynthesis
Undefined

Clinical Presentation

"Idiopathic" neonatal hepatitis appears to be associated with low birth weight, but a cause and effect relationship is unclear. The clinical course is highly variable: more than 50% develop jaundice, to a varying degree, within the first week of life. In our experience, the majority appear well; however, as much as one-third have evidence of chronic disease, such as failure to thrive. Acholic stools are uncommon with this disorder but may be present if the cholestasis is severe. The liver (and occasionally the spleen) is firm and enlarged. Biochemical evaluation reveals bilirubin and aminotransferase levels, which are mildly to moderately elevated (2 to 10 times the upper limit of normal). Alkaline phosphatase and γ-glutamyl transpeptidase levels are variably increased (see below). Serum bile acid levels are markedly elevated. A bleeding diathesis, resulting from vitamin K deficiency and/or decreased synthesis of clotting factors, may be present in those with a more fulminant course. Other signs or associated abnormalities such as microcephaly, chorioretinitis, or vascular or skeletal anomalies are unusual and should suggest alternative diagnoses. However, if these signs are absent, the child appears well, and there is a clear history of perinatal distress, "transient" neonatal cholestasis is likely, and the child should be biopsied at the earliest worrisome sign (failure to thrive, acholic stools).

Pathology

Although several histologic features such as giant cell transformation and extramedullary hematopoiesis are nonspecific and represent a stereotypic response of the neonatal liver to injury, the biopsy can be helpful in excluding other causes of neonatal hepatitis. In biopsy tissue obtained early (ie, within the first 2 months of life), there is disarray of the lobular architecture with hepatocellular swelling (ballooning), focal hepatic necrosis, and multinucleated giant cells (more than four nuclei per cell), representing fusion of adjacent hepatocytes (Figure 49-1). Portal triads may be expanded with inflammatory infiltrate of lymphocytes, neutrophils, and occasional eosinophils. There is extramedullary hematopoiesis, as well as varying degrees of portal fibrosis. Although hepatocellular/canalicular bile stasis in the lobule may be prominent, bile duct proliferation and bile duct plugging in portal triads are usually absent. Interlobular bile ducts/ductules are few in number in certain cases, suggesting paucity. The severity of hepatocellular injury usually correlates with the degree of cholestasis.[60,62]

Management

Neonatal hepatitis represents a heterogeneous disorder with no specifically delineated causative or perpetuating factors by definition. Management, therefore, is usually directed at nutritional support, vitamin supplementation, and general medical management of the clinical complications of cholestasis, such as pruritus. General medical management of chronic cholestasis is discussed in detail below.

Prognosis

The overall prognosis in idiopathic neonatal hepatitis is difficult to estimate owing to the variability of the clinical course and the generally ill-defined pathogenesis. The factors that allow perpetuation of the cholestatic process and hepatocyte injury are not fully understood. No specific biochemical or histologic correlates with clinical outcome have been identified. A composite of several large series reviewing outcome of patients with idiopathic neonatal hepatitis is presented in Table 49-5.[63–67] From these data, it is clear that sporadic cases (classic giant cell hepatitis) have a more favorable outcome than familial cases. The poor prognosis in a number of familial cases presumably relates to the presence of underlying inborn errors, specifically defects in bile acid metabolism or transport, as have been described in familial cases of clinically defined neonatal hepatitis (eg, progressive familial intrahepatic cholestasis).[6,54,55] As the underlying causes and pathogenesis of neonatal hepatitis are further defined, more precise prognoses can be established. It is therefore paramount to follow these patients well beyond the normalization of their biochemical markers because neonatal cholestasis may be the harbinger of a metabolic or immune defect manifesting itself later in life. Repeating a liver biopsy for histology, electron microscopy, and metabolic studies (respiratory chain enzymes) is crucial for any child who does not follow a "normal" course, for example, by having a prolonged cholestasis (> 3.5 months), by developing other symptoms such as fasting hypoglycemia, or by presenting with a recurrence of cholestasis.

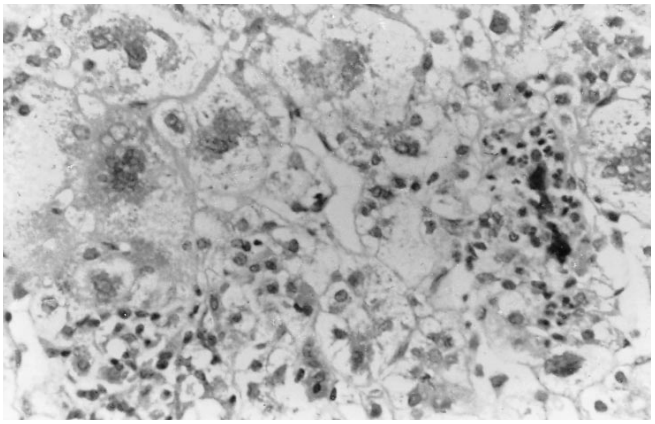

FIGURE 49-1 Liver histology in neonatal hepatitis. This biopsy specimen demonstrates disruption of hepatic lobular architecture with multinucleated giant cells. There are also inflammatory cells within the portal area (hematoxylin and eosin; ×400 original magnification).

TABLE 49-5 STAGED EVALUATION OF NEONATAL CHOLESTASIS

Differentiate cholestasis from physiologic breast milk jaundice and determine severity of disease
Clinical evaluation (history, physical examination, stool color)
Fractionated serum bilirubin (+ serum bile acids)
Tests of hepatocellular and biliary disease (ALT, AST, alkaline phosphatase, GGT)
Tests of hepatic function (serum albumin, prothrombin time, blood glucose, ammonia)
Exclude treatable and other specific disorders
Bacterial cultures (blood, urine)
VDRL test and viral serology as indicated (think HSV)
α_1-Antitrypsin phenotype
T_4 and TSH (rule out hypothyroidism)
Metabolic screen: urine-reducing substances (drugs may cause false positives), urine bile acids, serum amino acids, ferritin, urine organic acids
Sweat chloride/mutation analysis
Differentiate extrahepatic biliary obstruction from intrahepatic disorders
Ultrasonography
Hepatobiliary scintigraphy (not always essential)
Liver biopsy

ALT = alanine transaminase; AST = aspartate transaminase; GGT = γ-glutamyl transpeptidase; HSV = herpes simplex virus; T_4 = thyroxine; TSH = thyroid stimulating hormone; VDRL = Venereal Disease Research Laboratory.

EVALUATION OF THE INFANT WITH CHOLESTASIS

Conjugated hyperbilirubinemia in the newborn period always requires further evaluation, which must be prompt and decisive. Fractionation of the bilirubin, which allows identification of patients with cholestatic (as opposed to physiologic or breast milk) jaundice, should be obtained in any infant with prolonged (ie, more than 14 days) hyperbilirubinemia. Cholestasis traditionally is defined as the presence of a conjugated (or direct-acting) fraction of more than 2 mg/dL (35 μmol/L) or more than 20% of the total bilirubin[11]; however, we prefer to seriously regard any elevation of conjugated bilirubin. Cost-effectiveness should be considered, and a staged approach should be taken in the evaluation of neonatal cholestasis (see Table 49-5). First, treatable disorders such as sepsis, galactosemia, endocrinopathies, and inborn errors of bile acid synthesis must be identified to initiate appropriate therapy that may prevent further damage to the liver and/or reverse the existing injury. Next, biliary obstruction must be differentiated promptly from intrahepatic cholestatic disorders because early surgical intervention is associated with a better prognosis. Finally, the clinical complications of cholestasis, including coagulopathy owing to hypoprothrombinemia or vitamin K deficiency and the nutritional consequences of fat malabsorption, must be addressed because therapy may improve the ultimate outcome and the general quality of life.

HISTORY AND PHYSICAL EXAMINATION

During the evaluation of the infant with cholestasis, the family history, prenatal and postnatal clinical course, and physical examination on presentation may provide important clues. Irritability, poor feeding, and vomiting may indicate a generalized infection or a metabolic disorder such as galactosemia or tyrosinemia or suggest encephalopathy, which is particularly difficult to identify in this age group. Vertebral arch anomalies, posterior embryotoxon, and the murmur of peripheral pulmonic stenosis suggest the diagnosis of Alagille syndrome.[68] Hepatomegaly is the norm. Splenomegaly should lead to the consideration of a systemic disease, infectious or other. Dysmorphic signs suggest chromosomal abnormalities.

It is important to consider that many cholestatic infants appear well at the onset of their disease: normal weight gain and development do not preclude a condition as severe as biliary atresia. In fact, the hallmark of these children is that, initially, many appear to be prospering in spite of their cholestasis.

In differentiating biliary obstruction from intrahepatic cholestasis, the presence of persistently acholic stools is suggestive but not diagnostic of biliary atresia because they may also be associated with severe intrahepatic cholestatic disease. Conversely, the presence of pigmented stools suggests patency of the biliary system and generally excludes the diagnosis of biliary atresia. Alagille identified four clinical features that, although nonspecific, supported the correct diagnosis of intrahepatic or extrahepatic cholestasis in 82% of the cases.[69] These clinical variables included stool color within 10 days of admission, birth weight, age at onset of acholic stools, and the features of hepatic involvement, specifically the presence of hepatomegaly and consistency of the liver on palpation. In this study, addition of liver histology to the evaluation increased the diagnostic accuracy by only 3%. In other studies, despite the use of this scoring system, 10% could not be differentiated,[70–72] also suggesting that further evaluation is sometimes necessary.

Recently, the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) published the Neonatal Cholestasis Clinical Practice Guidelines; these are available on-line(<www.naspgn/sub/positionpapers.asp>). These guidelines represent the current practice in most tertiary centers in North America and are thought to be the most efficient and cost-effective way to approach the complex problem of neonatal cholestasis.

LABORATORY EVALUATION

There is no pathognomonic or prognostic biochemical feature of neonatal cholestasis. There is no single test consistently reliable in differentiating neonatal hepatitis from biliary atresia. It is not possible to predict either clinically or based on the result of a neonatal screen which infant will develop cholestasis. Nevertheless, several tests may help identify specific causes of cholestasis and assess and monitor the degree of hepatobiliary dysfunction.[11,70] The laboratory data (see Table 49-5) must be analyzed in the context of the clinical setting. For example, urine-reducing substances may be falsely negative if the infant is not receiving a galactose-containing formula or is vomiting. In these situations, the diagnosis of galactosemia may be

made by measuring the red blood cell galactose-1-phosphate uridyl transferase activity, provided that the infant has received no recent blood transfusions. Elevated serum methionine and tyrosine levels, detected during a metabolic screen, may reflect severe liver disease but not necessarily be diagnostic of an underlying metabolic defect. The diagnosis of tyrosinemia should be confirmed by identification of specific metabolites (succinylacetone, succinylacetoacetate). A phenotype is preferred in the evaluation for α_1-antitrypsin deficiency because neonates may have low levels of α_1-antitrypsin despite normal phenotypes, and heterozygotes may have elevated levels in the presence of inflammation. The traditionally requested TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) titers have a low diagnostic yield and should be replaced by a request for specific viral titers or cultures only if there are suspicious features. For example, cytomegalovirus serologies should only be obtained based on maternal history and the clinical setting. It is sometimes difficult to obtain an adequate amount of sweat for a sweat chloride test in a neonate, but this test or more specific testing should be performed if the diagnosis of cystic fibrosis remains in question.

γ-Glutamyl transpeptidase, an enzyme located in the epithelial lining of the biliary tree and canaliculi, is elevated in most cholestatic disorders,[73] including biliary atresia, Alagille syndrome, α_1-antitrypsin deficiency, and idiopathic neonatal hepatitis. Normal levels, however, are seen in progressive familial intrahepatic cholestasis and disorders of bile acid synthesis,[74–76] where there is an abnormality of bile acid export into the canaliculus—hence, no bile acid–mediated injury of the canalicular membrane.[77]

As recommended in the NASPGHAN consensus guidelines, part of the stepwise workup always involves assessment of synthetic function by obtaining coagulation studies and metabolic function by measuring glucose and ammonia in serum. Although not used routinely in all centers, quantification of serum bile acids can help orient the diagnosis in neonatal cholestasis syndromes. Elevated levels are found in most forms of cholestasis; low serum bile acid concentration in the face of persistently elevated conjugated bilirubin levels should suggest an inborn error of bile acid synthesis. Other third-line investigations are warranted according to the clinical context: transferrin immunoelectrophoresis should be considered when the constellation of signs is consistent with a congenital defect in glycosylation. Serum α-fetoprotein should be measured especially when considering tyrosinemia because of the associated risk of malignancy. This test can be diagnostic and serve as a baseline for subsequent follow-up. In the presence of splenomegaly, Niemann-Pick disease should always be considered and appropriately addressed by performing a bone marrow aspirate. Similarly, neurologic findings should raise the question of mitochondriopathies and fatty acid oxidation defects. Finally, dysmorphic features, as always in pediatrics, should warrant evalutation. Unfortunately, at the present time, there is no reliable antenatal screening method for most of the conditions leading to neonatal cholestasis.

RADIOLOGIC EVALUATION

Ultrasonography

Real-time ultrasonography is an important adjunct in the diagnosis of neonatal cholestasis.[78] The study is most helpful in ascertaining the presence of a choledochal cyst, or, rarely, a tumor, which can have a clinical presentation similar to that of biliary atresia. The absence of a gallbladder on a fasting study is suggestive but not diagnostic of biliary atresia. Similarly, the presence of a gallbladder does not exclude this diagnosis. Dilated ducts are usually not present in biliary atresia, reflecting the fibro-obliterative or sclerotic nature of the coincident intrahepatic duct lesion.

In recent years, emphasis has been on trying to find a reliable, noninvasive method of diagnosing biliary atresia. The triangular cord sign, when performed by an experienced sonographer, is a potentially helpful diagnostic tool. In one small study, the characteristic cone-shaped finding cranial to the portal vein bifurcation demonstrated a positive predictive value of 100% when visualized together with an abnormal gallbladder and 88% when the gallbladder was normal.[79] The main disadvantage is that this ultrasonographic finding is operator dependent.

Recently, pediatric surgeons have also looked at the value of antenatal ultrasonography in the diagnosis and management of hepatobiliary lesions. Indeed, routine ultrasonography at 20 weeks gestation has led obstetricians and radiologists on occasion to find cystic lesions at the hepatic hilum.[80] Little is known about the natural history of these findings. As more experience is gained in imaging the hepatobiliary system antenatally, this tool may become part of the diagnostic algorithm of neonatal cholestasis.

Finally, a plain chest radiograph should be performed in investigating neonatal cholestasis to look for situs abnormalities, as well as butterfly vertebrae, or rickets, which may help orient the diagnosis.

Radionuclide Imaging

Hepatobiliary scintigraphy, using technetium-labeled iminodiacetic acid analogs, may be used to differentiate biliary atresia from nonobstructive causes of cholestasis. The hepatic uptake and secretion into bile of these derivatives of iminodiacetic acid occur by a carrier-mediated organic anion pathway and depend on the structure of the specific analog, the integrity of hepatocellular function, and biliary tract patency.[81,82] In patients with biliary atresia, particularly early in the disorder, parenchymal function is not compromised; therefore, uptake of the radioisotope is unimpaired, although subsequent excretion into the intestine is absent (Figure 49-2A). Conversely, uptake is usually delayed in infants with neonatal hepatitis owing to hepatocellular dysfunction, but eventually excretion into the bile and intestine occurs (Figure 49-2B). Pretreatment with oral phenobarbital (5 mg/kg/d for 5 days) enhances biliary excretion of the isotope and can increase sensitivity to 94%.[81,82] There are limitations to this study, however; therefore, the diagnosis should not be made solely on the results of this test. Nonexcretion may be related to severe

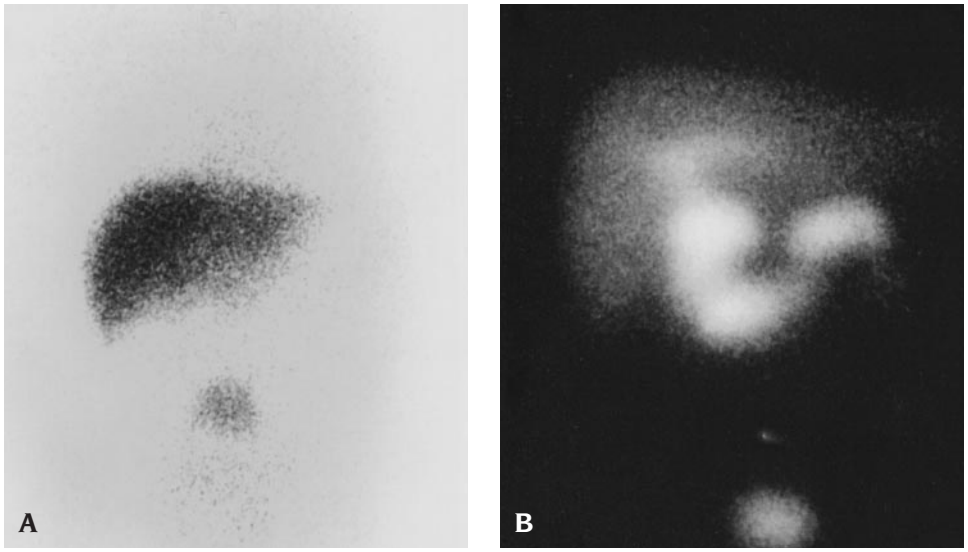

FIGURE 49-2 *A*, Radioisotope scan in biliary atresia. On a delayed scan, there is good uptake of the isotope by the liver, but there is no evidence of intestinal excretion. *B*, Radioisotope scan in neonatal hepatitis. Uptake of the isotope by the liver is delayed and decreased; however, excretion into the intestine is noted.

intrahepatic cholestasis rather than extrahepatic obstruction. In a retrospective study, 12 of 21 infants with intrahepatic causes of cholestasis had no excretion in their first study, despite the use of phenobarbital.[83] In our experience, one patient with isotopic demonstration of a "patent" biliary system was subsequently diagnosed with biliary atresia. In addition, the 5 days required for phenobarbital administration to optimize diagnostic yield may ultimately affect outcome by delaying surgical intervention. Whereas the passage of the tracer into the gastrointestinal tract is 100% sensitive in excluding biliary atresia, a nonexcreting result is only 60% specific for biliary atresia. This poor specificity, together with the time required to prepare for the study, is progressively excluding hepatobiliary scanning from the diagnostic algorithm.[77]

Although there has been much hope that magnetic resonance imaging would provide a means of exploring the biliary tract, there is no evidence at present to suggest that this method is of benefit in the diagnostic armamentarium when studying small infants.[84] Other radiographic studies, such as percutaneous transhepatic cholangiography or endoscopic retrograde cholangiopancreatography, are not only difficult to perform, but experience has been limited in these infants.[85–87]

Liver Biopsy

In our experience, the liver biopsy remains the most reliable and definitive procedure in the evaluation of the neonate with persistent conjugated hyperbilirubinemia. Tissue may be obtained, in most cases, using a percutaneous technique with local anesthesia.[11,70,88,89] Careful interpretation by an experienced pathologist yields the correct diagnosis in 90 to 95% of cases. Prompt diagnosis may expedite surgery for biliary atresia and preclude unnecessary surgical exploration. The typical findings in neonatal hepatitis are discussed above. Like the biochemical evaluation, the biopsy needs to be interpreted in the clinical context because the histology of neonatal hepatitis is nonspecific: giant cell transformation and hepatocyte ballooning with lobular disarray represent a nonspecific response of the newborn liver to an insult. Many of the characteristic histologic findings stem from observational studies in term infants in their first few months of life. Less is known about the histology of the early course of some neonatal cholestasis syndromes or of preterm infants with cholestasis. These conditions are evolving processes, and more information may be gained by performing a repeat biopsy to look for more characteristic findings and to appreciate the evolution.

Conclusions regarding Evaluation

In evaluating a neonate with cholestasis, both surgical and medical emergencies have to be excluded and attended to in a timely fashion. If galactosemia is suspected, appropriate dietary measures should be taken immediately. If sepsis is the likely cause of the cholestasis, this must be managed urgently. If biliary atresia is suggested, an exploratory laparotomy, often with an intraoperative cholangiogram, is performed to verify the nature and site of the obstruction prior to hepatoportoenterostomy. Finally, if no specific etiology is determined but extrahepatic obstruction is unlikely, the infant is followed and re-evaluated frequently. Empiric therapy may also be instituted to optimize growth and development and ameliorate the consequences of chronic cholestasis (discussed below).

The need to correctly differentiate biliary atresia from intrahepatic disorders is illustrated by a report from Markowitz and colleagues in which four patients who underwent hepatoportoenterostomies on the basis of hepatobiliary scans and intraoperative cholangiograms were subsequently found to have Alagille syndrome on histologic and clinical criteria.[90] None had adequate drainage postoperatively, two progressed to cirrhosis, and one died from hepatic failure, indicating that the intervening surgery had adversely altered the course of a usually benign disorder. If careful consideration is given to the history, physical examination, and these selected diagnostic tests (see Table 49-5), institution of appropriate surgery may be expedited, unnecessary surgery avoided, and, in many cases, the precise etiology determined.

MEDICAL MANAGEMENT OF CHRONIC CHOLESTASIS

In infants with intrahepatic cholestasis or those with biliary atresia in whom surgical attempts at establishing adequate biliary drainage are unsuccessful, the presence of the clinical consequences of persistent cholestasis directs medical therapy. These complications are related, either directly or indirectly, to diminished bile flow and reflect (1) retention of substances dependent on bile secretion, such as bile acids, bilirubin, and cholesterol; (2) decreased bile acid delivery to the intestine with resultant fat and fat-soluble vitamin malabsorption; and (3) progressive hepatocellular damage leading to portal hypertension and eventual liver failure (Figure 49-3). Currently, no specific therapy either reverses existing cholestasis or prevents ongoing damage; therefore, therapy is empiric and aimed at improving nutritional status, maximizing growth potential, and minimizing discomfort.[91] The success of this therapeutic intervention is limited by the residual capacity of the liver and by the rate of progression of the underlying disorder. The success is enhanced by introducing these measures in a timely fashion, namely as soon as abnormal weight gain is anticipated.

PRURITUS

Significant clinical morbidity may result from pruritus, and its management is a difficult and sometimes frustrating clinical problem. In some patients, the impairment in quality of life is so severe that liver transplant is indicated. The cause of cholestatic pruritus is not clear.[92,93] It has been reported that skin and serum levels of bile acids did not differentiate between patients with or without pruritus,[93] arguing against bile acids as direct pruritogens. Endogenous opioids have been implicated as mediators of pruritus, specifically cholestasis-induced pruritus.[94] Similarly, the serotonin neurotransmitter system has also been identified as one potential factor.[95] With these recent findings, new approaches to the management of cholestasis-induced pruritus are emerging.

Therapy directed at decreasing the concentrations of bile acids may be efficacious in some patients because of the nonspecific action of these agents. The anion exchange resion cholestyramine has been used historically to interrupt enterohepatic circulation. Because its use entails a complicated regimen, it is seldom used in pediatrics.

Phenobarbital, in therapeutic doses of 5 to 10 mg/kg/d, stimulates bile acid–independent flow and decreases the bile acid pool size.[96] The drug has not been consistently efficacious in relieving pruritus in intrahepatic cholestasis. The sedative side effects of phenobarbital may be a limiting factor in its usefulness. As a rule, its use in cholestasis is becoming more infrequent. The use of rifampin (10 mg/kg/d), which inhibits hepatic uptake of bile acids, has also been tried with variable success in relieving pruritus.[97,98] Like phenobarbital, it is a microsomal enzyme inducer, with the advantage of not having a sedative effect. Related side effects are minimal, but worsening biochemical liver markers can be suggestive of rifampin-induced hepatitis.[99]

Ursodeoxycholic acid (UDCA), which alters bile acid composition, has been shown to be beneficial in the relief of pruritus in studies of adults with primary biliary cirrhosis.[100] Preliminary studies, using 15 to 30 mg/kg/d, suggest that it may be of benefit in ameliorating pruritus in childhood cholestasis as well.[101,102] In our center, UDCA is routinely prescribed to all children with cholestasis for its potential cytoprotective effect on hepatocytes, as well as its

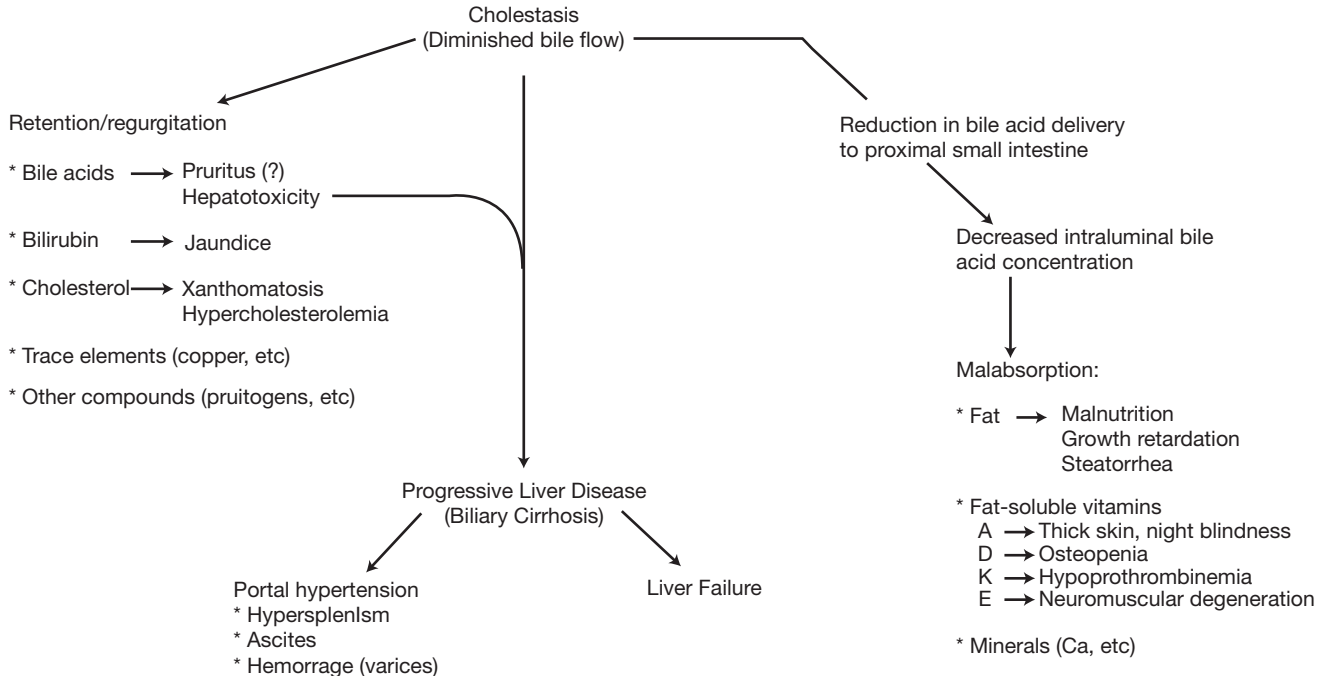

FIGURE 49-3 Clinical sequelae of chronic cholestasis. Numerous consequences of cholestasis become clinically manifest and result from retention of substances excreted in bile, reduction of intestinal bile acids, and progressive damage to the liver. See text for relationship between bile acids and pruritus.

role in relieving pruritus. The current trend is toward the higher dose of 30 mg/kg/d, although there is no documented evidence that the effect is dose dependent.

As mentioned above, interest in the role of the opiate receptor system in pruritus of cholestasis was prompted by the results of studies in which opioid antagonists relieved pruritus.[98,102] The presumed mechanism of action is that they prevent the binding of endogenous opioid agonists, which have been shown to be elevated in cholestasis. The three known opioid antagonists (naloxone, nalmefene, and naltrexone) have been studied and have demonstrated an aleviating effect, although none have completely abolished pruritus. There are problems associated with the use of opioid antagonists: they precipitate a withdrawal-like effect, and a "breakthrough" phenomenon has been described, which consists in an exacerbation of the pruritic symptoms after an initial improvement. Thus, determining the appropriate dose and management can be difficult, and consultation with anesthesia may be appropriate.[99] As mentioned earlier, there have been some studies implicating serotonin in the pathophysiology of pruritus. As such, the use of ondansetron in the relief of pruritus has been studied with some promising results, but more studies are required to confirm these findings.[99]

For those children with intrahepatic cholestasis and intractable pruritus unresponsive to therapy, partial external biliary diversion has been performed.[103] Patients with progressive intrahepatic cholestasis had a good response, with relief from itching and concomitant improvement in their biochemical tests of liver function and histology. In a retrospective review performed at our center, patients and parents reported a marked improvement in quality of life, as defined by school attendance and interactions with peers.[104] Finally, there have been anecdotal reports on the efficacy of a variety of other therapies, including phototherapy and plasmapheresis.

Malabsorption and Malnutrition

Lipids. One of the major and more immediate complications of chronic cholestasis is fat malabsorption related to decreased intraluminal bile acids, which leads to malnutrition and fat-soluble vitamin deficiency. Decreased excretion of bile acids leads to a low intraluminal micellar concentration; therefore, long-chain triglyceride lipolysis and absorption are ineffective. Medium-chain triglycerides (MCTs) are more water soluble than their long-chain counterparts and are therefore readily absorbed by the gastric and intestinal mucosa in the face of low intraluminal concentrations of bile acids, making them a more adapted source of fat calories; MCTs can best be administered as MCT-containing formulas. MCT oil alone is insufficient because it does not contain essential fatty acids. In those children who are unable to take in sufficient calories orally, nocturnal enteral feeding has been shown to improve nutritional indices in many patients with chronic liver disease.[105]

Liposoluble Vitamins. Intestinal absorption of fat-soluble vitamins (A, D, E, and K) that require solubilization by bile acids into mixed micelles is also compromised, and supplementation of at least two to four times the recommended daily allowance is often necessary (Table 49-6). Serum vitamin levels and laboratory tests such as serum calcium and phosphate levels and prothrombin time are useful indices of adequate supplementation. Chronic vitamin E (α-tocopherol) deficiency has been associated with a progressive neuromuscular syndrome characterized by areflexia, cerebellar ataxia, posterior column dysfunction, and peripheral neuropathy.[106,107] The most reliable index of vitamin E status is the ratio of serum vitamin E (mg/dL) to total serum lipids (g/dL) because elevated lipids, as seen in chronic cholestasis, allow vitamin E to partition into the nonpolar phase (plasma lipoprotein fraction), artificially raising the serum vitamin E concentration. In infants and children less than 12 years of age, a ratio of less than 0.6 mg/g indicates vitamin E deficiency.[108] In those children who do not respond to supplementation of vitamin E by traditional methods, oral administration of a water-soluble form of vitamin E, *d*-α-tocopherol polyethylene glycol 1000 succinate (TPGS), has been found to correct biochemical vitamin E deficiency in doses of 15 to 25 IU/kg/d.[109] In truly refractory cases, an admixture of all fat-soluble vitamins with TPGS may be more beneficial than administration of the supplement alone.[110] Although there are no data to support its use in neonatal cholestasis, vitamin E is part of the antioxidant armamentarium prescribed in many forms of acute and chronic liver disease.[111] Careful consideration should be given to fat-soluble vitamin replacement in the nutritional management of these patients because intracranial bleeding from vitamin K deficiency is still a frequent cause of death in infants and toddlers with cholestasis.

Carbohydrates. In animal models of biliary atresia, as much as a 20 to 30% decrease in brush border enzyme activity has been observed. Thus, although there is no published evidence to this effect in human subjects, one should consider changing the carbohydrate composition of the formula if the infant is demonstrating signs consistent with lactose intolerance. This is particularly important because the infant with cholestasis requires as much as 130% of the caloric intake of age-matched controls (as much as 150 kcal/kg/d), 60% of which should be in carbohydrate form.

TABLE 49-6 RECOMMENDED ORAL VITAMIN SUPPLEMENTATION

VITAMIN	PREPARATION, DOSE
Fat soluble	
Vitamin A	Aquasol A: 3,000–25,000 IU/d
Vitamin D	Cholecalciferol: 500–5,000 IU/d or 25-Hydroxycholecalciferol: 3–5 μg/kg/d
Vitamin K	Phytonadione (K1): 2.5–5 mg every other day
Vitamin E	Aquasol E: 50–400 IU/d or TPGS 15–25 IU/kg/d
Water soluble	Twice the recommended daily allowance

TPGS = *d*-α-tocopherol polyethylene glycol 1000 succinate.

Protein. Infants with cholestasis require a normal proportion (20–30%) of their diet in protein form. However, unless malnutrition is so severe, there is no evidence to suggest that protein hydrolysates are necessary. One study in a rat model suggested that adding branched-chain amino acids to the formula may impact growth and nitrogen retention favorably.[112] There is no such evidence in human subjects.

Other Vitamins and Nutrients.

1. Calcium. In spite of aggressive liposoluble enteral or parenteral vitamin replacement, most children with cholestasis suffer from severe osteopenia, often leading to pathologic fractures.[113,114] Thus, both additional calcium and magnesium[115] supplementation is advisable, ensuring that the child or infant receives at least 1,000 to 1,300 mg/d of calcium and 8 to 16 mg/kg/d of elemental magnesium. The time at which the supplement is taken is critical because it has been suggested that UDCA may affect calcium absorption negatively. Finally, monitoring a patient's calcium-phosphorus status using urinary indices and parathyroid hormone may be indicated because serum levels may not always be accurate because of acid-base abnormalities or hypoalbuminemia.
2. Zinc. Because of increased intestinal losses and fat malabsorption, zinc deficiency is more prevalent in cholestasis than is commonly thought. Because zinc is a common cofactor in numerous enzymatic reactions, including in the liver, zinc deficiency may further exacerbate the underlying liver disease.
3. Iron. Iron deficiency is common in these children. Early on, this may be due to insufficient dietary intake. As the course of the disease progresses, however, this is more often the sign of occult, or overt, gastrointestinal bleeding.

Portal Hypertension

In most patients with biliary atresia, and in certain patients with intrahepatic cholestasis, progressive fibrosis and cirrhosis ultimately lead to the development of portal hypertension, the most clinically significant sequelae being ascites and variceal hemorrhage. The medical management of ascites should be dictated by patient comfort and by the relative risk of peritoneal bacterial infection. The judicious use of sodium restriction and diuretics may be helpful in controlling the accumulation of ascites. Initial steps include restricting dietary sodium intake to 1 to 2 mEq/kg/d and introducing a diuretic such as spironolactone, which inhibits the effects of aldosterone. We usually start with 3 to 5 mg/kg/d divided into 3 to 4 doses and increase the dose as needed up to 10 to 12 mg/kg/d to maintain an increased urinary sodium-to-potassium ratio. Refractory ascites with respiratory compromise may be managed by therapeutic paracentesis with concomitant administration of an intravenous colloid such as albumin.[11] Albumin has been shown in adult studies to play a role in the preservation of renal function in large-volume paracentesis and to have a protective effect against the risk of spontaneous bacterial peritonitis.[116] Used together with furosemide, it participates in the elimination of free water and sodium while avoiding the prompt recurrence of ascites.[116]

Esophageal and gastric varices are a potentially life-threatening complication of portal hypertension. Acute variceal hemorrhage is managed in an intensive care unit with intravenous fluids and blood products, gastric lavage, and intravenous vasopressin infusion (0.3 U/1.73 m^2/min) as indicated. Balloon tamponade, used for severe or prolonged hemorrhage, may be associated with significant complications such as esophageal rupture, airway obstruction, and pulmonary aspiration. Endoscopic sclerotherapy is being used more extensively in infants and children for the acute and ongoing management of esophageal varices and may be superior to surgical alternatives,[117] particularly if eventual liver transplant is anticipated. Although not available for the infant population, banding is also used routinely in older children. However, to date, there is no literature to suggest that prophylactic banding or sclerotherapy is preferable to managing varices on an ad hoc basis following a bleed. This topic is covered in greater depth in Chapter 59, "Treatment of End-Stage Liver Disease." Gastric varices are not amenable to this therapy. There has also been interest in long-term administration of β-blocking agents such as propranolol to reduce portal pressure and prevent recurrent variceal bleeding in adults,[102,103] but the results have been variable, and there is limited experience in children. Furthermore, β-blockade may impede appropriate cardiovascular compensation in the event of an acute bleed and is therefore not used routinely in infants. In refractory hemorrhage, pediatric patients may be stabilized using intravenous octreotide, starting at 1 μg/kg/(min) and increasing as needed. Patients should be closely monitored for hyperglycemic side effects. The use of octreotide can be a convenient tool while the patient awaits emergent liver transplant.

Orthotopic liver transplant has become a viable option for infants and children who progress to end-stage liver disease.[118,119] The ability to determine the optimum time in the clinical course to pursue transplant requires careful monitoring and sequential evaluation of hepatic function. Although no one specific functional measure has been shown to reliably assess hepatocellular reserve, prognostic scores have been developed for predicting outcome without transplant. These scores may be compared with operative survival statistics for a particular patient group and thus aid in decision-making. In infants and children with end-stage liver disease, the deciding factor in timing organ transplant is usually organ availability. Therefore, it is important to carry out evaluation early in the course to develop supportive strategies and to stratify based on clinical criteria.

The major limiting factor for successful transplant in infants has been the supply of appropriately sized organs. This situation has been somewhat alleviated by introduction of the techniques of segmental or volume reduction liver transplant, living donor transplant, and "split" organ donation.[120] More effective means for supporting and monitoring infants with chronic liver disease are needed. Ultimately, a better understanding of the pathophysiology of specific underlying disease processes may

lead to more efficacious treatment of the sequelae of persistent infantile cholestasis and to therapeutic interventions that will prevent or reverse the development of chronic liver disease.
